First, it is clear that (after factoring out the common terms) the arguments in the first and third squared brackets are identical. Secondly, for the global validity of this condition, each of the three terms must be set equal to zero, thus obtaining

$$(6a)\quad B_{31}\alpha_2 - B_{21}\alpha_3 = 0$$

$$(6b)\quad B_{31}B_{2k} - B_{21}B_{3k} = 0,\quad k = 1, 2, 3,$$

which are exactly the conditions for direct separability as given by Blackorby, Primont, and Russell and also reported by PH (p. 148). Notice that, under global validity of the rank condition, the first term of (5) becomes

$$(7)\quad B_{31}\left[\sum_k B_{2k}\right] - B_{21}\left[\sum_k B_{3k}\right] = 0,$$

but this condition is either implied by (6b) or by the homogeneity property customarily imposed on flexible functional forms. Hence, in the case of the translog function, the rank condition of Pope and Hallam is of no help in alleviating the "unwanted restrictions" detected by Blackorby, Primont, and Russell.

Consider, now, the case of the generalized Leontief function for which $f_i(z_i) = z_i^{.5}$. The rank condition for indirect separability takes on the following representation:

$$(8)\quad \left(\frac{1}{2}z_1^{-.5}\right)\left(\frac{1}{2}z_2^{-.5}\right)\left(\frac{1}{2}z_3^{-.5}\right)\sum_k [B_{31}B_{2k} - B_{21}B_{3k}]\left(\frac{1}{2}z_k^{-.5}\right)z_k + \left(\frac{1}{2}z_1^{-.5}\right)\left[\left(\frac{1}{2}z_3^{-.5}\right)\cdot\left(-\frac{1}{4}z_2^{-1.5}\right)z_2B_{31}\alpha_2 - B_{21}\alpha_3\left(\frac{1}{2}z_2^{-.5}\right)\cdot\left(-\frac{1}{4}z_3^{-1.5}\right)z_3\right] + \left(\frac{1}{2}z_1^{-.5}\right)\sum_k\left[\left(\frac{1}{2}z_3^{-.5}\right)\cdot\left(-\frac{1}{4}z_2^{-1.5}\right)z_2B_{31}B_{2k} - B_{21}B_{3k}\left(\frac{1}{2}z_2^{-.5}\right)\cdot\left(-\frac{1}{4}z_3^{-1.5}\right)z_3\right]z_k^{.5} = 0.$$

After obvious simplifications, the first and third terms are identical but of opposite sign and, therefore, drop out of the rank condition altogether. Therefore, for the global validity of such a condition in the case of the generalized Leontief function, we simply have

$$(9)\quad B_{31}\alpha_2 - B_{21}\alpha_3 = 0.$$

As a third example, let us consider the quadratic function with $f_i(z_i) = z_i$. Then, the rank condition for indirect separability simplifies to

$$(10)\quad B_{31}B_{2k} - B_{21}B_{3k} = 0,\quad k = 1, 2, 3.$$

This expression is obtained from the first term of (4), while the other two terms vanish since the second derivative of $f_i(z_i)$ is identically equal to zero.

These results allow the testing of indirect separability associated with generalized Leontief and quadratic functions while breaking away from the "unwanted restrictions" detected by Blackorby, Primont, and Russell for the translog function and support Pope and Hallam's claim that "this (test) moderates in some cases the criticism by Blackorby, Primont and Russell" (p. 143).

Test for Indirect Separability

In order to illustrate their methodological result, PH chose to estimate a generalized Leontief function involving cotton lint as a dependent variable (y), and plant spacing (SP), irrigation water (WA), and nitrogen (NI) as inputs. For the purpose of clarity, this type of production function is specified as

$$(11)\quad y = a_0 + a_1SP^{.5} + a_2WA^{.5} + a_3NI^{.5} + b_{11}SP + 2b_{12}SP^{.5}WA^{.5} + 2b_{13}SP^{.5}NI^{.5} + b_{22}WA + 2b_{23}WA^{.5}NI^{.5} + b_{33}NI + u.$$

PH wished to test whether "nitrogen and water form a group which is nonadditively separable from spacing (p. 150)." For verifying the indirect separability of the associated dual function, they indicated that the relevant condition is

$$(12)\quad rank\begin{bmatrix} b_{12} & b_{22} & b_{23} \\ b_{13} & b_{23} & b_{33} \end{bmatrix} = 1,$$

which implies two restrictions: $b_{12}b_{23} - b_{13}b_{22} = b_{22}b_{33} - b_{23}^2 = 0$. As indicated above, however, a direct application of the rank condition to a generalized Leontief function with partition $N_s = (2, 3)$ and $N_s^0 = (0, 1)$, produces the following restriction:

$$(13)\quad rank\begin{bmatrix} -a_2WA^{-.5}/4 & b_{12}SP^{-.5}WA^{-.5}/2 \\ -a_3NI^{-.5}/4 & b_{13}SP^{-.5}NI^{-.5}/2 \end{bmatrix} = 1,$$

requiring simply that $a_2b_{13} = a_3b_{12}$ for the global validity of the condition. The discrepancy with PH's choice of implementation is based upon the erroneous second derivative. As a consequence, a rank condition test based on (12) is a chi-square variable with two degrees of freedom, while the same test based

on (13) has only one degree of freedom. We have performed an empirical verification that a generalized Leontief specification admits the possibility of indirect separability while rejecting direct separability. The empirical illustration of PH obscured this important point.

Conclusion

The implementation of Pope and Hallam's rank condition on a generalized Leontief function takes on a simpler specification than that suggested in their paper. Although for the translog functional form, the rank condition expresses restrictions which are identical to the direct separability conditions, the generalized Leontief and quadratic functions allow for a meaningful application of the rank condition. Thus, the obvious question, anticipated in the introduction, is whether other flexible functional forms can join the generalized Leontief and quadratic functions in that happy endeavor. The answer appears to be negative. The generalized Leontief and quadratic functions seem to "moderate the criticism of Blackorby, Primont, and Russell" only because each of them represents a case of singularity where two of the terms in equation (4) are eliminated. No other mean function of order ρ, ($f_i(z_i) = z_i^{\rho}$), generates similar cancellation, and its rank condition for indirect separability coincides with the conditions for direct separability.

For the moment, a conclusion about PH's rank condition is intimately tied to the structure of present-day flexible functional forms: the known forms are "separability-inflexible" and (except for the generalized Leontief and quadratic functions) PH's rank condition for indirect separability is another way of packaging the conditions for direct separability. Hence, the empirical resolution of the weak separability issue must be directed toward a search of functional forms which are "separability-flexible." When those functions will be available, we conjecture that weak and direct separability will be testable without restrictions. The corresponding dual functions will likely be of unknown form, as is the case for the current flexible functions. At that time, the full potential of PH's rank condition will also become transparent since it will be possible to test for weak separability of the indirect functions without imposing any restriction on the primal model.

Books Reviewed

Retrospective Review

Ciriacy-Wantrup, S. V. *Resource Conservation: Economics and Policies*. Berkeley and Los Angeles: University of California Press, 1952, 395 pp.

Since my tenure as a doctoral student at Berkeley (1958–61), I have been fascinated with the persona of Siegfried von Ciriacy-Wantrup, or "The Baron," as he was furtively referred to among the graduate students upon the infrequent occasions he was sighted in the halls moving directly to or from his office. Only a few students were involved in natural resources economics in the Agricultural Economics Department at Berkeley in those days. The Baron did not engage himself with those who were not, student or otherwise. He did not leave his office even to fetch a book or article from our convenient departmental library. The material was brought to him and handed in through the partially opened door. One did not enter without an invitation.

My field of concentration was called farm and ranch management. It was just evolving into production economics. We read Heady and articles on econometrics and linear programming. How I got into Wantrup's evening seminar on natural resources I have no idea. I entered confused and frightened. Wantrup turned out to be a gentleman of the old school, courteous and correct. Class, like his book *Resource Conservation,* was a groping to understand, to define in language, and to be educated. It was an intellectual experience. It was the only class I attended while at Berkeley that I realized that I did not understand and actively disliked. We did not read *Resource Conservation* for class. Wantrup assumed that if you had any intellectual pretensions you would read it on your own. I did, but found it too amorphous and nondirective.

It was only over time that I slowly evolved into being known as a natural resources economist. In Arizona, where I joined the University of Arizona faculty in 1961, water, a natural resource, is required to be applied artificially if any crops are to be grown. Cattle graze the public lands and are competitive (or complementary) with use of the lands for other products such as timber, wildlife, hunting, camping, and water for offsite use. Many of these products are nonmarket goods, or at least not sold in competitive markets. In studying the field of farm and ranch management, I entered the field of natural resources by the side door, at first without recognizing that I had done so.

Having become a natural resources economist, did I return to read and reread *Resource Conservation?* No. And despite the fact that Ciriacy-Wantrup ranked about fifteenth among the authors most cited as references in the *AJAE* during the period 1959–68 (Finley and Barger, 1973), I personally did not find my colleagues on the Western Agricultural Economics Research Council (WAERC) Natural Resources, Water Resources, and Range Committees using *Resource Conservation*. The field of natural resources was developing rapidly. The interest was in development of theory explicated in mathematical terms and in the application of empirical tools. There was little need for more than a passing reference to Wantrup as having mentioned the subject. I suspect that *Resource Conservation,* where referenced, had not been carefully read. An obvious exception to this generalization was my postgraduate mentor at the University of Arizona, M. M. Kelso, whose well-underlined copy I am now perusing. But Kelso, like Wantrup, was of a different age of agricultural and natural resource economist. He was trained in the appreciation of expressing theoretical concepts in nonmathematical language, and in treating real-life institutions as variables in the analytical framework of his analysis.

This rather lengthy preface leads me to the basic questions of this retrospective review. What does *Resource Conservation* contain, and are the contents relevant to issues of today? The answers are that as a basic frame of reference for conservation issues, *Resource Conservation* is as timely today as when published in 1952; and, as has been said of Alfred Marshall's *Principles of Economics* (1890), "it is all in Wantrup." The background for most current analyses are contained therein. Few answers are contained, however. As in Wantrup's 1958 seminar, there are only issues to be investigated. The effects of any policy may vary widely under given circumstances. Our job is to integrate specific circumstances with general theory.

Resource Conservation begins with an extensive section on definition and classification. As Kemeny has commented, definition and classification are extremely useful and necessary (if boring) early steps in a developing science. The tendency, particularly among social scientists who naturally desire useful social applications, is to rush into analysis before the problem has been properly defined.

Wantrup recognized that the word "conservation" has many contradictory definitions among many people. He defines the study of conservation simply as the quest "to understand the factors that affect the distribution of resource use over time, to inquire into the objectives of public policy with respect to this distribution, and to seek tools with which to implement policy objectives" (p. 12). Optimal distribution

of use over time will vary for different classes of resources; for example, for stocks versus flows, for exhaustible versus inexhaustible, and for primary versus secondary resources.

Given that conservation is about intertemporal distribution, the important analytical variables are interest rates, risk, and risk preference. These variables will be affected by all manner of private and public institutions, including, but not limited to, prices, incomes, price and income support policies, property rights, tenency rules, credit, taxation, and market form. Wantrup devoted chapters to each variable, examining the possibilities of complex interactions between the various forces. Of particular importance in Wantrup's view are the institutional effects on the security and flexibility of resource rights.

An earlier review commented on an apparent inconsistency in definition (Murdock 1953). Conservation is defined as the redistribution of a use "in the direction of the future," while depletion is "in the direction of the present" (p. 51). Value is not a component of the definition. Then, the optimum state of conservation is defined "as that time distribution of use rates that maximizes the present value of the flow of (expected) net revenue," a rule offered for both a private planning agent and for society in general. The argument is that the determining factor is value, an element absent from the definition. It appeared that Wantrup was avoiding explaining resource valuation by moving from one criterion (time) to the other (value). My reading of Wantrup simply is that while, as an economist, he stands up for the optimization rule, he recognized the complexity of selecting the correct rate of time preference, and opts for "the simplifications and approximations that are needed in reality" (p. 21). Directions toward conservation or depletion may be all we can hope for in practicality.

Castle et al., in the AAEA *Survey of Agricultural Economics Literature,* comment that Ciriacy-Wantrup was at least two decades ahead of most workers in agricultural and natural resources economics in treating institutions as explicit variables in his analytical framework. He was ahead in other areas as well. He had a clear recognition of the values for nonmarket goods and suggested that they could be obtained by questionnaire using hypothetical situations (now known as contingent valuation). He recognized that prices merely are normative expressions of values, and that because of the inequities in income distribution there are problems with the concept of consumer sovereignty. Further, resource conservation policies affect the distribution, just as the distribution affects policies.

Given the complexities of the world, Wantrup concludes that "the state in which social net revenues are maximized over time—is of only limited practical interest" (p. 249). The practical goal in conservation policy is a step-by-step improvement of the existing time distribution of use rates—analysis of policies at the margin. As a first approximation, and to guard against irreversible error, he offers the concept of a "safe minimum standard of conservation" (p. 253). Just as the possibilities for substitution and flexibility always provide for least cost solutions in private economics, the maintenance of a safe minimum standard is viewed as an increase in flexibility in the continuing development of society. "Costs of maintaining the safe minimum standard are not only small in absolute amount, but very small relative to the loss which is being guarded against, a decrease of flexibility (for) society" (p. 255). This standard may be expressed in any of a number of ways, but must be designed to avoid a use rate that avoids economic irreversibility. Thus, the standard could change over time. This standard is a conservative measure in that it is less than any higher (possibily optimum) state of conservation. Above the minimum standard, free private initiative may be allowed to operate. Minimal influence with private enterprise will occur.

The final three chapters focus on the tools (institutions) with which to implement conservation policy. They are a thorough survey of the then current and historical methods and economic conditions affecting conservation; but, as earlier reviewers commented, they are less imaginative and of less analytical interest than the first three-quarters of the book. Wantrup shows through as an idealist here. Everyone—resource users and nonuser alike—should be educated as to the complexities of resource use. Each policy should be coordinated with every other policy. But Wantrup is a realist as well as an idealist. Results from education alone will be small if economic and institutional factors stand in the way. The basic problem is that all methods of conservation policy have good points for some and bad points for others. Thus, the basic need for simple, practical, safe minimum standards of use arise. This final result is not eloquent economics, but the arguments presented in getting there are. *Resource Conservation* is well worth revisiting.

There was another personal experience relative to this gentle, idealistic scholar that I found rather poignant. Late in 1980, about a year after Ciriacy-Wantrup's death, I was visiting the Berkeley Department of Agricultural Economics in order to give a seminar on a subject in natural resources. As I was to be there for a couple of days and make myself available for discussions with students, the department decided that I should be given a temporary office. Professor Wantrup's office was empty, and because I was a visiting natural resources economist, it was made available for my use. There was quite a fuss as the secretarial staff searched for a key and started to make arrangements for a work-study student to clean off the desk and bookshelves. I assured them that the key was enough and went to the room.

Nothing had been touched since Wantrup's death. His desk was in orderly shape as he had left it. His umbrella and rubber overshoes were there in the corner. *Resource Conservation* was on a nearby shelf, and I began to browse through it for the second time. It was a restful and productive two days. Some very

pleasant and earnest graduate students, who were too new to have known Wantrup, made visits to my office. But all members of the departmental staff who had need for any dealings with me did so from the hallway, across the doorstep. They resolutely would not enter the office. For them, Professor Wantrup was still there.

New Reviews

Barbier, Edward B. *Economics, Natural Resources Scarcity and Development: Conventional and Alternative Views*. London: Earthscan Publications Limited, 1989, xvii + 223 pp., price unknown.

Current resource issues such as the greenhouse effect, deforestation, and the sustainability of current agricultural systems have caused economists to reevaluate the current treatment of natural resource issues and to look for an expanded framework which encompasses the multiple demands placed upon resources. This book provides a timely discussion of the limitations of the current treatment of resource problems and provides "a new way of looking at the inter-relationship between the economics of sustainable development" (p. xvi). The alternative view is offered not "as a replacement for conventional environmental and resource economics . . . , but as a necessary extension . . . into explicit analysis of environmental degradation and economic consequence of ecological disruption" (p. 92). The text introduces a conceptual framework in which constraints are placed upon economic systems through short-run environmental conditions which serve as an input to productive and consumptive activities, and the long-run potential for irreversible long-run environmental degradation.

The book has eight chapters that can be grouped into two sections. The first four chapters provide a discussion of the evolution of resource economics, while the last four chapters introduce and apply an alternative approach to resource economics. The book begins with a review of the treatment of resource issues by the classical economists. Chapter 2 supplies an overview of the contributions of conservationism, ecology, and thermodynamics. Chapters 3 and 4 discuss the neoclassical treatment of optimal depletion and externalities. Each of these chapters concludes with a discussion of the limitations associated with each treatment. These chapters provide a thorough and well-documented review of the evolution of the economic treatment of resource issues and the need for a broadened perspective to deal with emerging resource concerns.

Chapter 5 introduces an alternative model developed by the author which incorporates environmental quality constraints. Chapters 6 and 7 present the author's application of the alternative model to three problems: deforestation of the Amazon Basin, the greenhouse effect, and soil erosion in Indonesia. Chapter 8 provides a summary of the arguments presented and the need for alternative economic approaches to resource issues.

The thrust of the book is that economic and environmental systems are integrally intertwined; therefore, failure to incorporate the effect of environmental degradation on the sustainability of environmental systems will result in an analysis unable to capture fully the consequences of environmental degradation on social production and consumption and the sustainability of economic systems. Because the neoclassical treatment of resource issues has tended to treat optimal resource use and assimilative capacity of environmental systems as separate problems, the current treatment of resource problems needs to be extended to integrate resource use and environmental degradation.

In the first five chapters the author makes a sound case for the need to extend conventional economic treatment of resource issues and introduces a conceptual model to provide such an extension; however, the presentation falters in the ensuing chapters during the application of the new framework. In these chapters the author demonstrates his knowledge of the issues and policies involved but fails to demonstrate that the new framework provides a substantial improvement over previous treatments. Here, the author does not follow his own paradigm of fully integrating economic and environmental systems but, instead, paints a broad picture of the unsustainability of current economic practices given the ecological damage resulting from the bane of resource economics, incomplete information concerning the ecological and nonmarket economic ramifications of current practices. However, a more thorough integration of the economic and environmental systems would have resulted in a clearer presentation of the author's ideas.

Economists seeking an alternative approach to the interaction between economic and environmental systems will find the author's exposition an interesting and timely contribution, but his application is wanting.

Barry, Peter J., John A. Hopkin, and C. B. Baker. *Financial Management in Agriculture*, 4th ed. Danville IL: Interstate Printers and Publishers, 1988. xii + 500 pp., $24.95.

This fourth edition reflects refinements to the previous editions and updates the empirical data, examples, and organization. It remains a text focused upon financial management, organized into nineteen chapters and six sections. The sections cover nature and scope of financial management, measurement and analysis of financial performance, concepts of leverage, risk and liquidity, valuation and decision making, financial intermediaries, and related topics.

The authors consider the book to be targeted primarily to an audience of advanced undergraduate and beginning graduate students and to a lesser degree to others interested in understanding the application of economic and business principles in the financing of farm production.

I found the text to be quite readable but not exciting. I tried to picture myself as a student again and wondered if I could overcome the many external distractions long enough to get to each chapter's concluding "topics for discussion," where both significance and substance can be found. It takes effort. I do not consider this a shortcoming of this book as much as a general indictment of many college textbooks and some wishful thinking that more challenge could be incorporated with the concepts and principles.

Experiencing the credit problems of the 1980s drove me to chapter 3 on leverage and financial risk. The chapter is good and the discussion questions are excellent vehicles for providing a framework for classroom discussion, learning reinforcement, and illustration. Unfortunately the text on page 121 also is true: "Smaller-scale firms . . . main sources of equity capital is retained earnings whose costs are difficult to measure, whose amounts are subject to high uncertainty, and whose rates of growth often are not fast enough to finance large investments," thus heavy reliance on borrowing and land appreciation for unrealized capital gain. Applying concepts in practice, either classroom or business, is rarely easy. I would like to see use of some real-life, mini-case problems inserted in chapters such as this. I think it would help close a gap of understanding and application for many students.

Chapter 9 addresses the time value of money. It is straightforward and a traditional approach to net present value. Farm borrowers seem always to struggle with the same concept when applied not to investments but to the use of debt. The fact that interest is just the cost of using someone else's money for a specified period of time carries neither intrinsic rights nor borrower rights; yet, much of agricultural finance today has become intertwined with social goals not normally found in analytical equations. There may be a place for addressing in a text such as this some of the social issues that arise in the agricultural sector because of its importance to national welfare, unique appetite for debt capital, complicated family and business structure, and lumpy and often nonliquid asset structure. Chapter 17 addresses policy issues affecting agricultural credit markets but mostly from an economic efficiency perspective. There is little mention of a social dimension of policy, and yet it seems to be profoundly at the forefront of national policy debate.

As a book on financial management in agriculture, the text is strongest where it should be, in developing the underpinning theory and concepts of financial management. It is weakest in presenting applied material which students can more easily relate to practice. For example, new employees as beginning loan officers, most of whom have had finance courses, rarely have a good understanding of accounting and legal issues in finance. Legal issues have increased in importance over time as the Uniform Commercial Code (p. 352) has been supplemented with Truth-in-Lending (p. 319). Bankruptcy Code (p. 372), and various laws on borrower rights including equal credit opportunity and fair credit practices. Because many farm businesses also use credit for consumer purposes, the financing of agriculture is seldom a pure agricultural transaction. It might be helpful to pull several of these related topics together in a more prominent chapter with legal instruments, security recordings, and lien perfection. Likewise, the complexity of farm business accounting deserves more than the introductory disclaimer (pp. 29–30) and the simplified financial statement development of chapter 3. I would not expect this text to be an accounting course; but the failure to understand inventory, depreciation, and other cash accounting distortions continues to produce many misleading financial measures and erroneous decisions in farm financial management. Perhaps an expanded appendix on accrual accounting issues would complement this chapter.

Section five focuses on financial intermediation and takes a traditional institutional approach. It is accorded about the right amount of space and importance to complete the picture. *Financial Management in Agriculture* covers a broad scope of material from basic economic and business principles and concepts to analytical techniques to institutions to tax and legal issues to national policy making. It should be a versatile text for college courses.

Farm Credit Bank of Baltimore

Anne Booth. *Agricultural Development in Indonesia.* Sydney, Australia: Allen and Unwin, 1988, vii + 295 pp., price unknown.

Despite serving as the original stimulus for dual economy models of development, Indonesia's agricultural economy has attracted remarkably little notice in the modern development literature. This oversight is even more remarkable in view of the success story to be told. Both relative to its own historical performance and to the performance of most other countries in the past quarter century, Indonesia's agricultural sector has shown steady and rapid growth. And contrary to widespread expectations in the late 1960s, based on Geertz's views on shared poverty on Java and progressive limitations on capacity to absorb labor in its involuted rice culture, the rapid growth in agricultural output has been accompanied by a sharp reduction in poverty. Surely it is important to understand the causes of such a surprising success story in the world's fifth most populous nation.

Anne Booth understands that there is a paradox to explain and that this complicates the story considerably. First, the roots of both the early pessimism and the modern success are deeply historical, and Booth's analysis incorporates a detailed and masterful survey of the Dutch colonial record, now accessible to English-speaking scholars largely through her efforts. Second, Boeke's explanation of the limited response of Javanese peasants to colonial efforts to improve agriculture through irrigation and extension of modern cultural practices strongly conditioned how early development economists perceived the role of traditional agricultural sectors in the modernization process. Dualism, especially in labor markets, provided much of the rationale for the anti-agricultural biases of so many development plans in the 1950s and 1960s, including those of Indonesia. Models and ideas can have a permanence and influence far beyond the realities that (may have) once generated them, and this perserverance carries directly into development policies. At a time when many analysts and policy makers were worried about agricultural stagnation and immiseration, Indonesian farmers were busy expanding output by using new technology, more purchased inputs (including labor), and increased specialization made possible by far greater participation in rural product markets, which had been stabilized through active government price policies.

The third complexity that Booth recognizes, and the ultimate strength of the book, is that Indonesia's agricultural success story is set squarely in a supportive macroeconomic environment. Although she delineates in sharp detail the elements of the agricultural development efforts of the New Order government under President Suharto, Booth never loses sight of the policy context in which those elements were designed and implemented. The real test of this relationship, of course, is how the agricultural economy responded to the two oil shocks in 1973 and 1979. Indonesia suffered a severe case of Dutch Disease between 1973 and 1978, but many analysts were surprised to find that the most serious problems occurred in the rural sector, rather than in industry—in contrast to the Dutch industrial sector that was so badly hurt when prices went up for the country's North Sea gas exports (and hence the name for the phenomenon itself). Unlike other oil exporters with large rural economies, Indonesia (and Malaysia) undertook a series of macroeconomic policy adjustments designed to protect the rural tradables sector. The large devaluation announced by Indonesia in November 1978 was one of the earliest examples of exchange rate protection to help agriculture, and it was a key factor in the acceleration in agricultural growth between 1978 and 1983.

No short review can do justice to Booth's treatment of the historical antecedents to this growth record or to her skill in placing the Indonesian story in the context of both the internal debate over growth versus distribution and the external comparative literature on the role of agriculture in development. The internal debate has been three-sided, with neoclassical economics, Marxist and radical political economics, and cultural and sociological analysis competing to explain the Indonesian record. The earlier Geertzian view of low potential for growth in the context of shared poverty gave way in the 1970s to the view that capitalist growth mechanisms were spreading rapidly as village safeguards for the poor were eroded. Booth's judgment by the 1980s seems to be that neoclassical mechanisms of wage formation in the context of strong rural-urban links have translated rapid growth into poverty alleviation. Such mechanisms are at the heart of all the success stories in economic development.

Indonesia's emergence, even if tentatively, into this circle of success stories raises substantial hopes for the future. Booth's final chapter spells out the nature of the promise via a comparison of Indonesia's agricultural development since the 1960s with events in Japan during the Meiji era (1868–1912). Booth's argument for the validity of such a comparison is that the underlying historical precursors to modern agricultural growth, including government capacity to develop and disseminate modern agricultural technology, were laid down in the Tokugawa period in Japan but were not in place until the post-colonial era in Indonesia. By juxtaposing the two different historical times with similar historical conditions, Booth is able to show that Indonesia's recent agricultural performance was similar to that of Japan's and that very substantial further gains are possible if Indonesia merely continues to follow the Japanese pattern. Far from running out of opportunities for growth in agriculture, and the associated stimulus to local industry and the overall economy that comes from such growth, Indonesia still has decades of efficient growth in agriculture in prospect. Finding a way to encourage this agricultural growth will be a continuing challenge to Indonesia's policy makers, especially because the commodity focus used historically must give way to a more diversified and balanced

stimulus to rural incomes, but they can take heart that their efforts will be worthwhile. The analytical rationale and empirical evidence to justify these continuing efforts must surely be the two most important contributions of Booth's book.

Harvard University

Cohen, Ronald, ed. *Satisfying Africa's Food Needs: Food Production and Commercialization in African Agriculture*. Boulder CO: Lynne Rienner Publishers, 1988, 244 pp., price unknown.

This book addresses a very important, albeit complex, problem: How to help solve the food deficit problem facing Africa today. Obviously there is no easy answer, as reflected by the various views expressed in this book. The book serves as a forum in which a variety of social scientists spanning several disciplines (economic anthroplogy, economics, political science and geography) share their reflections on the current African food crisis.

Although not explicit, the book can be split into two general parts. The first part (chaps. 1–4) deal with Africa-wide issues, while the second part (chaps. 5–9) present focused articles on two countries: Kenya and Nigeria. In chapter I, Cohen opens the discussion with an essay on the factors responsible for the current food crisis in Africa and the alternative models for solving this crisis. He does a nice job in scrutinizing earlier colonial and post-colonial approaches, which were urban biased and consequently neglected the rural areas, and the "emancipatory ideas" of the 1960s and 1970s, which encouraged a greater role of the state in allocating resources. According to Cohen, this policy turned out to be a major constraint where it was applied. Cohen then discusses two polar opposite positions which have emerged. The unimodal and multimodal approaches.

The second chapter, by Christopher Delgado, provides an overview of the critical devices necessary for increasing food production in Africa. It stresses the importance of cutting agricultural production costs in order to improve farmers incentives. Delgado also writes that there are needs for (*a*) selecting the type of farmers to whom incentives must be provided, (*b*) setting regional and commodity priorities, and (*c*) concentrating resources along functional lines. Contrary to Cohen's view, Delgado believes that any serious development strategy must be addressed to smallholders, since it is this group that provides the largest share in the supply of food. Therefore, a vigorous smallholder sector will have widespread positive effects on net welfare. Delgado also argues that concentrating resources regionally and along commodity lines has the advantage that it ensures some success somewhere and in any case contributes to the increase in aggregate food supply.

In chapter 3, Goran Hyden asserts that Africa's food crisis is less a matter of the inability of the peasant producers to feed the continent than an institutional and policy problem. Therefore, satisfying Africa's food needs requires a redirection of not only African governments but also the official donor agencies. The reason for this is that development policies are designed with little or no regard for the complexity of development process. For this reason, Hyden concludes that Africa's capability to solve her food crisis depends on the evolution of a new paradigm that opens the door to a new development cycle in which Africa's own resources, whether human or natural, constitute the base for fresh policy action.

In chapter 4, Michael Lofchie uses the case of China's agricultural revolution to offer guidelines for the future recovery of the food crop sector in Africa. He has two concerns: first, there is a need to raise agricultural prices to improve incentives for producers. But Delgado (chap. 2) argues that food prices have risen substantially in Africa over the past few years and that cutting agricultural production costs will be necessary to improve incentives. Second, (like China) Africa's food policy should be guided by the principle of comparative advantage instead of seeking food self-sufficiency at all costs. The foreign exchange constraints are not necessarily alleviated given that cultivation and marketing of food crops in Africa are more import-intensive than the production of export crops for the world market.

Chapter 5 shifts to country studies. In this chapter Robert Bates examines the relationships between drought and famine in Kenya. Key factors identified are the magnitude and spread of the drought; farmers' skill in managing product stores; farmers' technology of food production (e.g., agriculturalist vs. pastoralist); the size of population and the relative rates of growth of population, and agricultural productivity. For example, if population increases at a rate faster than technical change, farming then must spread from areas of high-quality soils and abundant and reliable positive supports to more marginal agricultural regions which are more at risk to climatic fluctuation.

Chapter 6, by Paul Goldsmith, analyzes the productive and commercial success of Miraa, an indigenous tree (cash) crop. The success is due to the market incentives created by a growing salaritariat, the lack of government control and both increased consumption and trade. According to Goldsmith, this success clearly highlights the need to emphasize the dysfunctional role of government-managed agricultural development through parastatals and price controls. My only concern here is that Miraa is not a food product, which perhaps requires a different structure and conduct.

In chapter 7, Angelique Haugerud examines variation across seasons and among households in small farmers' food production levels. Using examples from Kenya, she argues that the "subsistence" nature of small farmers does not imply absence of response to market incentives nor a reflection of uniformly low productive capacity. It is rather a direct response to

market and state institutions as well as uncertainties. An empirical study on Kenya shows that despite several variations in rainfall, some small farm households do consistently produce more food than required to meet their customary consumption needs. This occurred because Kenya farmers' food-crop diversification and subsistence strategies are related to fluctuations in unofficial consumer prices of the food crop; to the unofficial fees charged by the uneven geographic distribution of official food-crop marketing agents; and to the inability of the state marketing board to protect consumers or producers from alternating cycles of gluts and deficits. The major lesson to emerge from this chapter, however, is the highlighting of some of the complexities of small farmers' economic strategies and indication of the importance of understanding local food production patterns.

Chapter 8 is the first of the two chapters that focus on Nigeria. In this chapter Akin Mabogunje does a nice job analyzing the current economic situation in Nigeria. This country is currently undergoing a structural adjustment program (SAP) and the chapter is therefore timely. Despite the strains and stresses of SAP, Mabogunje writes (p. 205), "A new ethos is emerging whose essential indication is a concern with production and individual productivity." Mabogunje notes that there is a trend toward increasing self-employment and enhancing the image of the private sector. But he has one concern: Is Nigeria trying to become a capitalist country with all the insensibility, the lack of human compassion for the weak, and the heavy wastage of human resources that go with this?

The book closes with chapter nine, which also focuses on Nigeria. It is the second contribution of the editor. Cohen argues that food deficit problems in Nigeria have resulted from causes similar to those in many other African countries: low level of technology and very little attention paid to the problem during the colonial era. Cohen argues that, with the mix of development policies followed by successive governments in Nigeria, smallholders alone may not hold the solution to per capita food deficits. It is therefore essential to support a wide variety of projects and programs designed to help rural peoples and to develop commercial food production for the home market under protected conditions.

In general, I like the book because of the varieties of opinions that it contains. Although the papers do not form one piece, the quality of the book is enhanced by this diversity of opinions which cut across several disciplines in social science. I regret that most of the country-focused articles do not give the readers a feel of the range of agricultural policies (successes and failures) currently employed on the continent. Too much emphasis is put on Kenya and Nigeria at the expense of the many other African countries. The articles vary in terms of quality, but this is common to most edited books. More contributions on the Africa-wide issues would have been appreciated. This could have been done perhaps by adding a discussion paper after each contribution. One thing I like about the chapters on Africa-wide issues is that they offer hypotheses which can be tested empirically. There are a few typographical and printing errors, but they do not in any case unduly diminish the quality of the book.

Simeon K. Ehui
International Institute of Tropical Agriculture

Dovring, Folke. *Farming for Fuel: The Political Economy of Energy Sources in The United States.* New York: Praeger Publishers, 1988, 152 pp., $37.95.

Although Dovring, as suggested in the subtitle, reviews several U.S. energy options, his book is primarily concerned with providing evidence for his advocacy of a single option. He argues "that the best future mainstay of energy supply in the United States is methanol, eventually to be produced entirely from biomass. This will solve not only the problems of energy supply and vulnerable oil imports but also the farm problems of surplus production, low prices, and soil erosion, and the ecological ones of air pollution and eventual overheating of the atmosphere" (preface).

The author discusses the foregoing proposal as "four problems—one solution" in chapter 1. This is followed by a review of the petroleum age in chapter 2 and a discussion in chapter 3 of the available options for replacing petroleum including liquid fuels from coal and natural gas, oil from shale and tar sands, nuclear power, solar electricity, and biomass. The evidence presented is critical of all the options except methanol from biomass. This is particularly true of the ethanol or gasohol subset of the biomass option, which is presented in chapter 4. Biomass production as a land-use diversification is developed in chapter 5, followed by biomass production as soil conservation in chapter 6. The final four chapters focus on possible supplies and costs of methanol raw materials, converting biomass to methanol, using methanol in vehicles, and some of the political obstacles to adoption of the methanol option.

The evidence presented on the petroleum energy supply and vulnerable oil imports problem is best summarized by the following quote from Dovring: "The Persian Gulf is hardly a place that the United States should trust with half or more of its transportation fuel. Supplies from that area already now carry heavy overheads in military and political costs. If these costs were factored into the price of petroleum (which is not done now) the continued reliance on petroleum as the primary source of transportation fuel would not look as favorable as it is now often made to appear" (p. 14).

The reduced dependence on petroleum would be made possible, according to Dovring, by converting at least 300 million acres of current or potential U.S.

cropland into methanol energy farms. Whereas the ethyl alcohol from grain option is criticized for high energy input and increased soil erosion, the author argues that tree and grass energy farms are more energy efficient and can have the effect of stabilizing soils and reducing the rates at which groundwaters are impaired by fertilizers or pesticides. In addition, fuels from sustainable biomass farms, unlike petroleum, will not add any new carbon to the atmosphere and its waste heat will be no more than the solar heat previously absorbed to build up the biomass.

Fairly detailed information is provided in Dovring's discussion of the possible supplies and costs of methanol raw materials. He concludes that both trees and grasses will produce yields at costs that will be competitive with fossil energy sources within a decade or two. However, the evidence is more mixed regarding the use of methanol in vehicles. While methanol is more efficient, has cleaner emissions, less risk of explosion and fewer environmental hazards from fuel spills than gasoline, it is also more corrosive and toxic, and has problems with cold start, emissions of unburnt methanol and aldehydes, and low visibility of flame when burning.

A major problem with the book is that the author's strong advocacy posture results in a number of subjective statements that take away from an otherwise serious analysis of an important set of problems. Examples include the author's statement regarding deep untapped natural gas reserves that "we should make up our minds never to tap these reserves lest we ruin our planet" (p. 4) or his statement "that the supply of oil will be exhausted can be shown easily" (p. 5). The author also misses other related options including promising evidence on the economics of co-combustion of crop and forest residues with high sulfur coal (Hitzhusen and Abdallah, Gowen and Hitzhusen). In addition, the discussion of soil erosion is weak in its development of externality and downstream cost arguments, and the comparison of net energy versus economic analysis shows little recognition of willingness-to-pay type arguments.

On balance, the book is useful in pointing out the interdependence of several energy, farm policy, and environmental problems. It also develops some evidence for "the methanol from biomass for transport fuel" option but appears to overstate the case. More analysis is needed to estimate the future demand for methanol fuels given the increased concerns with air pollution and global warming. More analysis is also needed on the farm-level and societal (including soil erosion, air pollution, and global warming) economics of tree and grass crops for methanol fuel, particularly on the more erosive acres within the current Conservation Reserve program. The earlier cited work by Gowen and Hitzhusen develops a "plantation forestry for wood gasification" scenario which appears promising in this latter regard.

Krabbe, J. J. *The Idea of Welfare Economics*. UNIPUB: Wageningse Agricultural University, Wageningen, Netherlands, 1989, x + 73 pp., $85.00

The aim of the essay by J. J. Krabbe is to incorporate the principles of welfare theory into the fields of natural resource and environmental economics. At issue are the functional relationships among natural resource depletion, pollution processes, various forms of technological development and the welfare function.

The static basic model is explicated through a system of production and welfare functions involving land, raw materials, and labor. The model is dualistic in the sense that prices and quantities are endogenous. Environmental technology is considered to be resource sparing. The model is extended to account for the multifunctional uses of land including agricultural production and the preservation of nature. Further, location theory is included in the modeling framework. An important attribute of the model is that unpaid functions, such as "nature" are internalized.

The author notes that the proportion of raw materials used, compared with quantities of land and labor, is rising steadily; depletion of natural resources and environmental pollution are direct consequences. He concludes that present-day technology policy should "cut this fatal tie" (p. 58) through restricting industry, stimulating environmental technology, and modifying the institutional framework relating to production and consumption. Two types of environmental policy are distinguished: complementary policies and interventionist policies. Complementary policies would involve direct government expenditures to ameliorate environmental pollution problems after they occur. Interventionist policies would directly regulate production processes and land uses to minimize or stop the source of environmental pollution.

The model described involves a "whole gamut of substitution elasticities between production and production factors" (p. 57). The author suggests that the possibilities for empirical work to estimate needed elasticities is limited; consequently, no empirical work is offered. Nevertheless the model has heuristic value, according to the author. Even with this caveat, Krabbe enunciates policy prescriptions, e.g., "The institutional alterations must be such that labor is comparatively cheap, in order to minimize the substitution

of raw materials for labor." This presumably will enhance welfare and the environment.

Krabbe is to be commended for his effort to conceptualize the welfare implications of the use of natural resources. The notion that land has multifunctional uses and has spatial qualities is not new. Also the idea that raw materials, land, and labor can substitute and complement each other to produce services and products is not novel. What is new and useful is the link with welfare theory.

The author rightfully acknowledges the lack of empirical work, and he states that the work is incomplete; additional conceptual development is needed. With these admissions, this reviewer feels that the policy prescriptions offered by the author are premature. The assertion that labor must be priced low compared to prices to owners for raw materials in order to promote welfare and the environment needs testing. If the costs of maintaining or enhancing the environment are internalized in the industrial and agricultural production processes, would not the production functions shift and elasticities change? Can we be certain that less raw materials should be used and labor priced comparatively low in order to maximize welfare and environmental values? Also an argument can be made that policies dealing with prices of labor and prices of raw materials relate to questions of equity, to which economics makes only a limited contribution.

The reader must be prepared to digest dozens of equations; however, the content of the work can be ascertained without complete immersion. The translation from the Dutch is somewhat stilted, making interpretation and understanding difficult. Even with the above concerns, this reviewer feels that those interested in natural resource issues will find the essay interesting and useful. It does have heuristic value.

Melvin L. Cotner

Leuthold, Raymond M., Joan Junkus, and Jean Cordier. *The Theory and Practice of Futures Markets*. Lexington MA: Lexington Books, 1989, 410 pp., price unknown.

The scope of this book is noteworthy for the effort to integrate the understanding of agricultural futures markets with that of financial futures markets. The book's scope is also noteworthy for the effort to integrate theory and practice, to which end the academic literature is abundantly referenced, and numerous examples are provided for the practitioner. Given the fact that the authors (especially Leuthold) have themselves made numerous contributions to the literature it comes as no surprise that a very useful book results. And given the fact that all three authors are teachers, it follows that they sought to produce, and succeeded in producing, a college-level textbook. Were I still engaged in teaching a course on futures markets, I should not hesitate to adopt this textbook.

This is not to say that I would accept the book as gospel. After all, the professor who does not use his bully pulpit to demonstrate that his knowledge goes beyond that contained in the textbook may incur the dread ego deflation complex. Seeking the road toward understanding of futures markets, I find one convenient juncture at which I would take a different route than they have chosen and be led to a different conclusion as to the primary role of (at least the traditional) futures markets. This occurs at p. 72, where the authors conclude that the portfolio approach, which they credit to Johnson and Stein, "reconciles differences between Keynes' and Working's theories by combining return maximization with risk (minimization)." It is not possible within the confines of a book review to do other than state my position in this matter. Keynes propounded a plausible sounding notion that recognized the need for the harvest surplus to be rationed throughout the year, giving rise to the risk of price decline for those who carried the inventory, thence to the shifting of that risk to speculators on futures markets (Keynes). In support of this simple proposition Keynes hastened headlong into hyperbole, exaggerating the value of the annual cotton inventory by at least an order of magnitude (equating it to the value of all the ships in the world); then fantasizing that the average underestimate of subsequent prices evoked on futures markets ranged between 10% and 20%. But he tried to ward off any empirical estimates of this "risk premium" by saying "the data do not lend themselves to tabulation." In fact the data had already been tabulated and analyzed (U.S. FTC, U.S. ICR) and Keynes had self-destructed on his own petard; but such studies had been little noted, least of all by Keynes.

Working, unlike Keynes, was no Chanticleer. Trusting in painstaking empirical analysis and employing a turgid prose style which eschewed not only hyperbole but any colorful phraseology, he demolished the Keynesian theory without saying so (Working). The great bulk of the hedging on agricultural futures markets was conducted by merchandising firms and processing firms, which prior to the wave of vertical integration after World War II were distinct entities. Working showed that this hedging had to be explained in terms not envisioned by Keynes, and that any risk aversion or risk transfer in the futures markets was incidental.

Back to the alleged reconciliation, there was none to be done, Working having allowed risk its proper place. At least insofar as the traditional (agricultural) futures markets are concerned, portfolio analysis has afforded no insight into their use or performance.

I should never have dwelt so upon the contents of p. 72 of this book, were it not that it reflects an underlying view of the role and purpose of futures trading which permeates the book, and with which I disagree at least as a matter of emphasis. The authors reiterate that the primary role of futures markets is risk management. I would point out that, insofar as the agricultural futures markets are concerned, they have served as the central coordinating mechanisms

of these major economic segments. Whenever government has not usurped this role, prices discovered on futures markets have played it, cash prices having been relegated to the subservient role of "on or off" futures by virtue of the great concentration of the forces of supply and demand in the organized futures markets, which in turn has enabled great reductions in search costs and transactions costs compared with those on any of the satellite markets.

Some ironies are involved here. Keynes, clearly a supporter of futures trading, misconceived and trivialized its role. Opponents of futures trading, whether agrarian populists or dealers in and processors of the commodity, have perceived the role of futures markets correctly but have not liked the results. Agrarian populist opposition has been mostly scapegoating, but at least it has not been gulled into the insurance metaphor. Dealers in onions and potatoes, meatpackers, etc., have had a much more rational basis for their opposition—futures markets erode monopoly power, which they do not like losing. Another irony lies in the fact that the rapid adoption of futures trading in at least some segments has had a great deal to do with risk—but not with the risk of price change addressed by Keynes and his followers. Rather the risk of contract default, so prevalent in private treaty forward contracting, gave rise to a rapid turn to futures trading where default is virtually unknown due to the mark-to-the-market rules. This was really a strong motivation at the Chicago Board of Trade, where first corn and then wheat futures were introduced more than a century ago. Soybean processors were similarly confronted, after World War II, with a "soft contract" problem which was alleviated by futures. Mortgage bankers turned to futures in the mid-1970s in large part because builders and developers were walking away from forward contracts, I dare say that the risk of default contributed more to the growth of traditional futures markets than did the risk of price change.

A third irony rests in the fact that the exchanges themselves, obviously representing their major users, have so willingly espoused the risk transfer raison d'etre. It has served their purposes as an alternative to the image of big traders manipulating price at the expense of producers and consumers—"risk transfer" has an innocent and beneficent ring to it. One successful speculator with whom I had been conversing over coffee, terminated his coffee break by saying to me, in broad jest, that he had to get back onto the floor and sell a little risk insurance to Cargill. They know of course that they are not peddling risk insurance, but they like to have their fun.

A final, somewhat compound irony, may help to explain how I can endorse this book after all the carping I have been doing. Mindful that all of the phenomenal growth in financial futures trading has occurred on the (hitherto) agricultural futures markets, it seems plausible that financial economists would have turned to agricultural economists to gain understanding of the institution in its original environment. That this has not happened may be attributed to a combination of factors; agricultural economists, by and large, have neglected the study of futures markets; exchanges generally purveyed their services to the financial community in terms of risk management; and financial economists, far from neglecting the study, have published more in the past decade than had ever been written before on the subject. They were ready with their portfolio models, their CAP models, and soon-to-be-developed optimal hedge ratios, not only to swamp the academic literature but to swamp the financial institutions with a host of M.B.A.'s. This could mean (I do not say that it does) that risk management is the leitmotif of hedging in the largest and still growing proportion of futures trading.

This book will afford opportunity to teacher and student alike to become familiar with the mechanics of the institution, its history and its regulation. More important, it presents a balanced treatment of issues not fully resolved, as well as a very fair guide to further reading. There is good reason to have a full course devoted to futures markets in an agricultural economics curriculum, good reason to include financial futures in the course, and good reason to choose this as a text.

Monke, Eric A., and Scott R. Pearson. *The Policy Analysis Matrix for Agricultural Development*. Ithaca NY: Cornell University Press, 1989, xi + 279 pp., $35.00.

This volume uses an organizational and accounting framework, the policy analysis matrix (PAM), to estimate the impact of a variety of government policies on the private profitability of agricultural systems and the efficiency of resource use, as measured by social profitability. The accounting framework which is explicit in PAM attempts to break down the divergence between private and social prices into three categories of effects attributable, respectively, to market failure, distorting policy and efficient policy. This last effect can be thought as countervailing government policies to offset, or partially offset, the negative effects of market failure and distortions.

In addition to a short introduction and concluding

section, the volume consists of three main parts, i.e., (*a*) "Evaluation of Agricultural Policy" (commodity policy, factor policy and macroeconomic policy); (*b*) "Social Valuation in the Policy Analysis Matrix" (social valuation of commodities and factors); and (*c*) "Empirical Estimation of the PAM" (the construction of PAMs for commodity systems; farm-level and postfarm budgets and analysis, the estimation of social profitability, and the interpretation of PAM results).

The reference price which is used for measuring efficiency or comparative advantage (i.e., the social price) for an agricultural commodity is border price, i.e., the world price including transportation costs. The authors claim that the appropriate world prices are "long-run equilibrium levels that approximate best guesses of expected future prices" (p. 29).

The volume contains a painstaking partial equilibrium (Marshallian) analysis of the impact of various types of subsidies and taxes on commodity and factor price distortions. This part is rigorous and useful in illustrating clearly the direct effects of these policy instruments on commodity and factor prices. Chapter 5, which extends the PAM analysis to the impact of macroeconomic (i.e., fiscal, monetary, and budgetary) policy is much less successful for reasons which are mentioned below. A few empirical illustrations of the PAM to specific Portuguese and Indonesian agricultural issues enrich what is otherwise a fairly dry and technical exposition.

The conceptual framework underlying the PAM is mainly an extension of project analysis. It is based on a partial equilibrium approach emphasizing the direct (price) effects of policy instruments rather than the indirect effects. The latter are only captured in a limited way and only to the extent that all shadow prices can be correctly estimated—a most ambitious task. The PAM strength lies in contrast with macroeconomic instruments—on different agricultural commodity systems. Hence, in a limited sense and within agriculture, this approach can be useful in identifying crops enjoying a comparative advantage and the appropriate set of price policies to encourage the production of the most efficient crops.

On the other hand, I have great doubts that the PAM provides a valid analytical and quantitative framework—as its authors seem to claim—when used in a broader sense to explore the impact of macroeconomic policies on efficiency (growth) income distribution and food security objectives. I have three reasons for skepticism. First, the PAM, as such, does not capture the indirect (e.g., intersectoral, interinstitutional) effects of policies within a general equilibrium framework. Models based and calibrated on a social accounting matrix (SAM) are far superior in tracing through the indirect effects of fiscal and monetary policies on growth and income distribution. These indirect effects are often more important than the direct effects. Second, the use of world prices as the main set of reference prices is not without serious risks. If the world agricultural trading system itself is heavily distorted because of agricultural protectionism in the developed countries, using present world prices as reference may only further distort worldwide resource allocation. If, as appears most likely, the EEC will be forced in the near future to reduce its level of support to its farmers, the world prices of many agricultural commodities are bound to go up. The authors are aware of this problem when they say that "observed world prices may be different from those expected in the future" (p. 189). Yet, they argue that "because prediction of the timing, magnitude, and price effects of such policy changes is usually impossible, most estimates of expected prices implicitly assumed constancy of agricultural policies in other countries" (p. 193).

Third, the treatment of the trade-offs among objectives (particularly between efficiency and income distribution) appears totally static in the PAM. For example, the issue is not how government expenditures between current and capital expenditures would be allocated currently to achieve a certain mix of efficiency and poverty alleviation today. Rather, the key issue is what are the consequences of alternative budgetary allocations on efficiency and poverty alleviation now and in the future. Allocating a large share of government expenditures to capital projects may worsen poverty in the short run but because of its positive impact on growth alleviate poverty in the medium run. (Incidentally, the lack of almost any discussion of intertemporal issues and discount rates within the PAM framework is evidence of time-myopia.)

In conclusion, the PAM may provide a valuable framework to identify efficient agricultural systems (and subsectors) within agriculture and help design appropriate price policies. To use it more broadly to explore, for instance, the impact of macroeconomic policy instruments on different development objectives would be to stretch it far beyond its analytical capability.

Pereira, H. C. *Policy and Practice in the Management of Tropical Watersheds.* London: Belhaven Press, 1989, xvi + 237 pp. Published in the United States by Westview Press, Boulder CO, $27.85.

Land degradation in the third world has become the subject of widespread concern. Erosion, salinization, and related environmental disturbance impinge on the capacity of many developing countries to satisfy expanding demands for agricultural commodities. As is the case farther from the equator, the benefits of water resource development in the tropics are being jeopardized by sedimentation and agricultural nonpoint source pollution.

Among the first to address the problem of watershed management in the tropics was Sir Charles

Pereira. Starting in the late 1940s, he worked for many years in eastern Africa. He has since participated in projects in a number of Asian countries. Distilled into this brief volume are insights gained over four decades of experience.

The author begins by putting watershed management problems of developing countries in perspective. Different forms of land degradation are described, and the costs they impose on society are explained. In addition, natural hazards of erosion, flooding, and the like are acknowledged, the author being careful to describe the "marginal" impacts of human occupation of environmentally fragile lands.

Most of the book addresses technical issues, with special attention given to forestry. The role of tree cover in the management of tropical watersheds with different climatic conditions is outlined. The third world fuelwood crisis is the subject of a separate chapter, as is agroforestry. Recognizing that the farmers and herders who now populate the upper reaches of most third world watersheds will never be fully displaced, Pereira goes on to describe soil conservation measures that can be applied on crop and rangeland in addition to describing less erosive techniques for meeting domestic animals' needs for fodder. Additional chapters are devoted to drainage and salinity issues arising in alluvial lowlands and to flood abatement strategies.

Concise and incisive, these surveys of technical issues are of enormous practical value to economists and other social scientists called upon to design or to evaluate watershed management initiatives. For example, the twenty-page chapter on the role of forests in watershed management contains highly readable descriptions of how the removal of tree cover affects erosion rates as well as sediment and water yield at lower elevations. Complementing the text is an informative set of photographs, figures, and drawings. Indeed, one of the principal charms of this book is that the author prepared most of the art work himself. He illustrates forest hydrology, for example, with a fine sketch showing trees, subsurface roots, bedrock, and a spring. In addition, one is not likely to forget the extent of an acacia tree's surface roots after seeing another drawing of five men holding a single tree's root network.

The surveys of technical issues in watershed management have one relatively minor shortcoming. No reference is made to literature written after the middle 1980s. As a consequence, one's ability to survey more recent thinking on any particular issue is inhibited. [The early chapters of Gregersen et al. (1987) contain a good survey of more recent literature.] However, Pereira compensates for the omissions of many other authors, who ignore older, often seminal, literature.

A more serious limitation of the book has to do with its lack of policy insights. Taking a Malthusian perspective, the author identifies rapid growth of human and livestock populations as the principal cause of land degradation in the third world. In the final chapter, he calls for national governments and donor agencies to commit more human, financial, and other resources to watershed management. How the latter initiative is supposed to overcome overpopulation is not made clear. In addition, other causes of land degradation, including policies pursued by national governments, are virtually ignored.

Better assessments of government policies, market forces, and other factors contributing to land degradation in the third world are available (Schramm and Warford). But for many of us, from undergraduates to senior social scientists participating in interdisciplinary research on land degradation in the tropics, this book's introductory survey of technical issues is of enormous value.

Reed, David A. *The Winnowing: Economic Change in Rural America*. Indianapolis IN: Hudson Institute, and University Press of America, 1989, v + 65 pp., paperback, price unknown.

Contextually, Reed's book is ideological. It favors a violent, survival-of-the-fittest, mercantilist, anti-Christian, anti-nationalist technocracy that exploits our own farmers by expecting them to produce more but not make a living doing it and by labeling government efforts to "save the family farm" as "unrealistic" (p. 7).

Reed favors "our [international] competitiveness (p. 64), "free trade in agricultural commodities" (p. 44), and the "inevitable trend" (p. 64) of letting the market "factors" [forces] of "technology and global economic restructuring" "restructure" (p. 44) the "agriculture, manufacturing, and national resource" sectors (p. 64) of rural America. Following Nicholls' argument that America's farm surplus is "too many farmers" (p. 158), Reed opposes public policies to contravene this trend (p. 44), even though its "most obvious effect" "will" be that "far fewer people will be able to make a living as full-time farmers" (p. 5).

He blames the victim by asserting that many farmers are unable "to deal with change when it confronts them" (p. 39), but he did not study their education or the source of their powerlessness. Yet, Reed advocates (pp. 42–45): (*a*) the elimination of income support payments, (*b*) the decoupling of income supports from production, (*c*) the replacement of non-

recourse production loans with market-based alternatives, and (*d*) the use of education vouchers to remove and retrain displaced farmers from rural America.

The policies suggested in the book fail in several ways. First, they divide and destabilize rather than unify American "agriculture": they neglect diversification or other programs (e.g., quality control, product differentiation, direct marketing) to help farmers add and retain value added. Second, they justify serious concerns (e.g., of Galbraith) over the textbook ideology that the market, not the firm or the individual, abuses power (p. 286), or (e.g., of Reich) over subversive collectivized forces of the corporate state, technocracy, and the rationalization of greed over the common good. Third, given the following definitions, they favor a violent, exploitive man. In contrast to an exploitive man, a developmental person values and supports (*a*) pro-developmental economic growth (i.e., a win-win gain in the life chances or quality of life of two or more individuals, groups, sectors, regions, or nations without a loss or sacrifice of the well-being of others); (*b*) rural development, following Cramer and Jensen (p. 450), "all the developmental activities that result in making rural America a better place to live and work"; (*c*) commodity programs which, following Tweeten (cited in Ray and Plaxico, pp. 35–36), promote (*i*) "parity of earning power of farm with nonfarm income," (*ii*) "economic vitality of the farming industry to provide adequate supplies of quality food at reasonable cost for domestic and export needs," (*iii*) "preservation of the environment," and (*iv*) "maintenance of the family farm structure"; and (*d*) peace, the opposite of violence (i.e., anything, including ignorance, insensitivity, or greed, which produces, or refuses to control, forces whose individual or structural effects ignore, harm, or destroy the livelihood or relationships of another).

Space restrictions permit only two examples of the methodological and analytical problems in this book. First, the Hudson Institute asserts (*a*) that "the success of democracies depends not only on economic, military, and scientific prowess, but equally on the moral commitment and values of their peoples" (Daniels, p. 7) and (*b*) its "independent research mission" (Daniels, p. 6). Despite these commitments, Reed's book ignores the morals, values, and economic position of individual farmers, workers, or communities in rural America, accepts the "generous support" (p. iii) of four agribusiness "organizations," and advocates a large volume of low-priced farm commodities. Second, it appropriately notes "the large gap between the economic well-being of rural Americans and their urban counterparts" (p. 1), but it misses the gap's structural source—a lack of competition and the conflict of interest within "agriculture." Following Lappé (pp. 2–3), price-taking farmers buy farm inputs from agribusiness oligopolists and sell (i.e., not market) standardized commodities (i.e., not unique differentiated products or services) to agribusiness oligopsonists.

Its failure to analyze the structure of "agriculture" causes problems throughout the book. For example, when it asserts that "the image of rural America as being dominated by and dependent on agriculture is no longer true" (p. 1) because fewer people "live and work on the farm" (p. 1), it misses the productivity provided to nonfarm sectors by farmers. Following Cramer and Jensen, "the efficiency of American agriculture is second to none" (p. 22) and is "vital to the U.S. economy" (p. 22). In effect, agribusiness and food consumers are dependent on farmers to provide an increased volume (p. 34) of "quality food and fiber at reasonable prices" (p. 22); indeed, "the farm and food system contributes 18 percent of the nation's gross national product" (p. 23). They also note that "advances in agricultural science and technology" (p. 29), "have increased output and lowered agricultural prices"; "as a result some producers have been forced to find other employment" (p. 29). Reed's book favors cheap food over parity by claiming that agriculture has been quick "to reap the large gains in productivity these technologies made possible" (p. 13). It denies the abuse of power and need for public policy observed by Ray and Plaxico (pp. v, x), who realize high farm productivity does not produce high net farm income: (*a*) "Highly *unstable* and chronically *low* farm prices and incomes originate from nature and *market structure*," (*b*) "excess capacity is back with a vengence," and (*c*) they "increasingly require relatively stable farm prices and predictable income." Do we perhaps need a farmer-administered Rural Development Bank to tax the volume and/or value added of the middleman to generate funds for farmers (*a*) to add value by differentiating and marketing their own products at home and abroad; (*b*) to use fewer farm chemicals; (*c*) to conserve and improve the quality of our soil, water, and air; and (*d*) to be less dependent upon costly subsidies?

This monograph provides an informed and thoughtful analysis of the historical record and the opportunities and challenges that face Canadian institutions with respect to their involvement in Human Resource Development (HRD) in the third world. It reports on a study sponsored by the International Development Research Center, in Ottawa, in which the professional experiences of the principal author have been supplemented with the results of a focused period of research and a wide-ranging series of interviews and discussions around the issues addressed. The core investigation was initiated in 1984. It did not involve any statistical surveys, and very little related data is presented. Rather, the report summarizes expert opinion with respect to a number of related issues and development in Canada.

The study sees HRD emerging as "the cornerstone" of Canada's aid efforts, and rightly so. This focus, it argues, has supplanted the 1960s emphasis on physical infrastructure development and the "basic needs" emphasis of the 1970s. HRD is broadly defined to include, in addition to traditional formal education; short-term professional training; on-the-job training; supporting food, health, and housing programs; and institution building. The importance of long-run perspective is emphasized.

This shift to a broad definition of HRD is reminiscent of the broadening of the "land reform" movements of the 1950s into the "agrarian reform" perspective of the 1960s, which, of course, while it helped to define that developmental bandwagon more realistically, also undermined the rallying power of simplistic solutions. This study finds a general consensus as to the importance of HRD emerging under the wider definitional umbrella, with less developed countries concluding that their progress depends very substantially on gaining access to western technology and training and with the more developed countries concurring, based on their own experience, that human resource development, broadly defined, is strategic to growth and development and to relevant aid programs. However, it also observes that the question of how to transform this general consensus into effective operational arrangements substantially remains in a state of flux.

One of the more interesting sections is entitled "Market Forces and Profit Making in International HRD." It argues that HRD is a legitimate export industry for economies like Canada in a context in which citizens and organizations in many countries, and especially in those falling in the middle and upper level income range, are actively bidding for the ingredients that they need to import from abroad if they are to transform their HRD initiatives into positive, profitable results. In other words, HRD is recognized to be not just an "aid" issue, but also a "trade" issue. However, the report itself does not specifically address the state of effective demand for the ingredients of HRD on the part of the poorest of the world's nations or the degree to which these nations have been substantially shut out of training opportunities in countries like Canada during the last few decades for want of the needed foreign exchange reserves.

The report recognizes a large potential role for the private sector in international HRD and the need for greater public and private sector cooperation in the process. It gives emphasis to the need for institution building within the public sector of Canada and identifies a number of its existing and potential centers of excellence and cooperative relationships between Canadian institutions and institutions in the less developed countries. New sources of finance are explored, and the need for greater entrepreneurial activity in this respect is emphasized. A small section is devoted to the need to develop better overall databases and networking among institutions within Canada and abroad to support more effective and cooperative programming.

Among the developed countries, in which are concentrated most of the resources and institutions capable of contributing to the HRD development process in the poorer countries, Canada has indeed an impressive record and one of which it deserves to be very proud. Some of its areas of comparative advantage are noted in this study, such as its bilingual capabilities. However, it also recognizes areas in which Canada is at a comparative disadvantage with respect to its major international competitors for HRD support.

The study is quite specifically directed to Canadian readers, and the non-Canadian reader is treated with a surfeit of parochial acronyms without the help of a glossary. The book should help to focus the attention of professionals and organizations in both the private and public sectors of Canada on the strategic issues and developmental possibilities that lie ahead in the HRD area. The study will also be of value to those in other countries who have similar professional interests. Most of these would probably agree that there is a need for comparable studies of existing and potential capacity in all of the advanced countries in order to set the stage for greater and more effective response by all of these countries, if, and when, the current third world debt issue ceases to preclude any major correction of the fundamental inequality in HRD throughout the world upon which so many things depend.

Tracy, Michael. *Government and Agriculture in Western Europe, 1880–1988*, 3rd ed. New York: New York University Press, 382 pp. $50. Agricultural policy has been a major concern of the European Community (EC) since the inception of the Common Agricultural Policy (CAP). The CAP has been the source of friction with the U.S. and other agricultural exporters and a major issue in the Uruguay Round of negotiations under the General Agreement on Tariffs and Trade. Tracy states, "It must seem surprising that agricultural policy should require so much attention at the highest level. After all, agriculture employs only 8 percent of the labour force and contributes on average only 4 percent of national income in the Community. Yet agriculture has been high on the Community agenda since its outset: it was described initially as the 'pillar' of European integration, but as problems have accumulated, it has appeared increasingly as a major stumbling-block" (p. vii).

The book seeks to explain how European policy arrived at its current state by examining the development of agriculture and government involvement over a long period of time. The study covers a somewhat longer time period and less geography than is implied by the title.

The account focuses on the United Kingdom, France, Germany, and Denmark, with some coverage of the Netherlands and Italy and, very briefly, of some other countries. The four that are treated in detail provide interesting contrasts during the period preceding their involvement in the EC and the CAP. The study provides background needed to appreciate the positions taken by these countries in the development of the CAP.

The book is in three parts plus a conclusion. Part one covers the depression of 1880 to 1910 that is characterized as the first wave of protectionism. Part two treats the second wave of protectionism, the crisis of the 1930s. Part three deals with the period since the Second World War and European integration. The first chapter of each of the first two parts provides an overview of the situation in Europe for the time period involved. Chapters on the United Kingdom, France, Germany, and Denmark follow. Chapters in part one cover the organization of agriculture in the centuries prior to 1880 in addition to the twenty-year period stated in the title.

Tracy's analysis reveals the sharp contrast in reactions to the challenge to European agriculture posed by the shift in comparative advantage in grain production to the New World. "The most advantageous response for European countries was to concentrate on foodstuffs whose production was labor-intensive rather than land-intensive, and for which nearness to the market was an important advantage: in particular, dairy products, meat, fruit and vegetables (these, moreover, were products for which, as a result of rising incomes, the trend of demand was favourable). If agriculture, even when adapted in this way, could no longer provide adequate incomes for the farming population, then the necessary course was to promote a shift of manpower from farming to the growing manufacturing sector" (p. 357). He points out that "in fact, Denmark and the Netherlands were almost the only countries to take positive action along these lines. They reaped an immediate benefit." "Great Britain did nothing, and the result was a forced adaptation, arable farming went into decline and the agricultural population, already small, fell still further" (p. 357). "France, Germany and Italy reacted defensively to the challenge of overseas competition, raising their tariffs on grains in particular, and thereby maintaining or even expanding grain production" (p. 358). The crisis of the 1930s forced all western European countries toward protection, yet the approaches taken in the late 1800s were evident in their positions in the development of the CAP.

The book is primarily a history of the organization of agriculture and the development of governments' roles in it. Despite Tracy's personal involvement as a director in the General Secretariat of the Council of the European Communities and his obvious understanding of the political decision process, he appears to be disappointed that the resulting policies are not more rational. At the end of the book he opines that "public choice" theory more nearly fits the facts than does the "rational choice" paradigm.

This well-documented story of the development of agricultural policy in Europe will be rewarding reading for the serious student of the CAP. It provides the background needed to understand how it came to be as it is. Tracy leaves the reader with an appreciation for the difficulty of change but with little direction for a solution to the current impasse. He finds encouragement in the fact that "it should be remembered that these inefficiencies are those which arise in free-enterprise economies and under parliamentary democracy. The abundance resulting from the dy-

namism of numerous individual farmers is undoubtedly preferable to the shortages which, so far, have characterized centrally-planned agriculture" (p. 363).

Tweeten, Luther. *Farm Policy Analysis*. Boulder CO: Westview Press, 1989, ix + 399 pp., $48.50.

Farm policy is growing in breadth, depth, and complexity. Anyone unconvinced of that fact need only take up the challenge of reading this volume. It incorporates a massive amount of research and literature on a wide array of traditional and nontraditional issues—farm structure, rural values and beliefs, chronic low returns in farming, macrolinkages, foreign trade, the efficiency of U.S. agribusinesses, and the more current agricultural issues relating to the environment, rural poverty, food safety, and rural development.

Coming from the author that it does, the volume will be widely read, and each reader will make his own assessment. Not all will agree with this review. From the standpoint of a Washington policy maker, however, the volume is a godsend of information on a wealth of problems facing the policy maker and administrator in the agricultural arena. And it fulfills its title: It draws together the results of analyses completed over the past quarter century by a large number of the profession's elite, including Tweeten's. And it interprets these results in a meaningful way.

Readers should be forewarned of one point, however. This volume is not an evening's reading. There is a wealth of information in it, in each chapter. Some of that information requires serious mental gymnastics to fully understand the points being made. The graphs once understood illustrate certain points and will be very useful in classroom environments. But many graphs represent an integration of economic theory and agricultural applications that are fairly complex. As such, they require the reader to have an understanding of both the basic discipline and the agricultural parameters. For the advanced undergraduate and graduate student in agricultural economics, it will prove to be a very useful exposition of research applications in the formulation of agricultural policy.

There are some nonanalytical parts to the volume. One is a "short history of commodity programs" (pp. 323–48) that synthesizes past farm bills. Tweeten observes that "two basic approaches to commercial farm policy are workable: one is to adequately control production and support prices, the other is to leave production uncontrolled and let prices fall to levels that will clear the market" (p. 323). In reviewing the 1950s, he notes that "a Democratic Congress and Republican Secretary of Agriculture Benson concocted an unworkable combination: Price supports with ineffective controls at an inopportune time when the technological revolution had struck full force. The result was unconscionable levels of stocks." The 1960s, he suggests, brought a change in programs that "was expensive to the government, but it did restrain production and reduce the burdensome carryover" (p. 334).

Those years also brought a turning point in farm policy. "The (Kennedy) Administration and the Farm Bureau, which had highly conflicting views on farm policy, chose the 1963 wheat referendum as the battleground for deciding which direction the farm would take" (p. 334). "Over a million farmers and their wives voted, five times the number who had participated in the referendum of the previous year. Only 48 percent voted for the mandatory program. It was a stunning defeat for the Administration" (p. 335). Tweeten adds: "Farmers had made a momentous decision, reversing the trend toward mandatory programs. Advocates of mandatory programs had argued that the public would not stand the high cost of voluntary programs needed to maintain farm income at satisfactory levels. They were wrong—the taxpayer was more tolerant of high Treasury costs than was the farmer of tight controls. And farmers continued to demonstrate their power to obtain favorable legislation even at high cost to taxpayers" (p. 335).

A little later he explains that this support continues despite the declining proportion of farmers in the electorate. "Support has been stronger in Congress than from the executive branch for farm commodity programs. The President mainly has acted to constrain Congress in recent years. To the extent that Congress represents special interests and the President the public interest, that trend will continue" (p. 347).

For those of us interested in program history, the history chapter was interesting reading. For others the technical chapters will be of greater interest. And for readers interested in the structure of agriculture, there is a chapter on family farm prospects. Tweeten notes, "Society may have many reasons to preserve the family farm as discussed in Chapter 3. However, the family farm need not be preserved to maintain farm output and food supplies. Output does not fall as family farmers exit because their operations are mostly taken over by other family farmers who produce more per acre than the operator who left" (p. 32).

Diehard family farm supporters will not welcome this message.

Finally, it seems fair to observe that the volume does not foreclose the opportunity for others to contribute to the literature on farm policy. A few questions are left unanswered. For example, the response of competitor countries to differing price levels is a critical issue in setting U.S. commodity loan rates. This volume refers only obliquely to that issue. It also makes assertions that need more evaluation. "Much raw farm output is produced with greater capital intensity than processed products, hence the U.S. has comparative advantage in the former. These factors help to explain why this nation is not more prominent in supplying high-value processed farm com-

modities in the world market" (p. 194). One wonders if we had as many export subsidy programs for processed commodities as we do for raw farm commodities if this assertion would hold.

von Witzke, Harald, C. Ford Runge, and Brian Job, eds. *Policy Coordination in World Agriculture*. Kiel, West Germany: Wissenschaftsverlag, Vauk Kiel, 1989, 247 pp., price unknown.

The good news is that the papers in this book are an excellent collection that is focused on world agricultural trade problems and have been edited to a readable form. But, the bad news is that they were prepared before a 1987 symposium in Minneapolis and will be nearly three years old when this review appears.

Compliments should be given to the organizers for getting fine work from the right people, but the acknowledgement to the publishers for "her unique efforts to publish this book quickly" seems to verge on the sarcastic considering the time elapsed. Shortcuts to publishing are too evident: the typed pages are reduced to half their original size; no comments are included, although the program included two respondents to each paper; and a paperback binding has been used that will irritate libraries and relegate it to the pamphlet file or incur the added cost of binding before it enters the stacks.

The nineteen symposium participants (7 from the University of Minnesota) had a broad range of papers to discuss. The volume opens with "Market Integration in Agriculture: An Historical Overview" by Vernon W. Ruttan and proceeds through a variety of presentations to a concluding chapter by Alex F. McCalla, probably the two best-known American writers on agricultural trade and development policy today. But, most of the material was prepared as background for those embarking on the GATT negotiations. It presents excellent history, good empirical analysis, and a number of suggested alternatives for the negotiators to use.

Ruttan's introductory paper sets the stage for discussion of disequilibria in world agricultural commodity markets. He sees little hope for change in the political will that creates trade problems but thinks that economic efficiency, budget constraints, market incentives, leverage, and hegemonic cooperation may overcome some political forces. The ninety references in his paper make a magnificent reading list for a graduate seminar if brought up to date.

Yujiro Hayami's contribution uses his unique knowledge of Japanese agriculture and his work on agricultural development to shed insight on how we got into the current problems, and he constructs "nominal rates of agricultural protection" to compare fifteen countries over the period 1955–84. He outlines a "better alternative" to the interest group battles waged throughout the agricultural policy world but sees no promoter who will stage a new drama.

The obvious promoter would be GATT, and three writers (Runge, von Witzke, and Thompson) use analytical game theory to show what that entity could do if trade were liberalized.

This theme is also covered by Rausser and Wright. After illustrating the global distortions that include Japanese sugar producers, who receive seventeen times the world price, and the Egyptian wheat farmers, who receive more for their straw than for their wheat, they use PSE's (producer subsidy equivalents) to compare country policies. Finding this concept wanting when looking at GATT accomplishments (or lack thereof), they propose producer incentive equivalents (PIES) that incorporate only the components of PSE's that have a net influence on output.

The final three papers are critical of the present agricultural trade structure, and each has proposals for change that could be used by GATT negotiators. Schuh's paper is titled "Redesigning International Institutions and Agricultural Sectors" and moves from the assumption that "a significant share of the world's agricultural output . . . is now produced in the wrong place" through several partial solutions and concludes that we need new international institutions.

Every symposium should have a "devil's advocate," a role played by Robert Paarlberg on the program in this volume. He attacks the basic assumption that world agriculture would benefit from greater international policy coordination and arrives at a conclusion that unilateral liberalization should be pursued, especially in the U.S. sugar and dairy programs.

Winding up the program, Alex McCalla is in his element as the eloquent summarizer. He senses that all the writers agree that "the game has to be taken out of the hands of entrenched agricultural interests but how is the big question." Nations need to "sit down and reason together," but "getting that process started is most vexing."

The process is ongoing in the GATT negotiations. Would that this volume were on every negotiator's reading list. For that purpose, it should have appeared two years earlier—and one more proofreading would have helped, as well.

State of California

Williamson, Jeffrey G., and Vadiraj R. Panchamukhi, eds. *The Balance between Industry and Agriculture in Economic Development*. Proceedings of the Eighth World Congress of the International Economic Association, Delhi, India, vol. 2, Sector Proportions. New York: St. Martin's Press, 1989, xxxii + 427 pp. $59.95.

This volume consists of eighteen papers brought to-

gether under four highly interrelated parts, i.e., (1) sector proportions and economic development: theory and evidence; (2) sector proportions and economic development: country studies; (3) industry versus agriculture in East European economies; and (4) unbalanced productivity advance, agriculture-led development, and rural activities.

The editors provide an excellent introduction to the volume in the form of an overview and review of the major findings and contributions of the papers. This introduction captures the essence of these contributions succinctly and clearly. It not only touches on most of the fundamental questions regarding the relationship between agriculture and other sectors throughout the process of economic development but proceeds also to answer a number of them authoritatively. This reviewer would agree with the editors' own evaluation that the papers make an "enormous contribution . . . and remind us just how far development economics has come . . . since the fifties" (p. xxii). (At the same time, the editors could have been somewhat more modest in their own praise; a number of papers are called, in turn, "excellent," "important," "stimulating," and "marvelous.")

Space limitation precludes more than a selective evaluation of the papers and rich issues covered by them. The volume starts, appropriately, with a paper by Lance Taylor, who provides a comprehensive and rigorous treatment of the anatomy of multisectoral models. The main message is that the extremely large number of alternative specifications of key causal mechanisms affecting supply and demand variables as well as closure rules in such models rules out adopting a "broadly applicable uniform model" (p. 26). Rather, good modelers must have a sense of history and understand the institutions, the structure, and the behavior of the major actors of the socioeconomic system which they tried to capture quantitatively. The very richness of Taylor's paper combined with a concise telegraphic style do not make for easy reading, but the analysis is bound to reward those patient enough to stay with it until the end.

The two papers by Syrquin and Panchamukhi et al., respectively, are excellent prototypes of the "patterns of development" approach. They rely on a database of about 100 nations across three decades since the end of the second World War. Even though a rigid adherence to the structural and intersectoral transformation paths generated by the patterns approach is suspect as a guide to the individual path likely to be followed by any given country in any given period of time, the authors come up with robust findings. Syrquin explicitly recognizes that there is no unique development path; the latter is bound to be influenced by structural characteristics and policies. On the other hand, "the overall nature of the transformation over long periods of time has had a remarkable degree of uniformity" (p. 48).

Among the findings of Panchamukhi et al. is that the thesis that industry is the engine of growth stands discredited when tested against the experiences of developing countries. In fact, "a strong linkage between the growth of the service sector and overall growth in GDP of these countries" (p. 80) is detected.

In an interesting study of the first industrial revolution in Britain, Jeffrey Williamson shows clearly that highly imperfect factors markets greatly constrained Britain from following anything near an optimal industrialization path—a conclusion which is based on the empirical application of a computable general equilibrium model to nineteenth-century Britain.

The final paper in Part I by Hwa shows clearly that "agricultural growth induces productivity increases and, therefore, facilitates overall economic growth" (p. 122). The policy implication which is suggested is that while agriculture is inevitably a "declining industry" from the point of view of its share of both output and employment in the economy, it should not be excessively squeezed to support nonagricultural activities in an early phase of the development process. If anything, an appropriate agricultural development strategy should be formulated so as to accelerate agricultural growth rates. This has by now become conventional wisdom in contrast with the earlier view of the 1950s and early 1960s, which assigned a much more passive and subservient role to agriculture.

Among others, Part II includes three detailed country studies (Korea, Nigeria, and India) of various aspects of the interrelationships between agriculture and other sectors throughout the development process. Leipziger and Petri demonstrate how the agricultural sector in Korea was gradually transformed from a sector facing unfavorable terms of trade to one of benefitting from the type of agricultural protection which is typical of the more industrialized countries.

The common themes which run through the five papers constituting part IV of the volume include (*a*) the link and complementarity between agriculture and industry—a process which is well analyzed for Japan from the late nineteenth century onward by Kaneda; (*b*) the key importance of rural nonfarm activities in contributing employment opportunities to the rural population and making a significant contribution to the alleviation of rural poverty. (This trend is well illustrated on the basis of a number of developing countries by Liedholm and Kilby.); and (*c*) the scope for agricultural development-led industrialization strategy (ADLI). Both Mellor, at the national level, and Irma Adelman et al. at the international level—using a general equilibrium approach—show the benefits which could be derived from an ADLI strategy.

In conclusion, this is an excellent volume—with the exception of part 3 on the experiences of Eastern European economies. It should be read by all serious students of the interrelations between agriculture and the rest of the economy in the development process. For the time being it can claim to be the most definitive and comprehensive treatment available—particularly as other IEA companion volumes come out to

supplement other aspects of the balance between industry and agriculture.

Erik Thorbecke
Cornell University

Zusman, Pinhas. *Individual Behavior and Social Choice in a Cooperative Settlement*. Jerusalem: The Magnes Press, The Hebrew University, 1988. 234 pp., price unknown.

Most of Israel's farm production historically has been the result of collective or cooperative arrangements. The predominant form of those arrangements has been and still is the *moshav*, "a farming community in which all farms are family owned and operated, and all farmers are organized in a village-level, multi-purpose service cooperative—the association" (p. 10). Its preponderance is evidenced by the fact that, as of 1981, the *moshavim* contained 51% of all farm units and 30% of the cultivated land and formed 39% of the gross value added in Israel.

Zusman's book provides an extensive, detailed, and systematic description of the *moshav* as a cooperative settlement-cum-village and an enlightening chronicle of its development, organization, functioning, government, and evolution. It is indeed a treatise on the *moshav*. To reduce its scope to the *moshav*, however, would be highly inappropriate, since the author develops an encompassing conceptual framework capable of handling alternative forms of cooperative organization. What makes this book exceptional is the breadth and depth of the topics and issues addressed and the rigor, both technical and intellectual, of their treatment. From his discussion of collective choice issues, to his treatment of the pricing of credit by the *moshav*, to his insights on behavior in group production, Zusman displays an uncanny keenness of analysis that makes reading this book a delight.

The breakdown of the book provides a complete and well-rounded picture of the *moshav*, featuring discussion of the historical development of the organization (chap. B), rich institutional description (particularly chaps. D, E, and J), and sound and rigorous theoretical analysis of individual behavior in groups and in cooperative settings (chap. C in particular), as well as treatment of the governance structure of the *moshav* (chaps. I and J).

With his insights on the history and workings of the *moshav*, the author displays knowledge usually associated only with insiders. Chapter B creates a well-documented historical record of the legal and economic foundations, as well as the evolution, of the organization. Chapters C and G in particular stand out for their completeness. With its development of the general theory of the *moshav* organization, chapter C provides the theoretical backbone of the book, while chapter G deals with the *moshav* association as a financial intermediary. In these chapters, Zusman has integrated a solid knowledge of strategic behavior in groups and organizations and theories of collective choice and risk management with his analysis of the institutional structure of the *moshav*.

In chapter M, Zusman analyzes the effectiveness of the *moshav* in adapting efficiently to changes in the environment. In the process, he uncovers a number of structural deficiencies in the *moshav* form of organization that tend to lead to over-borrowing and delinquency in loan repayments. This proves to be an interesting and relevant exercise because, shortly after the publication of this book, the potential disaster resulting from such structural problems became evident when the long period of run-away inflation in Israel was brought to a sudden halt in the mid-1980s. As a consequence of their overborrowing, the *moshav* organizations suffered financial collapse, clearly underscoring the seriousness of the problem. As the author points out, these structural deficiencies, coupled with a general weakening of the overall commitment to cooperative values, have put severe stress on the delicate fabric of the *moshav* and have called into question their long-term viability without fundamental structural changes.

Among the book's shortcomings, one could identify first the thin treatment that behavioral strategic dynamics receives. The relevance of a dynamic framework to the subject matter of the book and the policy instruments that a dynamic treatment provides suggest the need for greater coverage in this area. Second, although the author is aware and sympathetic to the fact that "attempts at explaining observed behavioral patterns in the *moshav* often involve appeals to noneconomic cultural factors such as ideology, cooperative ethics, solidarity, kinship relations, etc." (p. 9), he nevertheless minimizes the reliance on noneconomic factors in his analytical framework to explain the economic phenomena of the *moshav*. However, these problems do not overshadow the significant contributions this book makes to our understanding of cooperative settlements in general and to the *moshav* in particular.

Overall, this fascinating book significantly advances our knowledge about a very relevant, yet seldom explored, topic. It transcends the *moshav* in its applicability to many other cooperative modes. Such applications could prove quite useful for the process of development in low income countries, Eastern Europe, and the Soviet Union. Any student of cooperatives, cooperation within institutions, or the socio-economic dynamics of governance will be well-served by a careful reading of this book.

ESOP Special Issue

Membership dues of the Association include a one-year subscription to the journal. Subscription rates are: Regular $40; Sustaining $45. Library subscriptions are $60 per year. Members outside the U.S. add $6 per year to cover overseas postage. All fees must be in U.S. dollars drawn on a U.S. bank. Write Financial Management Association, College of Business Administration, University of South Florida, Tampa, FL 33620.

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter, the author(s) must state (*a*) that the material in the manuscript has not been published, is not being published or considered for publication elsewhere, and will not be submitted for publication elsewhere unless rejected by the *Journal* editor or withdrawn by the author(s); (*b*) that the material in the manuscript, so far as the author(s) knows, does not infringe upon other published material protected by copyright; (*c*) that the employer of the author(s), if any, either does not assert an ownership interest in the manuscript or is willing to convey such interest to the American Agricultural Economics Association (AAEA); and (*d*) that submission of the manuscript gives the AAEA exclusive right to publish, to copyright, and to allow or to deny reproduction of it, in whole or in part. If the applicability of point (*a*) is unclear, the author(s) must explain.
2. **Author's identification.** To protect their anonymity in the review process, authors should not identify themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on $8^1/_2$-by-11-inch standard weight white paper with margins on all sides of at least $1^1/_4$ inches.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of the *Journal*.
5. **Data and Documentation.** Authors are expected to document their data sources, models, and estimation procedures as thoroughly as possible, and to make data used in their analyses available to other researchers for replication purposes. If for legal or proprietary reasons, the data can not be made available to all potential users, this limitation should be noted. Submission of appendices, model documentation, and other supporting materials with the manuscript is acceptable in order to facilitate the review process.
6. **Mathematical notation.** Use only essential mathematical notation; it is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable.
7. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type all footnotes, double-spaced, on a page following the article. Footnotes should be only explanatory and not for citations or for directing the reader to a particular work. This information can be incorporated into the text.
8. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of a sentence, a parenthetical reference is unnecessary unless page numbers or a date are needed. A style sheet on references and citations is available from the editor.
9. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
10. **Figures.** For accepted manuscripts camera-ready figures must be prepared using professional techniques that are suitable for photographic reproduction. Typescript is not suitable.
11. **Four copies.** Send four fully legible copies to the editor. All copies should be inspected for completeness and quality of reproduction.
12. **Abstract.** Instructions for the preparation of an abstract will be sent when a manuscript is accepted for publication.
13. **Page charge.** Major support for this ***Journal*** comes from page charges of $55 per printed page, or fraction thereof, payable by the supporting institution or granting agency. Payment does not affect acceptance, scheduling, or form of publication. Instructions for payment are sent with galley proofs.

American Agricultural Economics Association

Objective

The American Agricultural Economics Association (AAEA) seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy.

AAEA

—publishes the *American Journal of Agricultural Economics*, the *AAEA Newsletter*, *Choices*—The Magazine of Food, Farm, and Resource Issues, and, periodically, a *Handbook-Directory* of AAEA members;
—plans and conducts an annual meeting of the membership;
—sponsors awards for Distinguished Undergraduate Teaching, Distinguished Extension Programs, Distinguished Policy Contribution, Publication of Enduring Quality, Outstanding Journal Article, Quality of Communication, Quality of Research Discovery, Outstanding Master's Thesis, and Outstanding Ph.D. Dissertation;
—recognizes prominent agricultural economists as Fellows;
—operates the AAEA Employment Service for agricultural economists.

Membership and Subscriptions

AAEA is a professional society for agricultural economists and others who are interested in agricultural economics. A nonprofit organization, AAEA is committed to furthering knowledge about the economics of agriculture, rural communities, and natural resources.

Membership in the AAEA will bring you *Choices*, the *AJAE*, the *AAEA Newsletter*, and other occasional AAEA publications, permit you to use the AAEA Employment Service, and allows you to attend the annual meetings.

Calendar year dues are: $45, regular members; $22.50, senior (retired and 65) and junior (student) members; $67.50, family members; $150, industry members. Lifetime membership is available for members who are at least 55.

Subscription prices: *American Journal of Agricultural Economics*—$65 per year ($73 overseas); single copies, $14.50. *Choices*—The Magazine of Food, Farm, and Resource Issues—$32.50 per year ($52.50 overseas); single copies, $10. *AAEA Newsletter*—$12 per year ($17 overseas).

For further information about the American Agricultural Economics Association, contact the AAEA Business Office, 80 Heady Hall, Iowa State University, Ames, Iowa 50011-1070 (515-294-8700).

AMERICAN AGRICULTURAL ECONOMICS ASSOCIATION

AAEA Annual Meeting
Vancouver
British Columbia, Canada
5–8 August 1990

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to:

Peter J. Barry, Editor
Department of Agricultural Economics
University of Illinois
305 Mumford Hall
1301 W. Gregory Drive
Urbana, Illinois 61801

Communications concerning book reviews and books submitted for announcement in the ***Journ*** should be sent to the book review editor:

Dale W Adams
Department of Agricultural Economics
Ohio State University
2120 Fyffe Road
Columbus, Ohio 43210

Editorial Policy

The purpose of the ***Journal*** is to provide a forum for creative and scholarly work in agricultur economics. Thus, acceptable manuscripts should have a relationship to the economics of agricultur natural resources, or rural and community development. Contributions, methodological or applie in the business, extension, research, and teaching phases of agricultural economics are equally e couraged. The ***American Journal of Agricultural Economics*** (ISSN 0002-9092) is published month in February, May, August, November, and December by the American Agricultural Economics A sociation, 80 Heady Hall, Iowa State University, Ames, Iowa and printed by Edwards Brothers, Inc Ann Arbor, MI. Second-class postage is paid at Ames, Iowa, and additional mailing offices. Pos master: Send address changes to the American Journal of Agricultural Economics, 80 Heady Hal Iowa State University, Ames, Iowa, 50011-1070.

Subscription

Subscription cost is $65 per year plus foreign postage; members receive copies as part of their me bership fee of $45 per year.

Acreage Decisions Under Risk: The Case of Corn and Soybeans

Jean-Paul Chavas and Matthew T. Holt

An acreage supply response model is developed under expected utility maximization. The resulting framework is used to specify and estimate a system of risk-responsive acreage equations for corn and soybeans in the United States. Particular attention is given to the truncation effects of government price supports on the distribution of corn and soybean prices. Also, a wealth variable is included in the acreage equations. The empirical results indicate that risk and wealth variables play an important role in corn-soybean acreage decisions. The analysis also shows that cross-commodity risk reduction is important in acreage allocation decisions.

Key words: corn-soybean acreage, expected utility maximization, risk, truncation.

Much research has focused on acreage response functions in agriculture. Following the relative success of the Nerlovian approach (e.g., Askari and Cummings), recent developments have attempted to strengthen the link between empirical supply response and economic theory either in a static framework (e.g., Weaver, Shumway, Antle) or in a dynamic framework (e.g., Vasavada and Chambers, Howard and Shumway). At the same time, evidence is increasing that risk and/or risk behavior are important in agricultural production decisions (e.g., Behrman, Just, Lin, Traill). However, the implications of decision theory under risk have played only a minor role in supply response analysis. A wide gap exists between the economic theory of risk behavior and aggregate supply analysis.

The objective of this article is to develop an acreage supply response model under expected utility maximization and to investigate its empirical implications for U.S. corn and soybean acreages. After the presentation of an expected utility model for acreage decisions, testable hypotheses of economic behavior under risk are developed. Multiple sources of revenue uncertainty are modeled, and linkages between government price support programs and the subjective probability distributions of uncertain output prices for decision makers are investigated. This is done by modifying the bounded price variation models considered by Maddala (1983a,b), Shonkwiler and Maddala, and others to include multivariate price distributions. The implications of the theory are then incorporated into the specification and estimation of a system of risk-responsive acreage decision functions for corn and soybeans in the United States, and the results are discussed.

The Model

Consider a farm household producing n crops where A_i is the number of acres devoted to the ith crop and Y_i is the corresponding yield per acre, $i = 1, \ldots, n$. Letting p_i be the market price of the ith crop, then agricultural revenue is given by

$$R = \sum_{i=1}^{n} p_i Y_i A_i.$$

Denoting the cost of production per acre of the ith crop by c_i, then the total cost of agricultural production is

$$C = \sum_{i=1}^{n} c_i A_i.$$

In the present case, revenue (R) is a risky variable because output prices $p = (p_1, \ldots, p_n)$ and

Jean-Paul Chavas and Matthew T. Holt are, respectively, a professor and an assistant professor in the Department of Agricultural Economics, University of Wisconsin. Senior authorship is shared.

The authors thank three anonymous reviewers for their helpful suggestions on an earlier version of this paper.

crop yields $Y = (Y_1, \ldots, Y_n)$ are not observed by the household when production decisions are made. Alternatively, input prices and per acre costs (c_i) are known at the time crop acreages are allocated.

The household then faces the budget constraint

$$I + R - C = qG, \text{ or}$$

$$(1) \qquad I + \sum_{i=1}^{n} p_i Y_i A_i - \sum_{i=1}^{n} c_i A_i = qG,$$

where I denotes exogenous income (or wealth) and G is an index of household consumption of goods purchased with corresponding price index q, qG denoting household consumption expenditures. Equation (1) states that exogenous income (I) plus farm profit ($R - C$) is equal to consumption expenditures (qG).

Let the constraints on acreage decisions be represented by

$$(2) \qquad f(A) = 0,$$

where $A = (A_1, \ldots, A_n)$. Assume that the household preferences are represented by a von Neumann-Morgenstern utility function $U(G)$ satisfying $\partial U/\partial G > 0$. If the household maximizes expected utility under competition, then the decision model is

$$\max_{A,G} EU(G) \text{ s.t. (1) and (2)},$$

where E is the expectation operator over the random variables. After substituting the budget constraint into the utility function, the maximization problem is expressed as

(3)
$$\max_{A} \left\{ EU\left[\frac{I}{q} + \sum_{i=1}^{n} \left(\frac{p_i}{q} Y_i - \frac{c_i}{q}\right) A_i\right]\right\} \text{ s.t. (2), or}$$
$$\max_{A} \left\{ EU\left(w + \sum_{i=1}^{n} \pi_i A_i \right)\right\} \text{ s.t. (2),}$$

where $w = (I/q)$ is normalized initial wealth and $\pi_i = (p_i/q)Y_i - (c_i/q)$ denotes normalized profit per acre of the ith crop, $i = 1, \ldots, n$, and all prices are deflated by the consumer price q.

This formulation illustrates that the acreage decision A is made under both price and production uncertainty. Both yields Y and output prices p are random variables with given subjective probability distributions.[1] Consequently, the expectation E in (3) is over the uncertain variables p and Y and is based on the information available to the household at planting time.

What are the economic implications of the optimization problem (3) for the acreage decision A? Letting A^* denote the optimal acreage choice in (3), such a choice depends on normalized initial income (or wealth) w, expected normalized profits per acre $\bar{\pi}_i = E\{p_i/q)Y_i - (c_i/q)\}$, as well as second and (possibly) higher moments of the distributions of normalized profits per acre π_i, $i = 1, \ldots, n$, denoted here by σ. In other words, the optimal acreage decision can be written as $A^*(w; \bar{\pi}; \sigma)$, where $\bar{\pi} = (\bar{\pi}_1, \ldots, \bar{\pi}_n)'$.

The acreage decision under risk $A^*(.)$ is homogenous of degree zero in (w, p, c, q). While this result does not depend on risk preferences $U(.)$, this well-known homogeneity property involves output price p, input cost c and initial wealth w and the consumer price q. The homogeneity condition implies that acreage decisions can be expressed as functions of the relative prices w/q, p/q and c/q (or their probability distributions). However, unless additional restrictions are imposed on risk preferences (see Pope), it does not imply that the acreage function $A^*(.)$ is homogenous of degree zero in output and input prices (p, c). In other words, the classical result of riskless production theory stating that production decisions depend only on input-output price ratios does not hold in general under uncertainty.

Properties of the Acreage Decision

The empirical implications of expected utility maximization have been investigated by Sandmo, Ishii, Chavas and Pope, Pope, and others. In this section we focus on the theoretical restric-

[1] The formulation in (3) is consistent with a yield function of the form

$$Y_i = \min\{a_i(x_i), b_i(x_i)\}, \; i = 1, \ldots, n,$$

where x_i is a variable input (e.g., fertilizer), and $\min\{a_i(x_i), b_i(x_i)\}$ is assumed to be a concave function of x_i. This is a kinked yield function if $\partial a_i/\partial x_i > \partial b_i/\partial x_i \geq 0$ at the point where $a_i(x_i) = b_i(x_i)$. Moreover, optimum input use $\bar{x}_i$ is not responsive to changing relative prices at the kink (at least within some range of prices). This formulation has been found to provide a reasonable representation of yield functions (e.g., Anderson and Nelson; Ackello-Ogutu, Paris, and Williams). In this context, letting r be the price of the input x_i, the variable cost of production per acre is $c_i = r\bar{x}_i$ in equation (3) (within some range of prices).

tions implied by (3) which can be tested and/or imposed in the empirical specification and estimation of the acreage decision $A^*(.)$.

First, Sandmo and others have examined the relationship between wealth effects, $\partial A^*/\partial w$, and the nature of risk preferences. In particular, a zero wealth effect, $\partial A^*/\partial w = 0$, corresponds to constant absolute risk aversion. Alternatively, $\partial A^*/\partial w \neq 0$ corresponds to nonconstant absolute risk aversion. Nonzero wealth effects are of interest here to the extent that decreasing absolute risk aversion is a maintained hypothesis in much of the economic literature (e.g., Arrow).

Second, the optimization hypothesis (3) implies symmetry restrictions on the slopes $\partial A^*/\partial \bar{\pi}$. These symmetry restrictions take the form

$$\frac{\partial A^c}{\partial \bar{\pi}} = \frac{\partial A^*}{\partial \bar{\pi}} - \frac{\partial A^*}{\partial w} \cdot A^{*\prime}, \tag{4}$$

where A^c is the wealth compensated acreage decision, holding utility constant. The matrix of compensated effects $\partial A^c/\partial \bar{\pi}$ in expression (4) is symmetric, positive semidefinite (Chavas). Expression (4) also indicates that the slope of the uncompensated function $\partial A^*/\partial \bar{\pi}$ can be decomposed as the sum of two terms: the compensated slope (or substitution effect) $\partial A^c/\partial \bar{\pi}$ which maintains a given level of utility plus the wealth effect $(\partial A^*/\partial w \cdot A^{*\prime})$. These results are quite general since equation (4) holds for any risk preferences.

Under constant absolute risk aversion, the wealth effect vanishes implying that $\partial A^c/\partial \bar{\pi} = \partial A^*/\partial \bar{\pi}$. In this case, compensated and uncompensated choice functions have the same slope with respect to $\bar{\pi}$ and $\partial A^*/\partial \bar{\pi}$ is a symmetric, positive semidefinite matrix from (4). This illustrates the influence of risk preferences on acreage choice functions since nonzero wealth effects reflect nonconstant absolute risk aversion. Also, note from (4) that non-negative wealth effects $(\partial A^*/\partial w \geq 0)$ are sufficient conditions to guarantee that an increase in expected returns per acre of the ith crop will result in an increase in the optimal acreage of that crop i.e., $\partial A_i^*/\partial \bar{\pi}_i \geq 0$.

Finally, Chavas and Pope (p. 229) and Pope have derived homogeneity restrictions in the context of the expected utility model (4). In particular, rewriting expression (2) as $f(A) = A_1 - g(A.) = 0$, where $A = (A_1, A.)$, Chavas and Pope have shown that the following restriction holds at the optimum under any risk preferences

$$\frac{\partial A^*}{\partial \bar{\pi}} \left(\frac{\partial f(A)}{\partial A}\right) - \frac{\partial A^*}{\partial w} \cdot \frac{\partial f(A)}{\partial A} \cdot A = 0. \tag{5a}$$

Let the first-order conditions associated with (3) be $E(\partial U/\partial w \cdot \pi) + \lambda \cdot (\partial f/\partial A) = 0$, where λ is the Lagrange multiplier associated with the constraint (2) and $\partial f/\partial A$ is a $(1 \times n)$ of vector. Given $\lambda \neq 0$, substituting these conditions into (5a) yields

$$\frac{\partial A^*}{\partial \bar{\pi}} (\bar{\pi} + \delta) - \frac{\partial A^*}{\partial w} (\bar{\pi}' + \delta')A = 0, \tag{5b}$$

where $\delta = COV(\partial U/\partial w, \pi)/E(\partial U/\partial w)$ is an $(n \times 1)$ vector. Under risk neutrality, $\partial A^*/\partial w = 0$ and $\delta = 0$, implying from (5b) that the acreage decision function A^* is homogenous of degree zero in $\bar{\pi}j$,

$$\sum_{j=1}^{n} \frac{\partial A_i^*}{\partial \bar{\pi}_j} \bar{\pi}_j = 0.$$

This homogeneity restriction of classical production theory states that production decisions are not affected by proportional changes in all input and output prices. However, under risk aversion, $\delta \neq 0$ and (5b) implies that this homogeneity-like restriction takes a different form.[2]

Some empirical implications of specific forms of risk preferences have been presented by Pope. In particular, under constant relative risk aversion, a positive scaling of wealth does not alter optimal decisions (Sandmo).[3] This implies that decisions functions are almost homogenous of degree one in initial wealth, degree one in mean returns $\bar{\pi}$, degree two in moments of order two, and degree s in moments of order s of π. Similarly, under constant partial relative risk aversion, a positive scaling of profit does not alter optimal choices. This implies that decision functions are almost homogenous of degree one in mean returns $\bar{\pi}$, degree two in moments of

[2] Under constant absolute risk aversion, $\partial A^*/\partial w = 0$ and (5b) takes the form $\Sigma_{j=1}^n \partial A_i^*/\partial \bar{\pi}_j(\bar{\pi}_j + \delta_j) = 0$. This illustrates the influence of risk preferences on the restrictions discussed by Chavas and Pope.

[3] The coefficient of relative risk aversion is defined as

$$\tau = \left(w + \sum_{i=1}^{n} \pi_i A_i\right)\kappa,$$

where $\kappa = -(\partial^2 U/\partial w^2)/(\partial U/\partial w)$ is the coefficient of absolute risk aversion. Similarly, the coefficient of constant partial relative risk aversion is

$$\psi = \left(\sum_{i=1}^{n} \pi_i A_i\right)\kappa.$$

order two of π, and degree s in moments of order s of π. (See Pope for details.)

Finally, it is well known that $\partial A^*/\partial\sigma = 0$ and $\partial A^*/\partial w = 0$ under risk neutrality. Alternatively, $\partial A^*/\partial\sigma \neq 0$ and/or $\partial A^*/\partial w \neq 0$ implies a departure from risk neutrality. In particular, under risk aversion, risk will influence the allocation of resources in agriculture.

An Application Under Government Price Support Programs

The acreage decision model (3) involves uncertainty about prices p and yields Y. In this section the influence of government programs on the subjective probability distribution of output prices p is considered by focusing on a price support program which places a floor under the market price. The resulting truncation of the subjective probability distribution of prices will affect expected prices as well as second and higher moments of the price distribution. Thus, a price support program will influence both price expectations and the riskiness of revenue.

Since the effects of multivariate truncation are best understood in the context of a normal distribution (see Johnson and Kotz, Maddala 1983a), we limit our discussion to the normal case.[4] Let $X = (X_1, X_2, \ldots)$ be a vector of normally distributed random variables with mean $\bar{X} = (\bar{X}_1, \bar{X}_2, \ldots) = E(X)$ and variance $V(X) = E(X - \bar{X})'(X - \bar{X}) = \{\sigma_{ij}\}$, where E is the expectation operator. Now, assume that each random variable X_i is truncated from below at a level H_i. Define the truncated random variables

$$x_i = \begin{cases} H_i \text{ if } X_i < H_i \\ X_i \text{ if } X_i \geq H_i \end{cases}, \; i = 1, 2, \ldots.$$

Consider the standardized random variable $e_i = (x_i - \bar{X}_i)/\sigma_{ii}^{1/2}$ and define $h_i = (H_i - \bar{X}_i)/\sigma_{ii}^{1/2}$. The mean and variance of e_i are derived in the appendix. The expected value of e_i is

$$\text{(6a)} \qquad \bar{e}_i = E(e_i) = \phi(h_i) + h_i\Phi(h_i),$$

where $\phi(.)$ and $\Phi(.)$ are the standard normal density function and distribution function, respectively. The second moments of e_i are given by (see appendix)

$$\text{(6b)} \quad M_{ii} = E(e_i^2) = 1 - \Phi(h_i) + h_i\phi(h_i) + h_i^2\Phi(h_i), \text{ and}$$

$$\text{(6c)} \quad M_{ij} = E(e_ie_j) = F(h_i, h_j)\rho_{ij} + [(1 - \rho_{ij}^2)/2\pi]^{1/2}\phi(Z_{ij}) + h_i\phi(h_j)\Phi(k_{ij}) + h_j\phi(h_i)\Phi(k_{ji}) + h_ih_j\Phi(h_i, h_j), \; i \neq j,$$

where $F(h_i, h_j) = \text{prob}(X_i \geq H_i, X_j \geq H_j)$, $\rho_{ij} = \sigma_{ij}/(\sigma_{ii}\sigma_{jj})^{1/2}$, $Z_{ij} = \{(h_i^2 - 2\rho_{ij}h_ih_j + h_j^2)/(1 - \rho_{ij}^2)\}^{1/2}$, $k_{ij} = (h_i - \rho_{ij}h_j)/(1 - \rho_{ij}^2)^{1/2}$, and $\Phi(h_i, h_j) = \text{prob}(X_i < H_i, X_j < H_j)$. It follows that the mean, variance, and covariance of $x = (x_1, x_2, \ldots)$ are

$$\text{(7a)} \qquad \bar{x}_i = E(x_i) = \bar{X}_i + \sigma_{ii}^{1/2}\bar{e}_i$$

$$\text{(7b)} \quad V(x_1) = E(x_i - \bar{x}_i)^2 = \sigma_{ii}(M_{ii} - \bar{e}_i^2), \text{ and}$$

$$\text{(7c)} \quad \text{COV}(x_i, x_j) = E(x_i - \bar{x}_i)(x_j - \bar{x}_j) = (\sigma_{ii}\sigma_{jj})^{1/2}(M_{ij} - \bar{e}_i\bar{e}_j).$$

Expressions (7) provide an analytical evaluation of the truncation effect of a price support program on the mean, variance, and covariance of commodity prices. These results will be used to investigate the influence of government programs on corn and soybean acreage decisions.

Data and Estimation

Assuming that aggregate behavior can be represented by a representative farm household making decisions according to model (3), we propose to specify and estimate the acreage function $A^*(w, \bar{\pi}, \sigma)$ from aggregate data. This is done by analyzing annual time-series data for U.S. corn ($i = 1$) and soybean ($i = 2$) acreage decisions from 1954–85. The acreage variables A_1 and A_2 measure acreage planted to each crop (in millions of acres) and were obtained from various U.S. Department of Agriculture (USDA) publications. The market prices (p_1 and p_2) are average prices received by farmers and were also obtained from USDA publications. The costs of production per acre (c_1 and c_2) were obtained from USDA's cost of production surveys for the 1975–85 period. For years prior to 1975, the cost of production data reported by Gallagher were used. Following Houck et al. and Gallagher, effective diversion payment and support price (p_1^s and p_2^s) variables were used to quantify the price support and acreage set-aside provisions of government programs.[5] The consumer

[4] The normal distribution has also been used widely for modeling truncation effects in a single commodity context. See, e.g., Shonkwiler and Maddala or Holt and Johnson.

[5] Following Gallagher, the effective support prices for corn during the nonprogram years (i.e., no set-aside requirements) 1974–77 and 1980–81 were determined as weighted averages of the loan rate and the target price. The weights in turn are derived from the proportion of total corn acreage planted eligible for target price protection.

price q was measured by the consumer price index as reported by the Bureau of Labor Statistics. Yields per acre were obtained from USDA publications.

To analyze supply behavior under risk, assumptions about the (untruncated) expectations of prices and yields are needed. We use adaptive expectations for the untruncated normalized prices. That is,

$$E_{t-1}\left(\frac{p_{it}}{q_t}\right) = \alpha_i + \frac{p_{i,t-1}}{q_{t-1}}, \tag{8a}$$

where

$$\alpha_i = E\left(\frac{p_{it}}{q_t} - \frac{p_{i,t-1}}{q_{t-1}}\right)$$

as measured by the corresponding sample mean. Similarly, the variance measure used for untruncated normalized prices is

$$\mathrm{var}\left(\frac{P_{it}}{qt}\right) = \sum_{j=1}^{3} \omega_j\left[\frac{p_{i,t-j}}{q_{i,t-j}} - E_{t-j-1}\left(\frac{p_{i,t-j}}{q_{i,t-j}}\right)\right]^2, \tag{8b}$$

where the weights ω_j are .5, .33, and .17.[6] The assumption stated in (8a) that expected prices are a function of the average price of the previous year has been successfully employed in previous research (e.g., Houck et al.; Chavas, Pope, and Kao).

Expression (8b) states that the variance of price is a weighted sum of the squared deviations of past prices from their expected values, with declining weights. These measurements of price risk are also consistent with those used previously in the literature (e.g., Lin; Traill; Brorsen, Chavas, and Grant).

Expressions (8) give the untruncated mean and variance of the price distributions. These results, along with the expressions in (7), determine the mean and variance of the truncated multivariate price distributions associated with price supports p_1^s and p_2^s.

To measure yield expectations, actual yields were regressed on a trend variable. The resulting predictions were taken as expected yields, and the estimated residuals were used to generate the variance of yield and the covariance between price and yield. For simplicity, both the variance of yield and the correlation between price and yield were assumed constant over time.[7]

The farm value of proprietor equity was used as a proxy for initial wealth. Farm equity of corn-soybean producers was obtained by multiplying the U.S. farm value of proprietor equity by the percentage of U.S. farm acreage planted to corn and soybeans.[8]

The acreage equations $A^*(w, \bar{\pi}, \sigma)$ were specified using these data. Consider the first-order Taylor series expansion

$$\begin{aligned} A_{it} = a_i &+ (\partial A_i/\partial w)w_{t-1} \\ &+ \sum_{j=1}^{2} (\partial A_i/\partial \bar{\pi}_j)\bar{\pi}_{jt} + \sum_{k\geq j}^{2} \sum_{j=1}^{2} (\partial A_i/\partial \bar{\sigma}_{jk})\bar{\sigma}_{jkt} \\ &+ \Theta_i t + \eta_i D83_t + u_{it},\ i = 1, 2, \end{aligned} \tag{9}$$

where A_{it} is the number of acres planted to the ith crop at time t,

$$\bar{\pi}_{jt} = E_{t-1}\{(p_{jt}/q_t)Y_{jt} - (c_{jt}/q_t)|p_t \geq p_t^s\}$$

is the truncated mean return per acre of the jth crop,

$$\bar{\sigma}_{jjt} = \mathrm{var}\,(p_{jt}|p_t \geq p_t^s) \text{ and}$$

$$\bar{\sigma}_{jkt} = \mathrm{cov}(p_{jt}, p_{kt}|p_t \geq p_t^s)$$

are the truncated variances and covariances of output prices, and u_{it} is an error term. A trend variable is included to capture the systematic effects of any omitted variables on acreage decisions over time. Last, a dummy variable $D83_t$ is included to discount the effects of the payment-in-kind program offered in 1983.

Letting $\beta_{ij} = \partial A_i^c/\partial \bar{\pi}_j$ be the compensated slopes with respect to $\bar{\pi}$ and using (4), it follows that equation (9) can be expressed alternatively as

$$\begin{aligned} A_{it} = a_i &+ \alpha_i\left(w_{t-1} + \sum_j A_j\bar{\pi}_{jt}\right) \\ &+ \sum_j \beta_{ij}\bar{\pi}_{jt} + \sum_{k\geq j} \sum_j \gamma_{ijk}\bar{\sigma}_{jkt} + \Theta_i t \\ &+ \eta_i D83_t + u_{it},\ i = 1, 2, \end{aligned} \tag{10}$$

[6] Several weighting schemes were used to gauge the sensitivity of the results obtained to the specification of the ω_j coefficients. The alternative weights used were (.8, .15, .05), (.7, .2, .1), (.5, .3, .2), and (.33, .33, .33). In all instances, the results compared favorably with those obtained using (.5, .33, .17) in terms of signs, significance of coefficients, and model fit. In addition, the conclusions regarding symmetry, wealth effects, and the nature of risk preferences were unaffected by the weighting scheme.

[7] The (untruncated) correlation between price and yield was estimated to be .320 for corn and .279 for soybeans. The (untruncated) correlation ρ between p_1 and p_2 was also assumed to be constant for all years. The estimated value was $\rho = .753$.

[8] Initial wealth was also constructed by multiplying U.S. farm equity by the proportion of net income from corn and soybean production to total net cash farm income. The results obtained using this alternative wealth measure were comparable to those obtained using acreage-weighted wealth. This result is encouraging since the wealth variable is only a proxy for the true equity positions of corn and soybean producers.

where $\alpha_i = \partial A_i/\partial w$ and $\gamma_{ijk} = \partial A_i/\partial \bar{\sigma}_{jk}$. In the absence of a priori information about functional form, equation (10) provides a local approximation to the decision function $A^*(.)$. Also, the symmetry of (4) implies that $\beta_{ij} = \beta_{ji}$, $i \neq j$. Thus, equation (10) is convenient for testing and/or imposing the symmetry restrictions (4).

Equation (10) can be used directly for an empirical analysis of acreage decisions for soybeans. The corn acreage equation ($i = 1$) is specified according to (10) except that corn diversion payments (*DP*) are also included as an intercept shifter. The model parameters are estimated by seemingly unrelated regression.

Results and Implications

The econometric model (10) is used to test various hypotheses about economic behavior under risk. The first hypothesis examined is the symmetry restriction (4) implied by expected utility maximization. This test is general since the symmetry restriction holds for any risk preferences. The null hypothesis associated with (4) is H_o: $\beta_{12} = \beta_{21}$, and the F-value for the test was $F(1, 45) = 0.002$. Thus, the symmetry restriction cannot be rejected at any usual levels of significance. The implication is that acreage decisions, as represented by equation (10), are consistent with the symmetry restriction implied by expected utility maximization.

With the symmetry restrictions imposed, the parameter estimates of equations (10) are reported in table 1, along with several key measures of model fit and performance. The estimated model explains historical variations in corn and soybean acreages well as indicated by the high R-squares. Serial correlation is also apparently not a problem as reflected by the single-equation Durbin-Watson statistics. Many of the parameter estimates are large relative to their standard errors and have signs consistent with the theory.

The compensated own-revenue elasticities are .068 and .279 for corn and soybean acreage, respectively (table 1). Alternatively, the compensated own-price elasticities for corn and soybeans are .158 and .441, respectively.[9] These mean-response elasticities appear reasonable and compare favorably with those reported elsewhere (e.g., Gallagher; Lee and Helmberger; Tegene, Huffman, and Miranowski). The risk elasticities are generally small, although soybean acreage appears more risk responsive than corn acreage. This result is not surprising because government intervention has been less important in the soybean market than in the corn market. Finally, the elasticities with respect to initial wealth are .087 and .270, for corn and soybean acreage, respectively.

Having found evidence in favor of the expected utility model (3), the next step is to test for the nature of risk preferences taking the symmetry restriction $\beta_{12} = \beta_{21}$ in (10) as maintained. The hypothesis of risk neutrality is treated as H_o: $\gamma_{ijk} = 0$ and $\alpha_i = 0$ for all i, j, k. The F-value for this test was $F(8, 46) = 7.367$, which implies that the null hypothesis can be rejected at the 5% level.

Table 1. Estimated Corn and Soybean Acreage Equations with Symmetry Imposed, 1954–85

[a] Standard errors are in parentheses below the parameter estimates. Elasticities evaluated at the sample means are presented in brackets. A double (single) asterisk indicates significantly different from zero at the 5% (10%) significance level.

[9] The uncompensated own-revenue elasticities for corn and soybean acreage are .071 and .285, respectively. Similarly, the uncompensated own-price elasticities are .166 and .450, respectively, for corn and soybean acreage.

The hypothesis of constant absolute risk aversion can be tested as H_o: $\alpha_1 = \alpha_2 = 0$. The F-value for this test was $F(2, 46) = 17.589$, indicating a rejection of the null hypothesis at the 5% level. This result provides evidence that the risk preferences of corn and soybean growers are not characterized by constant absolute risk aversion over the period of analysis.

The empirical results presented in table 1 also show positive wealth effects $\partial A^*/\partial w > 0$. In the single-product case, Sandmo has shown that a positive wealth effect in supply response implies decreasing absolute risk aversion (DARA). To the extent that Samdmo's result holds in the multiproduct case, our analysis indicates that farmers are decreasingly absolute risk averse.[10] While it is well accepted that agricultural producers may exhibit DARA, this appears to be the first empirical illustration of positive (and significant) wealth effects in an aggregate agricultural supply model.

From equation (4), having wealth elasticities $\partial \ln A^*/\partial \ln w$ that are different from zero or one implies that the uncompensated slope matrix $\partial A^*/\partial \bar{\pi}$ is not symmetric.[11] Yet, the symmetry of uncompensated price slopes has been imposed as a maintained hypothesis in many previous studies of aggregate supply response (e.g., Shumway, Antle). Our analysis indicates that the implications of riskless production theory may not apply to supply response analysis under risk.

Finding evidence against the hypothesis of constant absolute risk aversion also raises questions about the appropriateness of mean-variance risk analysis. Indeed, the mean-variance approach is typically motivated under constant absolute risk aversion and normality, which imply zero wealth effects. Our results suggest a need to incorporate a wealth variable in programming models of risk.

The existence of wealth effects may also have policy implications. If corn-soybean farmers exhibit DARA, then higher private wealth tends to offset their need for income and price protection. Hence, the existence of positive wealth effects could provide a possible justification for income transfers to corn-soybean farmers with low initial wealth.

In order to obtain additional insights into the nature of risk preferences, the tests proposed by Pope were performed at the mean values of the sample data. Testing the hypothesis of constant relative risk aversion (CRRA) consists of testing whether a rescaling of terminal wealth has a zero effect on acreage decisions. The F-value for the CRRA hypothesis was $F(2, 46) = 28.429$. Also, testing the hypothesis of constant partial relative risk aversion (CPRRA) considers whether a rescaling of profit has a zero effect on acreage decisions. The F-value for the CPRRA hypothesis was $F(2, 46) = 9.126$. Using normal significance levels, these results indicate that neither CRRA nor CPRRA characterize the risk preferences of corn-soybean producers. In short, many of the simple utility function representations are not supported by the data.[12]

Finally, the supply models were simulated at alternative support price levels. Because of the truncation effects, changing the support price levels will influence the means, variances and covariances of producer prices [see eq. (7)]. Selected static simulation results for the effects of support prices on expected prices, price risk, and acres planted are reported in table 2. As expected, increasing the support price of a crop tends to expand its acreage, although the relationship is nonlinear. For example, when the support price is much below the expected market price, the truncation effect is negligible and the price support program has only a limited impact on acreage decisions. Alternatively, as support price levels, the truncation effects become larger, and the resulting impact on acreage decisions is more pronounced.

The cross-commodity price effects reported in table 2 are of interest since increasing the support price for a commodity tends to increase its expected price and thus decrease the acreage of the substitute commodity. However, the risk-reducing effect of a price support program also influences acreage substitution. The net effect of the soybean support price on corn acreage is negative (table 2). However, the net effect of the support price for corn on soybean acreage is positive for low price support levels (e.g., effective support prices less than $1/bu), and negative otherwise (see table 2). Thus, within some price range the risk-reducing effect of corn support prices on soybean acreage is positive and

[10] This is also consistent with much of the economic literature (e.g. Arrow, Binswanger).

[11] The null hypothesis that the wealth elasticities equal one was also tested. It was rejected at usual significance levels.

[12] The acreage elasticities with respect to a proportional increase (rescaling) of terminal wealth were −.025 for corn and .368 for soybeans when evaluated at the sample means. Similarly, the acreage elasticities with respect to a proportional increase (rescaling) of profit were −.117 for corn and .082 for soybeans. While the test results indicate that corn and soybean producers do not exhibit CRRA or CPRRA, it is not clear whether relative risk aversion or partial relative risk aversion is increasing or decreasing.

Table 2. Simulation of the Effects of Support Prices for Corn and Soybeans

Support Price of Corn ($/bu)	.2	.4	.6	.8	1.0	1.2	1.4	1.6	1.8
Expected corn price	1.30	1.30	1.30	1.30	1.31	1.35	1.45	1.61	1.80
Variance of corn price	.055	.055	.055	.054	.046	.029	.011	.002	.0002
Covariance corn/ soybean prices	.085	.085	.085	.084	.078	.059	.030	.009	.002
Corn acres	74.119	74.119	74.120	74.147	74.426	75.611	78.021	80.734	82.959
Soybean acres	44.655	44.656	44.659	44.673	44.566	43.624	41.088	37.741	34.716
Support Price of Soybeans ($/bu)	**.4**	**.8**	**1.2**	**1.6**	**2.0**	**2.4**	**2.8**	**3.2**	**3.6**
Expected soybean price	2.90	2.90	2.90	2.90	2.91	2.95	3.07	3.30	3.62
Variance of soybean price	.283	.283	.283	.279	.261	.207	.118	.043	.010
Covariance corn/ soybean prices	.085	.085	.085	.084	.082	.072	.051	.026	.009
Corn acres	74.704	74.704	74.701	74.672	74.547	74.278	74.010	73.770	73.127
Soybean acres	44.313	44.314	44.317	44.345	44.460	44.691	44.925	45.309	46.438

Note: Untruncated expected prices are $1.30 for corn and $2.90 for soybeans, while support prices are $1.0 for corn and $2.20 for soybeans. All other variables are set equal to their sample means.

dominates the mean price effect. This result emphasizes the importance of cross-commodity risk effects and the risk-reducing role of price supports.

Conclusions

This study presented a framework for analyzing multiple acreage decisions under uncertainty. A household decision model that includes both output price and yield uncertainty was developed and the resulting behavioral relationships were tested with a system of U.S. corn-soybean acreage equations. The truncation effects of government price supports on the distribution of corn and soybean prices were carefully considered. Expressions relating the truncated means, variances, and covariances for joint normally distributed random variables were developed. Moreover, a wealth variable was included in the estimated acreage equations to facilitate tests of hypotheses about risk attitudes.

The empirical results indicate that both risk and wealth effects are important in corn-soybean acreage allocation decisions. The symmetry restriction implied by expected utility maximization could not be rejected; however, the results also suggest that many commonly used hypothesis about risk attitudes, including CARA, CRRA, and CPRRA, are not supported by the data. These results cast doubt on the use of CARA utility functions. They also suggest that targeting policy benefits toward low income producers may be warranted.

The importance of considering risk in a multicrop framework was illustrated by simulating the acreage models at various price support levels for corn and soybeans. The model simulations illustrate that cross-commodity risk reducton is potentially important since there is some range over which increasing the support price for corn will actually result in more acres planted to soybeans. Such results could not be obtained with a single crop focus.

While the results of this study shed new light on the role of risk in farmers' decisions, further study is required. For example, future research could consider the effects of voluntary participation on acreage response under risk. The analysis could also be expanded to include other sources of risk and a richer set of risk responses than acreage adjustments alone. For example, issues pertaining to financial risk and financial management have become increasingly important in recent years. Finally, the present model could be couched in a rational expectations framework in order to evaluate price support policies in a market equilibrium context.

Appendix

The Mean of e_i

Let $\phi(.)$ be the standard normal density function. We have

$$E(e_i) = h_i \int_{-\infty}^{h_i} \phi(y)dy + \int_{h_i}^{\infty} y\phi(y)dy$$
$$= h_i\Phi(h_i) + \phi(h_i),$$

where $\Phi(.)$ is the standard normal distribution function.

The Second Moments of e_i

(*a*) M_{ii}.

$$\text{(A1)} \qquad E(e_i^2) = h_i^2 \int_{-\infty}^{h_i} \phi(y)dy + \int_{h_i}^{\infty} y^2\phi(y)dy.$$

But the second term in (A1) can be shown to be equal to $1 - \Phi(h_i) + h_i\phi(h_i)$ (e.g., see Maddala 1983a, p. 365). It follows that

$$E(e_i^2) = h_i^2\Phi(h_i) + 1 - \Phi(h_i) + h_i\phi(h_i).$$

(*b*) M_{ij}, $i \neq j$. Let $\phi(.,.)$ be the bivariate standard normal density function. Then,

(A2)

$$E(e_ie_j) = h_ih_j \int_{-\infty}^{h_j}\int_{-\infty}^{h_i} \phi(y, z)dydz + h_i \int_{h_j}^{\infty}\int_{-\infty}^{h_i} y\phi(y, z)dydz + h_j \int_{-\infty}^{h_j}\int_{h_i}^{\infty} z\phi(y, z)dydz + \int_{h_j}^{\infty}\int_{h_i}^{\infty} zy\phi(y, z)dydz.$$

Note that the second term in (A2) can be written as

$$\text{(A3)} \quad h_i \int_{h_j}^{\infty}\int_{-\infty}^{h_i} y\phi(y, z)dydz = h_i \int_{h_j}^{\infty}\int_{-\infty}^{\infty} y\phi(y, z)dydz - h_i \int_{h_j}^{\infty}\int_{h_i}^{\infty} y\phi(y, z)dydz.$$

The first term on the right-hand side of (A3) is equal to $h_i\phi(h_j)$. From Rosenbaum, and using the notation defined in the text, the second term on the right-hand side of (A3) can be written as

$$-h_i\{\phi(h_j)[1 - \Phi(k_{ij})] + \rho_{ij}\phi(h_i)[1 - \Phi(k_{ji})]\},$$

which implies that

$$h_i \int_{h_j}^{\infty}\int_{-\infty}^{h_i} y\Phi(y, z)dydz = h_i\phi(h_j) - h_i\{\phi(h_j)[1 - \Phi(k_{ij})] + \rho_{ij}\phi(h_i)[1 - \Phi(k_{ji})]\}.$$

By symmetry, the third term on the right-hand side of (A2) is given by

$$h_j \int_{-\infty}^{h_j}\int_{h_i}^{\infty} z\phi(y, z)dydz = h_j\phi(h_i) - h_j\{\phi(h_i)[1 - \Phi(k_{ji})] + \rho_{ij}\phi(h_j)[1 - \Phi(k_{ij})]\}.$$

Likewise, following Rosenbaum, the fourth term on the right-hand side of (A2) can be shown to be

$$h_j \int_{h_j}^{\infty}\int_{h_i}^{\infty} zy\phi(z, y)dzdy = F(h_i, h_j)\rho_{ij} + \rho_{ij}h_i\phi(h_i)[1 - \Phi(k_{ji})] + \rho_{ij}h_j\phi(h_j)[1 - \Phi(k_{ij})] + [(1 - \rho_{ij}^2)/2\pi]^{1/2}\phi(Z_{ij}).$$

After making the appropriate substitutions and collecting terms, (A2) can be shown to be

$$E(e_ie_j) = F(h_i, h_j)\rho_{ij} + [(1 - \rho_{ij}^2)/2\pi]^{1/2}\phi(Z_{ij}) + h_i\phi(h_j)\Phi(k_{ij}) + h_j\phi(h_i)\Phi(k_{ji}) + h_ih_j\Phi(h_i, h_j),$$

where $F(h_i, h_j) = \Phi(h_i, h_j) + 1 - \Phi(h_i) - \Phi(h_j)$.

Designing Expert Systems for Effective Delivery of Extension Programming

Russell L. Gum and Steven C. Blank

Expert systems offer potential as important additions to the current methods used to deliver extension programming to clients. This paper discusses the design of such systems from the viewpoint of learning theory and assesses the cost effectiveness, relative to standard extension programming approaches, of a sample system developed for use with/by cattle ranchers. Results indicate that hybrid expert systems have greater educational impact than traditional programming methods and are more cost effective.

Key words: expert systems, extension, simulation.

The delivery of extension education programs to clients in commercial agriculture is a cornerstone of the extension service charter. Unfortunately, effective delivery of relevant extension programs has become more difficult as (*a*) agriculture has become more technologically advanced; (*b*) relatively homogenous family farms have been replaced by a mixture of large-scale commercial enterprises and smaller part-time farms resulting in a heterogenous mix of clientele, programs, and clientele resources available to solve problems; (*c*) institutional intervention in the form of regulations and government participation in agricultural markets has increased; and (*d*) extension budgets for commercial agriculture programs have decreased in real terms. To counteract the increased difficulty of delivering extension programming to commercial agriculture clientele, new approaches are being sought. For example, computer-based expert systems (hereafter ES), computer driven multimedia programs, and use of electronic media to replace or supplement the traditional one-on-one extension approach are often mentioned as means of improving the effectiveness of extension programming.

This study contributes to the discussion of this issue by evaluating the potential for designing computer-based expert systems as a means of improving the delivery of extension programs to agricultural clients. Of particular concern are extension programs aimed at improving the understanding of managers and providing them with advice on important management decisions. The evaluation process presented here involves application of a teaching program model. The educational impact model developed by Joyce and Showers is used first to guide the design of a sample ES and then as a basis for qualitative evaluation of the contents and expected effectiveness of that ES compared to other extension tools. A summary analysis of costs for the sample system provides a quantitative assessment of the approach's effectiveness.

This paper is organized into five major sections. First, a description of expert systems and a sample application are presented. Next is a brief outline of the educational impact model. Third, training components of the samples ES are evaluated using the educational impact model. This is followed by an analysis of the cost effectiveness of the sample ES compared to other methods used in extension. Finally, conclusions and implications of the study are outlined.

Expert Systems

Many definitions of expert systems can be found in the computer science and artificial intelligence literature. Discussion of two concepts, "function" and "process," are almost always included in those definitions. The standard definitions state that the function of an ES is to "du-

Russell Gum is an extension specialist and adjunct professor in the Department of Agricultural Economics, University of Arizona; Steve Blank is an extension economist in the Department of Agricultural Economics, University of California, Davis.

plicate as nearly as possible the problem solving techniques and rules of the expert" (Hayes, p. 52). The processes used by an ES are usually defined in terms of knowledge representation, inference engines based on symbolic reasoning, and use of heuristics. Waterman (pp. 22, 31) provides the following definitions:

Knowledge representation is "the process of structuring knowledge about a problem in a way that makes a problem easier to solve."

An *inference engine* is "that part of a knowledge-based system that contains the general problem solving knowledge."

Symbolic reasoning is "problem solving based on the application of strategies and heuristics to manipulate symbols standing for problem concepts."

Heuristic is "a rule of thumb or simplification that limits the search for solutions in domains that are difficult and poorly understood."

The most common type of ES is a rule-based system (see Harmon, Maus, and Morrissey for detailed information on building rule-based systems and Rauch-Hinden for a description of commercial applications of such systems). In a rule-based ES, knowledge is represented in terms of rules. For example, a cattle-marketing ES might include a rule stated as "only full truckload lots of cattle can be sold on satellite video auctions." Given a set of rules about cattle marketing and a ranking of marketing alternatives, the inference engine determines the order in which the rules are to be tested. For instance, a strategy termed "backward chaining" could be used to test all rules that are relevant to establish video auctions as the preferred alternative method of selling cattle for a particular rancher. In this example, heuristic knowledge is used to define rules as well as to define the ranking of alternatives. The rules would be tested using a series of questions for the client, and the results would take the form of a recommendation to the client concerning the problem at hand. This ES result is intended to duplicate the recommendation an expert would give clients in that particular situation.

Rule-based systems are extremely useful for certain types of well-defined problems, like diagnosing diseases or trouble-shooting problems with complicated machinery. In general, rule-based expert systems are appropriate under the following conditions: (*a*) The problem is well defined. For example: "My tractor won't start. What is wrong with it?" (*b*) The ES user has confidence in the system's ability to provide correct answers. Such confidence can be acquired if the client is knowledgeable about the subject matter dealt with by the ES and uses the system frequently. Doctors using disease diagnostic programs or mechanics using mechanical trouble-shooting programs are examples of clients who could develop confidence in an ES after frequent use if the knowledge programmed into the system produces correct results.

Unfortunately, many of the questions asked of extension's experts would not satisfy either of the conditions above. Also, the role of extension experts is not simply to solve diagnostic types of problems. Extension experts must spend much of their effort in correctly defining problems for clients. Once problems are defined, extension experts must also spend time educating clients about the problems. Extension programming aimed at problem definition and education would find a rule-based ES of only limited use. Finally, extension experts do spend time solving problems. However, because a large portion of extension clientele do not use extension experts on a regular basis and/or do not have extensive knowledge in technical areas, their confidence in these experts or ES must come from interaction. A computerized ES which just asks a few questions and provides a solution to a problem without significant interaction with the client is not likely to generate the necessary level of confidence in its answers. Therefore, traditional rule-based expert systems which simply ask questions and give advice are not well suited for many types of problems in which extension agents and specialists are involved.

Hybrid Expert Systems

Systems falling under an expanded definition of ES offer potential for use in extension. The role of hybrid expert systems, which incorporate both artificial intelligence and more traditional computer techniques, has been recognized by practitioners in both operations research and artificial intelligence fields. These hybrid systems may be viewed as trying to duplicate the problem-solving techniques and rules of an expert who has access to computer tools such as data bases, statistical analysis, and simulation solftware. Such hybrids have been described as Intelligent Decision Support Systems (Hertz) and Knowledge-Based Management Support Systems (Hayes, p. 53) when their main purpose was to assist managers, and as Intelligent Tutoring Systems (Katz and Schultz or Psotka, Massey, and Mutter) when their main purpose was to provide expert training to students. It is simply a semantic problem

to classify such systems because the real distinctions between these approaches are being challenged, as noted below.

> Operations research (OR) has developed both formal and heuristic solutions to a broad spectrum of real world issues. Artificial intelligence (AI) through its expert systems (ES) approches has recently begun to attack similar problems. I believe that AI/ES or OR applications have similar objectives to permit the executive or decision maker to improve his understanding of, and take desirable actions in a particular domain. Both must build computable models which have equivalent model structure. The surface differences are programming devices that may be stripped away. In the not too distant future, all significant programs intended to provide advice, diagnosis and analysis to aid decision makers will be hybrid. (Hertz, p. 9)

To minimize semantics, this paper uses the generic term "expert system" to describe the sample application presented in the next section. The ES is a hybrid in that it uses a wide mixture of computer techniques as appropriate to accomplish its dual goals of education and problem solving.

System Design

Using this general perspective, an ES was designed to provide extension programming to cattle ranchers. Problems concerning both marketing and production were included to make the test of the sample ES's value as broad as possible. The marketing problems included selecting the type of marketing institution to use in selling cattle and deciding whether to use commodity futures or options markets for hedging. Production problems included the nutritional management of a range cow herd and the associated management of breeding and weaning schedules. The goal of the system is to augment the abilities of ranchers to manage their businesses profitably by providing both the education programs and advice of extension experts in the form of computer software. From extension's viewpoint, the system is designed to provide county extension agents with a tool they can use to give ranchers the equivalent of both a workshop and one-on-one consultation by a team of specialists who are experts in the areas of marketing, range management, and animal science.

The first step was to develop traditional published materials and computer tools necessary for the team of extension experts to present effective workshops and provide useful one-on-one consultation to ranchers. In the marketing area, several extension publications and spreadsheet decision aids were used. To address range nutrition problems, a simulation model relating range conditions to cow performance was developed. A simulation model was chosen as the only practical approach, other than simple rules of thumb, to define the range production process in terms useful to analysis of alternative management decisions by ranchers. A graphics-based simulation modeling program, called Stella™, was used to facilitate development of the simulation by a multidisciplinary team. The basic structure of the model is (*a*) to calculate the nutritional intake of a cow based on the animal and the nutritional value of the forage species consumed; (*b*) to calculate the nutritional requirements of the cow as a function of her weight and stage of pregnancy; (*c*) to calculate the gain or loss in weight of the cow; (*d*) to determine the pregnancy probability of the cow based on her weight at breeding and on her rate of gain in the time period preceding breeding; (*e*) to determine calf weights; and, most important, (*f*) to determine expected economic returns for the lifetime of the cow for a specific management strategy. The model was calculated with daily time steps for a seven-year period in order to determine the present value of a cow under a specific management strategy.

The next step was to design the ES to accomplish the same results as a team of extension experts that present workshops and then work one-on-one with ranchers who had attended the workshops. The design approach had two major components. First, the ES was designed to include all of the learning components described by Joyce and Showers (explained in the next section). Second, HyperCard™ was chosen as a software platform. This allowed the ES to be developed without the necessity of programming in a complex artificial intelligence language such as Lisp or Prolog. It also allowed easy linkages of the ES to the simulation model through a HyperCard™ front end to Stella™, called StellaStack™. In addition, it gave access to a rule-based ES shell programmed as a HyperCard™ application, HyperX™, and the flexibility to link modules programmed in Fortran, Pascal, or C to the HyperCard™ application.

Educational Impact Model

The key to making this package of computer programs a single educational tool which could

achieve the goals of the extension project was using a model of teaching to guide the system's design. The educational impact model of Joyce and Showers (hereafter JS) was used in this effort.

JS state that, when students use what has been learned to solve problems, they are demonstrating that their training has had the highest level of impact possible. Because this is exactly what extension programs need to do, train managers to solve problems, their framework for judging educational impact is appropriate in the context of extension program design and evaluation. JS concluded that the level of impact a teaching program will have is affected by the following training components: (*a*) presentation of theory or description of skill or strategy, (*b*) model or demonstration of skills or models of teaching, (*c*) practice in simulated and classroom settings, (*d*) structured and open-ended feedback, and (*e*) coaching for application.

Further, JS indicate that components (*a*) through (*e*) have increasingly greater levels of impact on students' abilities to solve problems. When all five components are included in a teaching program, up to 75% of students are able to apply what has been learned. The research by JS supports the notion that teaching techniques which incorporate more of the five components will have greater impact than techniques involving fewer training components. This conclusion and the conceptual framework of the five training components are used as a guide to the following description and analysis of the sample ES as an effective extension programming method.

System Design Using the Educational Model

The first training component, presentation of theory is included in the sample ES through an introductory module which includes definitions of terms and concepts, and short courses in alternative cattle-marketing techniques, hedging using futures contracts, hedging using options, range cow nutrition, cow diets, and range forage nutritional values. The specific computer technique used in this module, commonly called hypertext in the computer literature (see Brent or Blank and Gum for more detail on hypertext applications for expert systems), involves presenting text on the screen with bold-faced text being linked to further explanatory sections. For example, in the section introducing video auctions as an alternative livestock-marketing method, reference is made to the concepts of futures and options which are presented as bold-faced words. By selecting the words (moving the cursor over them and clicking with the mouse), the user is presented with the index of a detailed section on hedging which includes both text and working spreadsheets to calculate the results of hypothetical examples. The user can select any of the index items to have the computer display the screens relevant to those topics. If a user selects the option calculator, for example, a working spreadsheet appears which allows the client to calculate the expected results of a hedge using option contracts.

The series of computer screens is displayed in figure 1–3. If a user chooses to obtain the detailed information on hedging and to use the spreadsheets, he or she has at that point been exposed to the theory of hedging (component one of the JS model) and has seen a working example of how to calculate the results of a hedge (component two of JS). Further, the hypertext approach makes effective use of the user's time because the client chooses which material is displayed on the computer screen. If a rancher is not interested in using the futures market to hedge, the computer does not require him or her to page through screens full of that material to get to the information of interest. By using such a free choice system of displaying material, theory can be effectively presented.

The second training component, model or demonstration of skills, is implemented with a walk through of a typical range cow annual production process. This involves a hypertext presentation which includes (*a*) animated computer graphics illustrating the nutritional links to the range cow production processes using the simulation model as a basis, (*b*) a schedule of operations, (*c*) an illustration of hedging using the futures market, and (*d*) a budget for the ranch showing costs and returns.

The third component, practice in a simulated setting, is included as the ES guides ranchers through the process of modifying the computer simulation model to reflect their own ranching situation, and then guides them through the simulation process to evaluate different management alternatives. This is facilitated through the use of an intelligent user friendly front end for the simulation model, called StellaStack, which runs as a HyperCard™ application.

The fourth training component, structured and open-ended feedback, involves a series of evaluation questions the computer system asks the rancher which allows the rancher to comment, discuss, or question the system and/or the re-

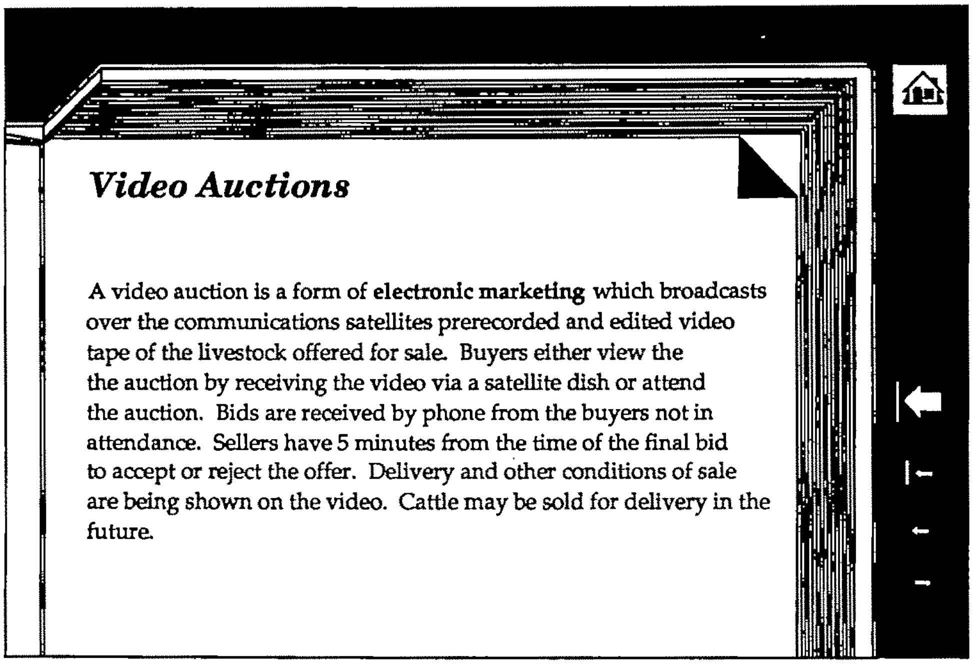

Figure 1. Video auctions

sults generated. This can involve electronic communication with the specialists who designed the system. In addition to setting up a mechanism to provide additional feedback to ranchers, this approach allows the developers of the ES to monitor its use and collect data on its effectiveness. Such information can provide a valuble basis for continuing modification and improvement of the heuristics included in the system.

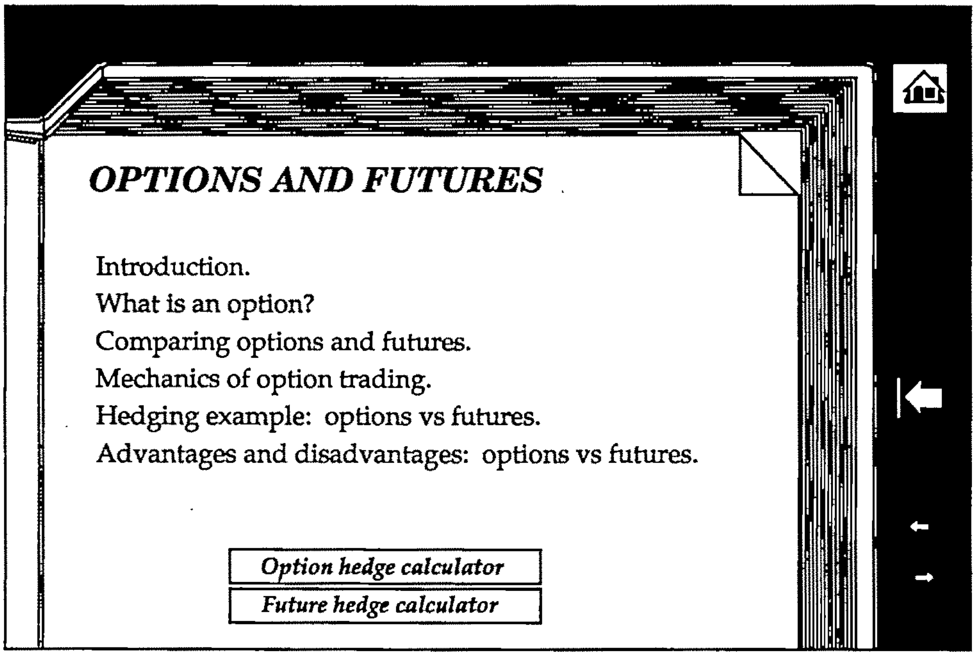

Figure 2. Options and futures

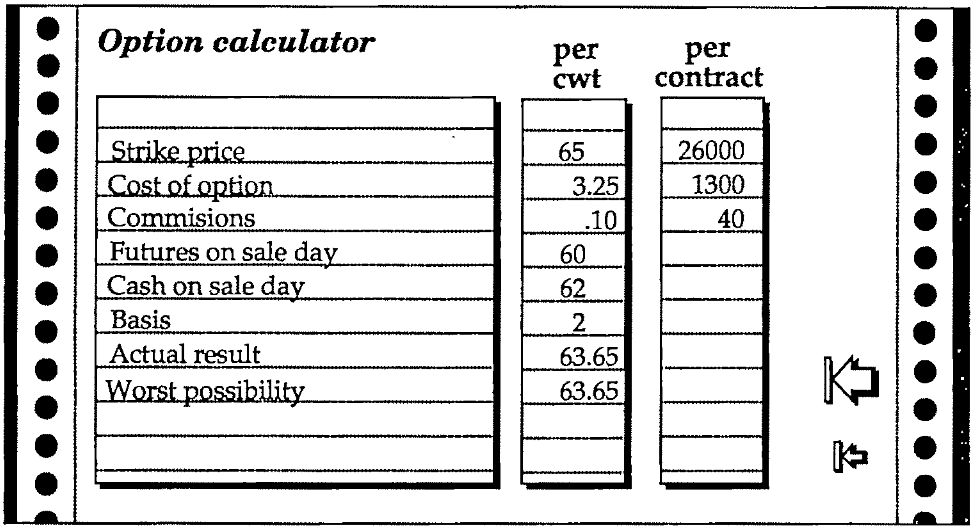

Figure 3. Option calculator

The fifth component, coaching for application, is accomplished by the computer using a rule-based analysis of the simulation results developed by the rancher for a specific management alternative and then suggesting economically reasonable alternatives. For example, if phosphorus is a limiting factor for cow gain under the management alternative being simulated, the coaching module would point this fact out and suggest a reasonable mineral supplementation strategy.

Comparison of Programming Approaches

To provide a base for comparison, the JS model was used to assess other extension programming approaches in terms of their learning components. The results of that qualitative assessment are presented in table 1. The information illustrates that traditional extension outreach techniques can be categorized as those designed for general audiences and which stress presentation of theories, concepts, and general models of the applicability of a potential practice, and those which involve direct contact with a client for the purpose of real-world problem solving. No traditional approach includes more than three training components and only agent/specialist "one-on-one" contact with clientele includes the desirable components of feedback and coaching.

The expanded ES designed as an example is expected to have great impact as a teaching tool because it includes all five learning components, as described earlier. Currently only extension programs designed using a mixture of techniques include all five components. Thus, based on the educational model, the expanded ES approach is expected to be a more effective means of information delivery than any other single programming approach.

Table 1. The Learning Components of Extension Programming Approaches

	Learning Components[a]				
Programming Approach	1	2	3	4	5
General audiences targeted:					
Extension bulletins	X	X			
Spreadsheets			X		
Video tape		X	X		
Interactive video disk	X	X			
Personal contact, small audiences:					
Agent/specialist "one-on-one"				X	X
Agent/specialist workshops	X	X	X		
Traditional expert systems				X	
Expanded expert system	X	X	X	X	X

[a] 1 is presentation of theory; 2, model or demonstration of skills; 3, practice in simulated settings; 4, feedback; 5, coaching for application.

Observations from users of the sample ES have supported this expectation. They have revealed:

(*a*) Cattle producers are significantly more interested in the nutrition module than in the marketing module. This is probably because there are no noncomputerized alternatives which are as effective as the computerized simulation model

in analyzing nutrition management, while noncomputerized alternatives do exist for analysis of marketing decisions. This observation supports the hypothesis that ranchers' analytical abilities are augmented by the simulation model embedded in the ES.

(*b*) The computer is accepted as a valuble tool when a user-friendly interface is in place. Ranchers simply do not have the time or interest to learn how to run a computer. The application of HyperCard™ and the user-friendly animated graphical interface (with numerous on-screen prompts) allows ranchers to overcome their fear of computers and to begin using them as a tool.

(*c*) Ranchers accepted advice from the computer after the ES led them through the simulation and analysis of their nutrition management. This observation is consistent with the hypothesis that the tutorial components of the ES were effective in teaching the principles necessary for nutrition management and that the analytical components provided advice for alternative management strategies that the ranchers viewed as useful.

To provide a quantitative assessment of the sample ES's value relative to other extention programming approaches, a simple cost effectiveness analysis is presented. The costs presented below are derived from the sample system described earlier. The costs represent current estimates for systems configured as outlined. The benefits specified are also best estimates from clients using the sample ES. The costs of the ES are compared to those for an extension program composed of only traditional approaches, yet which is expected to produce similar benefits. That "straw man" program includes both agent/specialist one-on-one and workshop approaches. As shown in table 1, a combination of these two teaching approaches will include all five training components of the JS model, making such a program approximately equal to the ES in expected educational impact. Therefore, the most effective program is that with the lowest cost.

The costs for the range cattle module of the ES are approximately:

Computer hardware	\$4,000 per unit
Computer software	\$600 per unit
Development costs	\$20,000 one time
Maintenance & training costs	\$5,000 per year

Unfortunately, expert systems of the type described here require powerful microcomputers. A reasonable computing platform for the sample system is Macintosh SE 30 with a 40 megabite hard disk and two megabites of memory, a 2,400 baud modem, and a printer. The ES requires HyperCard™ (the all-purpose computer program construction set which is used as a shell to put together the necessary parts of the ES) and is bundled with all Macintoshes, StellaStack™ (the graphics-based simulation program), and Timbuctu Remote™ (the communication program to allow remote control of the ES). The one-time development cost must be divided between the effort necessary to develop information and to do applied research on the problems covered by the ES, and the additional effort required to package the results of the applied research into an ES format. These costs are estimated to be \$20,000 for the cattle ranching ES and do not include the costs of developing the basic simulation model. Maintenance and training costs are incurred because any complicated system needs to be kept up to date and new personnel must be trained in its use. The present value of these cost streams at a 10% discount rate, assuming a five-year life of the ES and associated hardware, is approximately \$44,000 for one unit and \$52,500 for three units. (Each unit would be located in a different county extension office.)

The benefits to the client derived from the sample ES are significant. A rancher saves \$10 per head per year resulting from changes in management suggested by the ES. For an average ranch with 200 mother cows, this would mean an increase in profits by \$2,000 per year. This result (for Arizona) may be an underestimate; savings of over \$70 per head have been reported for similar integrated management programs elsewhere (see Eftink and Walter).

Because of the complicated nature of providing advice about nutrition management, it was judged that quarterly visits by an extension specialist would be required for a similar level of benefits to be obtained by clients. Thus, the extension budget "savings" from using the ES would equal \$250 per day of specialist time and travel or \$1,000 per year per ranch. For problems which are less complicated, such as providing information on marketing alternatives, the savings would be less as specialist one-on-one input could be obtained over the phone.

The cost effectiveness breakeven point for extension can be roughly calculated in terms of the number of ranches which must use the ES to pay for the model by reducing expenses incurred in providing this training. With just one unit in operation, approximately ten ranches must participate to make the sample ES more effective (in

present value terms) than the "straw man" program. However, with three systems in operation, only two additional participants are needed to cover the marginal cost of the two extra ES units. In the sample project, during the first meeting (at which the basics of the system were introduced) more than ten ranchers from one region indicated strong interest in utilizing the system. Thus, with units located in county offices around the state, the odds of the ES being a cost-effective educational tool for extension are extremely high.

Conclusions and Implications for Extension

The expanded ES approach offers a cost-effective means of extension program delivery. Specialists can make more efficient use of their limited time and travel resources by interacting one-on-one with clients through the computer network connections. They can utilize training materials with multiple clients as the computer system has to be developed only once. In addition, once developed, the ES can serve as a focal point for the collection, organization, and dissemination of information, knowledge, and analytical tools relevant to a subject area. Such a focus serves to facilitate the interaction of specialists in different disciplines towards multi-, inter-, and cross-disciplinary approaches to problem solving. Because of this broad range of advantages, the development of expanded expert systems for delivery of extension programs will be a popular activity for extension faculty in the future. Whether these systems are called expert systems, hybrid expert systems, Intelligent Decision Support Systems, Intelligent Tutoring Systems, computer driven multimedia programs, or the newly popular "hyper something or other," only sound design, based on proven learning techniques, will result in truly effective advances in the delivery of extension programming. The expanded ES described in this paper demonstrates the possibilities of developing educational programs which include the full range of training components, suggesting that this approach holds realistic promise for improving the effectiveness of extension's operations.

The bad news is that there is not a simple evolutionary path between the current way of providing extension programming and large-scale use of expert systems. This is typical of so-called "lumpy" technologies which require major changes for them to be used at all. Because expert systems are a lumpy technology, extension operations without the financial flexibility to invest in the human and computer resources necessary to develop and use these new techniques will continue to fall behind in their ability to deliver relevant and effective programs to their clientele. In some cases the lumpy nature of this innovation will not be recognized, and resources may be diverted into the development of expert systems with restraints attached, such as the requirement that any systems developed must work with the existing set of extension computers. Restraints such as this may reduce the likelihood of being able to develop truly effective expert systems. This leads to questions concerning the optimum path of adoption of expert systems. The answers to these questions are specific to each extension organization and, therefore, will be debated at length.

The analysis presented here, both in terms of learning efficiency and cost effectiveness, strongly suggests that the concept of enhanced expert systems should be an important new addition to the toolbox of extension personnel. If extension is to be an agent of change in the effort to make the agricultural sector more efficient, then advances in technology (which have the potential for making extension itself more efficient) need careful consideration and evaluation. While mass conversion of extension delivery techniques to the ES approach cannot be justified at present, the results for the sample ES suggest that development and implementation of expert systems dealing with some types of problems should proceed and be closely monitored to test their long range effectiveness in delivering extension programming.

Cholesterol Information and Shell Egg Consumption

Deborah J. Brown and Lee F. Schrader

U.S. per capita shell egg consumption has declined steadily since 1955 despite a falling real price. This paper investigates how information about cholesterol, as measured by a newly constructed index based on medical journal articles, has affected U.S. demand for shell eggs. The results of a fixed coefficient model indicate that information on the links between cholesterol and heart disease had decreased per capita shell egg consumption by 16% to 25% by the first quarter of 1987. A simple changing coefficient model indicates that cholesterol information has changed shell eggs' own price and income elasticities, so that the 1955–87 falling egg price and rising income increased egg consumption less than they otherwise would have.

Key words: cholesterol, demand analysis, eggs, health information.

U.S. per capita shell egg consumption has declined steadily since 1955 despite a large downward trend in real price. One suggested reason for the decline is increasing consumer concern with the cholesterol content of eggs (Putler, Schrader et al., Stillman). However, this issue has received little empirical investigation except for Putler's diffusion process model. Putler modeled the effect of cholesterol information on egg consumption by including a nonlinear function of time in the demand equation.[1] He concluded that cholesterol information first had an effect in the second quarter of 1969 and had reduced egg consumption by approximately 14% by the fourth quarter of 1980, with no further reductions between 1980 and 1985.

Time trends long have been used to account for changes in consumer tastes (Stone). More specific data on consumers' changing tastes are difficult to obtain. In the case of eggs, however, one can go beyond a time trend variable to construct a measure of information which may have strongly affected consumer taste for the product. This paper describes the construction of a measure of cholesterol information available to physicians and investigates how this information has affected consumer demand for shell eggs.

Cholesterol Information

The links between cholesterol in the diet and heart disease developed gradually since at least 1963. Initial epidemiological studies linking populations with high fat diets to a high incidence of heart disease (Kato et al.) were countered by other epidemiological studies of populations with high fat diets and a low incidence of heart disease (Biss et al.). Articles indicating a link between dietary cholesterol and blood cholesterol (reviewed by Keys, Grande, and Anderson) were countered by articles that argued against the link (Reiser, Allard et al., Albrink). Even the 1972 joint policy statement by the American Medical Association Council on Foods and Nutrition and the Food and Nutrition Board of the National Academy of Sciences, while recommending that those with elevated blood cholesterol lower their cholesterol consumption, recommended that "high priority be given to the conduct of studies that will determine reliably the extent to which the modification of plasma lipids, by dietary or other means, . . . can reduce the risks of developing coronary artery disease" (p. 1647). At the same time, controversy swirled over the link

Deborah J. Brown is an associate professor, and Lee F. Schrader is a professor, Department of Agricultural Economics, Purdue University.

The authors would like to thank James K. Binkley, B. Wade Brorsen, and several anonymous referees for helpful comments on earlier drafts; Louis B. Raffel, of the American Egg Board, for copies of portions of their attitude-tracking surveys; and Mark Weiner, of the U.S. Department of Agriculture, for unpublished egg price data.

[1] The term in Putler's demand equation is $\exp[(B + \alpha)T] - 1/\exp[(B + \alpha)T] + \beta/\alpha$. T is $\{(t - t^*) + (t + t^*)\}/2$, where t is the current time period and t^* is the time at which cholesterol information begins to affect egg consumption. T is thus zero until period t^* and 1, 2, 3, etc. thereafter. t^*, β, and α are coefficients estimated using nonlinear regression.

between blood cholesterol levels and arteriosclerosis or heart attacks (Benditt 1974, Borhani, Levy, McNamara et al.).

As clinical studies linked cholesterol in the diet to cholesterol in the blood and cholesterol in the blood with mechanisms that damage arteries, the articles in the medical literature became increasingly unambiguous about the importance for at least some part of the population of reducing one type of cholesterol in the diet (e.g., Grundy et al.). Studies of public awareness of possible danger from high cholesterol diets reflect this slow build-up of medical evidence (Scott et al., Ostrander et al.). Shekelle and Liu found that only 13% of a population sampled in 1978 were aware that too much cholesterol or fat in the diet might increase the risk of heart attacks.[2]

Consumers receive health information from many sources including physicians, neighbors, and the popular press. The hypothesis underlying the cholesterol index in this paper is that consumers' attitudes toward cholesterol changed slowly as scientific information accumulated, so a lagged index based on articles in medical journals could serve as a proxy for information reaching consumers from many sources. Because the diffusion of health information is a complex process (Smith, van Ravenswaay, and Thompson), this is a heroic simplification.

The cholesterol index was constructed by first scanning all articles in English dealing with humans and with clinical implications on the Medline data base. Medline is operated by Dialog Information Services. The data base includes materials from approximately 3,200 journals published in over seventy countries. It contains over four million citations for 1966 to 1987. It does not include articles prior to 1966.

Approximately 520,000 human, English, clinical articles are contained in the Medline data base. These were scanned for any connection with cholesterol. Approximately 8,000 of these articles dealt with cholesterol. Many of these articles were considered irrelevant because they focused on smoking, obesity, alcohol abuse, or linked cholesterol with eye, joint, skin, or gall bladder disease. The 8,000 titles were therefore read, and those which did not appear relevant to the links between diet cholesterol, serum cholesterol, and heart disease or arteriosclerosis were discarded. In cases where the content was unclear from the title, the decision to include the article was based on a review of the article's abstract. Approximately 1,000 such abstracts were consulted. All Scandinavian, British, and Canadian articles were discarded based on the belief that they are less likely to be read by U.S. physicians.

The numbers of articles supporting and attacking the linkage were calculated by quarter. A running total, lagged two quarters, was then calculated, with each article supporting the link adding one unit to the total and each article attacking the link subtracting one unit from the total. The equal weighting of pro and anti articles was later supported by the results of a demand equation including the number of articles supporting and the number of articles attacking the link as separate variables; their coefficients were of similar size but opposite in sign in the directions predicted.[3]

There are several ways to model the effect of cholesterol information apart from a simple sum. One might hypothesize that an article's influence will decline over time, as occurs with advertising campaigns. Alternatively, once a link is established, additional articles supporting that link might have little effect. An Almon lag procedure was used to investigate the lag structure of changes in the cholesterol index on egg consumption. It appears that there is a two-quarter lag before a new article has an effect on egg consumption, but the pattern of decay of influence after this initial period is unclear. Articles appear most consistently influential in the first sixteen quarters, but significant coefficients occur up to thirty-two quarters. Lacking a clearly preferable alternative, a simple sum, lagged two quarters, was used as the cholesterol information index. The cholesterol information index is given in table 1.

The Egg Sector: Supply and Demand Specifications

The supply of eggs is relatively simple to model. A pullet chick grows to production age in five months. A layer remains in production for about twelve months unless a molt and rest period are used to induce a second or third laying cycle. A low egg/feed price means a layer becomes

[2] One reviewer suggested that people may know something is bad for them without knowing why it is bad for them.

[3] The coefficient on the lagged sum of articles supporting the links between cholesterol, diet, and heart disease or arteriosclerosis was −.000245 and was different from zero at a 6% significance level. The coefficient on the lagged sum of articles attacking the links was .000524, but it was not different from zero at a 10% significance level.

Table 1. Components of the Cholesterol Information Index

Note: The cholesterol information index (*CHOL*) is the sum of articles supporting a link between cholesterol and arterial disease minus the sum of articles questioning such a link.

[a] Lagged six months.

unprofitable at an earlier stage and is withdrawn sooner from laying. The civilian shell egg supply equation is, therefore,

$$(1) \qquad S_C = g(P_C, H, F),$$

where P_C is the real twelve-city metro price for grade A large eggs to retailers; H is a twelve-month moving total of egg type chicks hatched, lagged two quarters; and F is feed cost = .75 (real price in ¢/lb. of No. 2 yellow corn at Chicago) + .25 (real price in ¢/lb. of 44% bulk soybean meal at Decatur). See appendix for data sources.

For the demand specifications, following Smith, van Ravenswaay, and Thompson, a consumer's utility function is expressed as $U(X(Z(N)))$, where X is a vector of goods with qualities Z, and N is information which affects a consumer's perception of the quality of a set of goods. Let consumers' information, N, be a function of the available scientific information, I. This yields a demand equation in which quantity demanded is a function of prices, income, and available scientific information.

Apart from own price, a reasonable demand equation should include the prices of close substitutes. It is not clear which, if any, foods are substitutes for eggs. Huang and Haidacher and Chavas and Johnson found meat a significant substitute, but George and King, Schrader et al., and Stillman did not. Because some investigators have found significant relationships, the price of meat will be included in the demand equation. Most eggs are eaten at breakfast; therefore, bakery and cereals products are also possible substitutes. However, Putler tested and discarded them in his egg demand model, so they were not used in this model.

The cholesterol information index described above represents the available scientific knowledge. Two other variables which reflect changing tastes are also included in the demand equation: percentage of women in the workforce and time. Stillman suggested that the increase in the percentage of women working outside the home may have reduced the quantity of eggs served for breakfast at home because of time constraints. On the other hand, more working women might mean more breakfasts eaten away from home. Surveys for the American Egg Board indicate that egg consumption away from home has been increasing since the late 1970s. Although the anticipated relationship is ambivalent, quarterly values for the percentage of women who are in the labor market, WW, represent this structural change.

Time is the black box of structural change. Its use indicates a recognition of structural change without the ability to identify, or perhaps obtain data on, the cause. The time variable here is the number of the quarter from 1 in the third quarter of 1955 to 128 in the second quarter of 1987.

The civilian demand for shell eggs used in this analysis is[4]

$$(2) \qquad D_C = f(P_C, P_S, Y_C, Q_2, Q_3, Q_4, CHOL, WW, TIME),$$

where D_C is the civilian disappearance of shell eggs (production − change in stocks − hatching use − eggs broken + imports − exports − military use); P_C is the real twelve-city metro price for grade A large eggs to retailers; P_S is the real price of meat; Y_C is real civilian per capita income; Q_2, Q_3, Q_4 are quarterly dummies to account for changes in seasonal demand; $CHOL$ is the cholesterol information index; WW is the percentage of women in the labor force; and $TIME$ is the quarter number.

Estimation Results

The estimation results reported in this section represent model specifications for both constant and changing coefficients.

Constant Coefficients

Supply and demand equations were expressed in per capita terms and assumed to be variants of a double log. The resulting equations are:

$$(3) \qquad \log(S_C/N) = C_0 + C_1 \log P_C + C_2 \log H + C_3 \log F, \text{ and}$$

$$(4) \qquad \log(D_C/N) = b_0 + b_1 \log P_C + b_2 \log P_S + b_3 \log Y_C + b_4 Q_2 + b_5 Q_3 + b_6 Q_4 + \sum_k b_k \text{ structural variable}_k.$$

[4] Military demand, exports and imports, and eggs for breaking are not estimated in this study. The military have historically consumed more eggs per capita and are unlikely to be affected in the same way by structural change. Military consumption has recently averaged less than 1/2% of total egg production. Exports and imports are typically less than 2% of egg production, and they are heavily influenced by policies in other nations. Eggs for breaking are sold liquid, dried, or frozen to food manufacturers and food service institutions. Unlike shell eggs, this demand has increased since 1955. The price of eggs for breaking is highly correlated with the price of shell eggs.

The demand equation was estimated using weighted two-stage least squares as described by Kmenta (pp. 705–8) to correct for simultaneity and first-degree autocorrelation. The Box-Cox transformation technique was used to test the appropriateness of the double-log form. The results supported the use of a loglinear form rather than a linear form.[5]

The results for all possible combinations of structural change variables are shown in table 2. These combinations allow one to observe the effect of removing various structural variables on the size and sign of the remaining coefficients.

Initially, egg demand was estimated using data from 1966–87, the period in which the cholesterol information index could be calculated. However, severe multicolinearity occurred between time and women in the workforce, time and income, and time and the cholesterol information index (ρ greater than .98 for all). Thus, egg demand was reestimated using data from 1955 to 1987 assuming that the cholesterol information index was zero prior to 1966. This assumption seems permissible given Putler's estimate, using 1960–85 quarterly data and a nonlinear time trend, that cholesterol concerns first began to have an effect in 1969. Table 3 shows the Pearson correlation coefficients for this expanded data set. Large correlations still occur between income and time, women working and time, and women working and the cholesterol information index; however, the problem is less severe than when only 1966–87 data were used.

Price is expected to have a negative effect on per capita egg demand. Huang and Haidacher recently obtained an annual own-price elasticity of −.14. Other own-price estimates, summarized in Chavas and Johnson, range from −.092 to −.40. This study's quarterly own-price elasticity ranged from −.02 to −.17. depending on the structural variables included in the equation. The model with all structural variables included had an own-price elasticity (−.17) similar to Huang and Haidacher's and significantly different from zero at the 1% level.

The expected sign on the income coefficient is not clear a priori. Huang and Haidacher obtained an annual expenditure elasticity of −.06, but it was not significantly different from zero. This study obtained a negative income elasticity for 1966–87 which was not different from zero at a 5% significance level. The income elasticity

[5] The Box-Cox power transformation is $y(\lambda) = \begin{cases} (y^{\lambda}-1)/\lambda & \lambda \neq 0 \\ \ln y & \lambda = 0 \end{cases}$. The log-likelihood function for $\lambda = 1$, the linear transformation, was −80.1. The loglikelihood function for $\lambda = 0$, the log transformation, was −42.7.

Table 3. Pearson Correlation Coefficients, 1955–87 Data

	$\ln P_c$	$\ln Y_c$	*WW*	*CHOL*	ln*Meat Price*	*TIME*
$\ln P_c$	1.00					
$\ln Y_c$	−.83	1.00				
WW	−.87	.96	1.00			
CHOL	−.86	.93	.98	1.00		
ln*Meat Price*	.13	.20	.12	.08	1.00	
TIME	−.86	.99	.98	.95	.15	1.00

for 1955–87 was negative only when *TIME*, which is closely correlated with income in this period, was omitted from the demand equation.

Huang obtained annual cross-price elasticity estimates for eggs of .047 for beef and veal, −.02 for pork, and −.0075 for other meat; however, none of these were significantly different from zero at a 10% level. In this study, cross-price elasticities for all meat ranged from .004 to .10. Only when *TIME*, *WW*, and *CHOL* were included in the equation was the coefficient on meat prices different from zero at a 10% level.

The seasonal dummy variables, not shown in table 2, were significantly different from zero regardless of which structural change variables were included.

The choice among structural change variables is difficult. Before considering the empirical results, one can argue that both *WW* and *CHOL* have changed the demand for eggs, and that other structural changes could best be captured by *TIME*. Moreover, the effects of the different structural variables would be difficult to distinguish empirically because they, along with per capita egg consumption and per capita real income, are all strongly trended variables in the sample period.

The $\bar{R}^2$ is highest if two or three shifters are included in the demand equation, but the differences in $\bar{R}^2$ are not great once one shifter is included. The coefficients on *TIME* and *CHOL* are both consistently and significantly negative. The coefficient on women in the workforce for 1955–87 is only significant at a 5% level if *CHOL* is omitted from the equation. Moreover, its omission does not greatly affect the signs, sizes, or significance levels of the other variables in the equation for this period. However, the coefficient on women in the workforce is positive and different from zero at a 1% significance level for 1966–87.

When nonnested hypothesis tests (Kmenta, pp. 595–98) were used to compare equations with two structural variables, none of the equations dominated another. The predicted value from each equation was significant at the 1% level in every other equation. This result suggests that all three structural variables should be included in an egg demand model.

Estimation of the demand equation with all structural change variables included for 1955–87 indicates that cholesterol information had decreased per capita shell egg consumption by 16% by the first quarter of 1987. Estimation using only the 1966–87 period indicates that cholesterol information had decreased per capita shell egg consumption by 25% by the first quarter of 1987.

A recursive estimation technique was used on the equation containing all structural change variables to explore the stability of the *CHOL* coefficient over time (Brown, Durbin, and Evans; Dufour). The *CHOL* coefficient was negative and different from zero at a 5% significance level after 1974. The *CHOL* coefficient declined in absolute value after 1983. The decline is expected if additional medical articles on cholesterol began to have a declining effect on egg consumption. One might hypothesize that, as knowledge accumulates, the importance of new articles on cholesterol which merely confirm previous articles should decline.

The equation with all structural change variables was reestimated with the addition of the variable *CHOL-SQUARED* to further explore a possible declining effect of cholesterol articles. The estimated coefficient on *CHOL-SQUARED* was not different from zero at a 10% significance level.

Changing Coefficients

The effect of cholesterol information can be modeled in alternative ways. One possibility is to assume that price and income coefficients are not fixed but vary with the cholesterol index:

$$(5)\quad (D_c/N) = b_0 P_c^{b_1} Y^{b_2} P_S^{b_3} Q_2^{b_4} Q_3^{b_5} Q_4^{b_6} WW^{b_7} TIME^{b_8},$$

where $b_1 = f_1(CHOL)$ and $b_2 = f_2(CHOL)$. If one assumes that f_1 and f_2 are simple linear functions: $b_1 = a_0 + a_1 CHOL$ and $b_2 = d_0 + d_1 CHOL$, taking logs of both sides yields equation (6).

$$(6)\quad \ln(D_c/N) = b_0 + a_0 \ln P_c + a_1(CHOL \cdot \ln P_c) + d_0 \ln Y_c + d_1(CHOL \cdot \ln Y_c) + b_3 P_S + b_4 Q_2 + b_5 Q_3 + b_6 Q_4 + b_7 WW + b_8 \ln Meat\ Price + b_9 TIME.$$

When estimated using the 1955–87 data, this specification yielded

$$(7)\quad \ln(D_c/N) = \underset{(3.00)}{2.04} - \underset{(-3.3)}{.265}\ \ln P_c - \underset{(-6.7)}{.007}\ TIME + \underset{(4.4)}{.355}\ \ln Y_c - \underset{(-8.4)}{.069}\ Q_2 - \underset{(-10.5)}{.049}\ Q_3 + \underset{(5.4)}{.020}\ Q_4 + \underset{(1.5)}{.004}\ WW + \underset{(2.0)}{.096}\ \ln meat\ price + \underset{(1.8)}{.00017}\ (\ln P_c \cdot CHOL) - \underset{(-2.2)}{.00009}(\ln Y_c \cdot CHOL),$$

where t-statistics are in parentheses. The coefficients on the interaction terms ($P_c \cdot CHOL$) and $Y \cdot CHOL$) are different from zero at, respectively, 10% and 5% significance levels.

The positive interaction of egg price and cholesterol seems to indicate that cholesterol information has decreased the absolute price elasticity of shell eggs in this period. As real egg prices dropped, egg consumption increased less than would be the case without cholesterol information. The negative interaction of income and cholesterol suggests that cholesterol information has also decreased the income elasticity of shell eggs in this period. As income rose, egg consumption increased less than would have occured without cholesterol information. According to these results, cholesterol information decreased per capita egg consumption by 16% by the second quarter of 1987 using 1955–87 data.

Conclusions

This paper described the construction of a cholesterol information index based on citations of the link between cholesterol and arterial disease in medical journals. When the index was used to predict per capita shell egg demand in a fixed coefficients regression, its coefficient was always negative and different from zero at a 1% significance level regardless of other variables included in the regression. Moreover, the resulting estimates of price and income elasticities were plausible. In a variable coefficients model which specified price and income elasticities as functions of cholesterol information, the presence of cholesterol information decreased the absolute own-price and income elasticities of the demand for shell eggs. As egg prices dropped, shell egg consumption increased less than would have been the case without the cholesterol information. Similarly, as income rose, consumption increased less than it would have without cholesterol information. Thus, information about cholesterol appears to have had a substantial effect, decreasing per capita civilian shell egg consumption by 16% to 25% by the first quarter of 1987, depending on the data period used.

A logical extension of this analysis would consider the performance of the cholesterol index in demand equations for red meat and poultry, for various fats, and for dairy products; these products may also have experienced structural changes in demand as consumers' information about cholesterol changed. This study provides evidence that the stock and dissemination of health information may need to be considered when food demands are estimated.

Testing Restrictions on a Model of Japanese Meat Demand

Dermot J. Hayes, Thomas I. Wahl, and Gary W. Williams

Tests for quasi-separability, net substitutability, and perfect substitutability are developed and implemented on an almost ideal demand system model of the Japanese meat sector. The data set satisfies both symmetry and homogeneity. There is evidence of net complimentarity between chicken and dairy beef and chicken and pork. The tests indicate that Japanese Wagyu beef is considered a separate commodity to both imported beef and dairy beef. The results also indicate that fish can be treated as separable in the Japanese meat demand system.

Key words: demand analysis, Japanese meat preferences, separability.

Japanese imports of beef have grown slowly over the years because of a restrictive Japanese beef import policy. A 1988 agreement between the United States and Japan, however, will significantly curtail Japanese intervention in its beef market in the future and force the Japanese cattle industry to adjust to greater market determination of the supply, demand, and prices of beef. Although research on the economic effects of Japanese beef policy has been growing (e.g., Hayami; Anderson; Wahl, Williams, and Hayes), a clearer understanding of the Japanese meat sector is needed to measure more precisely those effects. In this paper, a model of the Japanese meat demand system is estimated and used to test three hypotheses regarding meat consumer behavior in Japan. The tests were developed specifically for the linear approximate almost ideal demand system (LA/AIDS) used in this study.

The first hypothesis tested is that fish is not separable from meat in Japan and, therefore, should be included in the Japanese meat system. The role of fish in purchase decisions of Japanese meat consumers has been controversial. A test for quasi-separability of the cost function for the AIDS is developed and used to test the hypothesis. The test provides modelers with a general method to choose groups of commodities that belong together in a separable model. This is particularly important when modeling demand systems of foreign markets where social and cultural differences affect dietary habits and preferences.

The second hypothesis tested is that imported beef is a perfect substitute for beef from the native beef breed. The test is important because the extent of any impact of changes in Japanese beef policy will depend crucially on the degree of substitutability of beef types in Japan. The final hypothesis is that all meats in Japan are net substitutes in consumption. Here a Bayesian procedure recently developed by Geweke is used to impose restrictions on the Hicksian cross-price elasticities. The test is quite useful because unexpected findings of complementarity among related commodities in demand system studies is common. Incorporating a demand system with such complementarities present into larger simultaneous system commodity models can lead to counterintuitive policy simulation results.

The first section of this paper describes the Japanese meat sector and highlights the differences between the United States and Japan. The second section presents the results of the LA/AIDS model of the Japanese meat sector. Tests of the three hypotheses regarding demand behavior in the Japanese meat sector are constructed and the results discussed. The final section offers some summary comments on the major results.

Overview of the Japanese Meat Sector

Japanese cattle inventories include the native (Wagyu) beef breed and dairy cattle. A large number of farmers raise small herds of Wagyu as a sideline to crop production. In contrast, dairy farming is a highly specialized activity. Herds are correspondingly larger. However, both Wagyu and dairy calves are fattened for slaughter. A rapid increase in per capita income in Japan has resulted in a rapidly increasing demand for beef. On average over the last twenty years, however, the per capita consumption of beef has not expanded nearly as rapidly as that of pork or chicken meat. In 1965, for example, the per capita consumption of beef, pork, and chicken meat were nearly equal at about 1 or 2 kilograms per year (retail cuts basis). By 1986, per capita pork and chicken meat consumption had jumped to 9.9 kilograms per year and 9.8 kilograms per year, respectively, compared with that of beef at only 4.1 kilograms per year (retail cuts basis). Given the historically restrictive beef import quota, this disparity in growth rates reflects a similar disparity in relative rates of growth in production and an opposite disparity in price movements over time. The more rapid production growth of pork and chicken meat has been caused primarily by the rapid adoption of modern confinement feeding technology for hogs and chickens in Japan over the last twenty years. Thus, although the real retail price of beef in Japan increased by 17% between 1965 and 1986, those of pork and chicken meat decreased by 43% and 56%, respectively. The Japanese consume significantly more fish than do Americans, which is reflected in the fact that the Japanese spend as much on marine products as they do on beef, pork, and chicken meat combined.

Imported beef is more lean than the beef produced from Japanese cattle. The Japanese place great emphasis on the degree of marbling in beef cuts. Japanese milk producers run a profitable sideline by fattening their holstein calves to weights that are similar to those of U.S. choice steers. There is reportedly much greater similarity between the beef imported from the United States and Japanese dairy steer beef than between imported U.S. beef and Wagyu steer beef (Mori, Gorman, and Faminow).

A Model of the Japanese Meat Demand System

Given the perceived differences between U.S. and Japanese beef, import-quality beef and Wagyu beef are treated as separate commodities in the model.[1] The validity of this assumption is tested in the third section of this paper. This is a significant distinction because the principal Japanese justification for restricting beef imports is that increases in beef imports reduce the profitability of Wagyu production. This implicitly assumes that Wagyu beef and U.S. beef are perfect or at least very close substitutes.

The LA/AIDS technique was chosen to estimate the parameters of the Japanese meat demand system. It combines the best of the theoretical features of both the Rotterdam and translog models with the ease of estimation of the Linear Expenditure System (LES). The LA/AIDS provides an arbitrary first-order approximation to any demand system, satisfies the axioms of choice exactly, and, under certain conditions, aggregates perfectly over consumers (Deaton and Muellbauer 1980a, b). In addition, the LA/AIDS is directly nonadditive (Blanciforti and Green 1983a). Although LA/AIDS does not implicitly impose the theoretical restrictions of homogeneity, Slutsky symmetry, and adding up, these restrictions can be imposed easily. These last two characteristics are particularly important for an analysis of Japanese meat demand. Use of a directly additive system such as the LES would imply independent marginal utilities between Wagyu and import-quality beef.

The expression for the budgetary share (W) allocated to the ith meat item in the LA/AIDS is

$$(1) \quad W_i = \alpha_i + \sum_{j=1}^{n} \gamma_{ij} \ln P_j + \beta_i \ln\left(\frac{X}{P}\right),$$

where P_j is the price of meat j, X is the per capita expenditures on all five meats, and P is a suitable price index.[2] For P, Deaton and Muellbauer suggest using Stone's index (defined as $\ln P = \sum_{i=1}^{n} W_i \ln P_i$).

Adding up, homogeneity, and Slutsky symmetry can be imposed on this system as follows:

$$(2) \quad \sum_{i=1}^{n} \alpha_i = 1; \sum_{i=1}^{n} \gamma_{ij} = 0; \text{ and } \sum_{i=1}^{n} \beta_i = 0;$$

$$(3) \quad \sum_{j} \gamma_{ij} = 0; \text{ and}$$

[1] Import-quality beef is defined as either Japanese dairy beef or imported beef.

[2] Because we use the expenditure on meats rather than total expenditures, the resulting system is a conditional one. The elasticities are all second-stage estimates.

(4) $\gamma_{ij} = \gamma_{ji}$.

Provided that equations (2), (3), and (4) hold, the estimated demand functions add up to the total expenditure (2), are homogenous of degree zero in prices and income taken together (3), and satisfy Slutsky symmetry (4) (Deaton and Muellbauer 1980a, p. 314).

The expenditure and price data are from various yearbooks and reports published by the Japanese Ministry of Agriculture, Forestry, and Fisheries (MAFF). These publications include various issues of *Statistical Yearbook, Statistics of Meat Marketing, Meat Statistics in Japan, Monthly Statistics of Agriculture, Forestry,* and *Fisheries,* and the *Annual Report on the Family Income and Expenditure Survey*. Expenditures are calculated as price times disappearance (retail basis). Disappearance for Wagyu beef, import-quality beef, pork, and chicken are calculated as production plus imports, which are available from the *Statistical Yearbook*. Retail fish disappearance is also available from the *Statistical Yearbook*. Retail prices for pork and chicken meat are from *Meat Statistics in Japan*. Retail fish price, from the *Annual Report on the Family Income and Expenditure Survey,* is an average of fresh and salted fish price series weighted by the disappearance of each.

A retail beef price is available in the *Meat Statistics in Japan,* but individual retail prices for Wagyu and dairy beef are not published. Retail Wagyu and dairy beef prices are calculated by multiplying the respective wholesale prices available in *Statistics of Meat Marketing and Meat Statistics in Japan* by 2.1156. This coefficient is the average ratio of total retail beef expenditures to the sum of wholesale Wagyu beef expenditures and wholesale dairy beef expenditures. (See Wahl for further details on the data and sources.)

Because the meat expenditure shares (W_i) sum to one, a demand system composed of the five individual expenditure share equations would be singular. Therefore, one of the equations must be dropped to estimate the equations as a system. The fish share equation was chosen for deletion in this study. However, the parameters for the omitted share equation can be calculated by using the adding-up restrictions from (2). In the absence of other restrictions, these restrictions are costlessly imposed. That is, the omitted share equation parameters calculated by using the restrictions are identical to those that would be estimated directly by using ordinary least squares (OLS). In the remainder of this paper, estimates of the parameters of the expenditure system were derived by using an iterated nonlinear, seemingly unrelated regressions (ITSUR) estimator.[3] As suggested by Berndt and Savin, the system was corrected in each case for autocorrelation by using the same autocorrelation coefficient for each equation. These procedures provide maximum likelihood estimates that are invariant to the equation chosen for deletion (Chalfant).

Slutsky symmetry was then imposed on the parameters of the system. Because symmetry cannot be tested equation by equation, a test statistic, such as the asymptotic likelihood ratio, for the system as a whole is required. The imposition of Slutsky symmetry automatically imposes homogeneity in the LA/AIDS (McKenzie and Thomas). Consequently, the unrestricted model for testing Slutsky symmetry alone had homogeneity imposed. Slutsky symmetry was accepted at the 5% level.

Both Marshallian and Hicksian measures of elasticities can be computed from the estimated parameters of the LA/AIDS model as follows:

(5) $\epsilon_{ii} = -1 + \gamma_{ii}/W_i - \beta_i,$

(6) $\epsilon_{ij} = \gamma_{ij}/W_i - \beta_i(W_j/W_i),$

(7) $\delta_{ii} = -1 + \gamma_{ii}/W_i + W_i,$ and

(8) $\delta_{ij} = \gamma_{ij}/W_i + W_j,$

where ϵ denotes Marshallian elasticities and δ denotes the income-compensated, or Hicksian, measure. These formulas were derived from the LA/AIDS equation with total meat expenditures rather than total expenditures in the numerator of the last term. Expenditure elasticities can be obtained as well:

(9) $\eta_i = 1 + \beta_i/W_i.$

These elasticities have been calculated for the demand system with Slutsky symmetry imposed and are presented along with their standard errors in table 1. The standard errors (in parentheses) were calculated by using the method proposed by Chalfant. This method assumes that budget shares are exogenous; consequently, the standard errors are only approximations. For comparative purposes, Chalfant's estimates of similar elasticities for the United States are also presented in table 1. Chalfant employed a nearly

[3] The ITSUR estimator used is an option in the SYSNLIN procedure of the Statistical Analysis System (SAS) software.

Table 1. Japanese and U.S. Meat Data: Price and Expenditure Elasticities

Type Expenditure	Hicksian Elasticities for Japan Household Model		Hicksian Elasticities for Japan Per Capita Model		Marshallian Elasticities for Japan Per Capita Model		Marshallian Elasticities for the United States Per Capita Model[a]	
Wagyu beef demand

Note: IQ beef is import-quality beef, which includes both imported and domestic dairy beef. All models have Slutsky symmetry and homogeneity imposed. Numbers in parentheses are standard errors. The parameters of the fish expenditure share equation are calculated by using the adding-up restriction.

[a] Source of U.S. per capita model Marshallian elasticities is Chalfant.

identical estimation procedure to the one used here using annual data from 1947 to 1978.

Almost all empirical applications of the AIDS model deflate total expenditures by population. This is not strictly correct. The exact aggregation property of the AIDS model is based on a household cost function and not on individual members of the household. Also, the assumption of weak separability is more intuitively appealing in the context of household budgets rather than those of individuals. Deaton and Muellbauer (1980a) acknowledge this and present the version of the model that satisfies exact aggregation:

$$(10)\qquad \bar{W}_i = \alpha_i + \sum_{j=1}^{n} \gamma_{ij} \log P_j + \beta_i \ln(\bar{X}/kP),$$

where $\bar{W}_i$ is the share of aggregate expenditure on good i in the aggregate budget of all households and $\bar{X}$ is the average level of household expenditure. The index k, known as the household income equivalence scale (Muellbauer), is a sophisticated theoretical construct defined by

$$\log \bar{X}/k \equiv \sum_{n} X_h \log(X_h/k_h)/\Sigma X_h,$$

where X_h is the expenditure level of individual

households and k_h can be defined as the household specific income deflator, which must be used so that all households have the same budget shares as a reference household for which $k = 1$. Accurate measurement of k, if possible, would be very expensive. As a consequence, the index is ignored in empirical studies. If k is assumed to be closely correlated with household size, the common practice of deflating total expenditure by total population is defensible. Even if this were the case, however, the number of people per household would have to remain constant as real expenditures increase to avoid an omitted variable bias (Deaton and Muellbauer 1980a, p. 315). Unfortunately, average household size in Japan has fallen as real expenditures have increased. Without an accurate measure of the household specific deflator, it is impossible to measure this bias. Consequently, table 1 presents two sets of Hicksian elasticities from the demand system in which population and household numbers, respectively, have been used as expenditure deflators. The per capita demand system was used in the rest of the paper to facilitate comparison with the results of other AIDS models.

The estimated elasticities in this study for the Japanese meat demand system are, in general, in accordance with a priori expectations. All own-price elasticities are negative while most of the compensated cross-price elasticities are positive. The results, however, suggest that chicken is a complement of import-quality beef and perhaps pork. This conclusion is not the case for Chalfant's estimates for the United States, which indicate that chicken is complementary only to fish. Note that, for all relevant meats, the (Marshallian) own-price elasticity of demand is greater in Japan than in the United States.

The estimated expenditure elasticities indicate that both Wagyu and import-quality beef are luxury goods in Japan (table 1). When total population is used to deflate expenditures, the expenditure elasticity of demand for import-quality beef was greater than that for Wagyu beef. This latter result is somewhat surprising because Wagyu beef is much more expensive than import-quality beef. Japanese consumers consider Wagyu beef to be more desirable than imported beef (Miyazaki). Nevertheless, the import-quality beef expenditure share more than doubled over the sample period, while that of Wagyu beef was virtually constant over the sample period. Teal et al. also find that the income elasticity of demand for low-quality beef is above that for high-quality beef in Japan.

The income elasticity of Japanese demand for meats was estimated to be 1.54 by Sasaki and Fukagawa. A 10% increase in real income, therefore, implies that the demand for import-quality beef would increase by almost 40%. This figure was derived by multiplying the per capita expenditure elasticity for import-quality beef by the income elasticity of demand for the meat group as a whole (Blanciforti and Green 1983b).

The Japanese expenditure elasticities for both poultry and fish are greater than the pork expenditure elasticity. Again, this is not the case in the Chalfant study of the United States, where poultry has the lowest expenditure elasticity of all meats. The implication is that pork occupies the same position in Japanese spending priorities as poultry does in the United States.

Testing Hypotheses About the Japanese Meat System

In this section, tests of three hypotheses concerning meat consumer behavior in Japan are developed and applied to an LA/AIDS model for the Japanese meat sector. The hypotheses relate to the (*a*) separability, (*b*) perfect substitutability, and (*c*) net substitutability of meats in Japan. The results provide insight into demand systems modeling in general and the Japanese meat system in particular.

Testing for Separability in an AIDS Model

Japanese consumers spend almost as much on fish as they spend on all other meats combined. In addition, the government collects much more detailed data on consumption and prices of different fish species than on meats. Defining "fish" as a single commodity in a meat demand system, rather than defining several subcategories of fish as was done with red meats, reflects a Western bias. However, data limitations preclude the estimation of a model with individual red meats and individual fish species. The possibility remains, however, that fish should be considered as separable from other meats at a more aggregate level. This section demonstrates how this separability hypothesis can be tested by using parametric restrictions on the AIDS model.

Separable demand models have been developed by Barten (1964, 1968), Brown and Heien, Jorgenson and Lau, and Barnett. Where tested in these highly aggregated models, separability restrictions have been rejected. Eales and Un-

nevehr derive a restriction which they use to test for weak separability in a first-difference AIDS model.[4]

Many concepts of separability are in use, including the distinction as to whether there is weak or strong separability, separability of the utility function (direct), separability of the indirect utility function (indirect), separability of cost or distance function (quasi), separability of an implicit representation of the direct utility function (direct pseudo), and, finally, separability of an implicit representation of the indirect utility function (indirect pseudo). Pudney provides a formal definition of each and uses each to impose and test separability in a simple constant elasticity model. Although each definition requires a different set of parametric restrictions, Pudney shows that the various definitions available make little difference to the empirical results. Consequently, only quasi-separability of the cost function was tested in the Japanese meat AIDS model. This approach was chosen because AIDS is based on a flexible functional form of the cost function.

Assume that $M = G^*(p, u)$ is an arbitrary definition of the cost function that gives the minimum cost (M) of reaching indifference curve u at price p. This function is assumed to be concave, homogenous of degree one in p, and increasing. For such an arbitrary cost function, preferences are said to be quasi-separable if the function can also be written as

$$M = G[g_1(p_1, u), \ldots, g_r(p_r, u)], \tag{11}$$

where $G(\cdot)$ and the functions $g_r(\cdot)$ also have the general properties of cost functions, goods are portioned into r groups with price subvectors $p_1 \ldots p_r$, and the functions $g_r(p_r, u)$ are increasing in u and G (Gorman). Deaton and Muellbauer (1980b, p. 134) discuss separability of this type (which they term implicit separability) and show that the group budget shares ($W_r = X_r/X$) may be derived from

$$W_r = \frac{\partial \ln G}{\partial \ln g_r}. \tag{12}$$

Intragroup budget shares ($W_{ri} = q_i p_i / X_r$) may be derived from

$$W_{ri} \equiv \frac{\partial \ln g_r(p_r, u)}{\partial \ln p_{ri}}, \tag{13}$$

where $g_r(p_r, u)$ can best be considered "as group price indices that depend on the level of utility u" (Deaton and Muellbauer 1980b, p. 134). Each vector p_r is composed of the prices of the individual i commodities within the group r.

From Shephard's lemma, the share of subgroup i within X (total group expenditures), or $W_{Gi} \equiv q_i p_i / X$, may be derived from

$$W_{Gi} = \frac{\partial \ln G}{\partial \ln g_r} \frac{\partial \ln g_r}{\partial \ln p_{ri}} = W_r W_{ri}. \tag{14}$$

Differentiating (16) with respect to the price of good j in group S (P_{sj}) and holding u constant, the form of the between-good Slutsky terms can be derived as follows:

$$\gamma_{risj} = \frac{\partial W_{Gi}}{\partial P_{sj}} = \frac{\partial^2 \ln G}{\partial \ln g_r \partial \ln g_s} \frac{\partial \ln g_r}{\ln p_{ri}} \frac{\partial \ln g_s}{\partial \ln p_{sj}}. \tag{15}$$

Taking each variable on the right-hand side of (17) in turn,

$$\text{(i)}\ \frac{\partial \ln G}{\partial \ln g_r} = W_r \quad \text{(ii)}\ \frac{\partial \ln W_r}{\partial \ln g_s} = \gamma_{rs}$$

$$\text{(iii)}\ \frac{\partial \ln g_r}{\partial \ln p_{ri}} = W_{ri} \quad \text{(iv)}\ \frac{\partial \ln g_s}{\partial \ln P_{sj}} = W_{sj},$$

where γ_{rs} is the estimated cross-price parameter between groups r and s, estimated from an aggregate AIDS model that has shares W_r and W_s as dependent variables. This result (ii) is derived by specifying an equation for share r and taking the derivative with respect to the group price index holding the level of utility (or X/P) constant. Hence, the restriction that is implied by quasi-separability of the cost function may be written in terms of known shares and estimated parameters as

$$\gamma_{risj} = W_{ri} W_{sj} \gamma_{rs}. \tag{16}$$

In other words, two groups, r and s, may be considered separable if the compensated cross-price effects between the share of good i in group r and the price of good j in group s ($s \neq r$) satisfy the restriction in (16). For Japan, W_{ri}, W_{sj}, and γ_{rs} may be respectively considered to be the share of each meat of nonfish meat expenditures, the expenditure share for a particular fish within the fish group, and the cross-price parameter between the meats and fish in a more aggregate AIDS model. Because one aggregate fish group is used, W_{sj} can be set to 1 so that the restriction becomes

$$\gamma_{ris} = W_{ri} \gamma_{rs}. \tag{17}$$

[4] The technique in this paper differs from that used by Eales and Unnevehr in that the former allows comparison of restricted and unrestricted parameters whereas the latter does not.

The procedure for implementing this restriction is straightforward. An estimate of γ_{rs} was obtained by using a two-good AIDS model to explain the shares of meat and fish. A second model was then estimated in which individual meat shares and fish group share were dependent variables. The predicted shares of the individual meats within the meat groups were multiplied by γ_{rs} to obtain a set of parametric restrictions that were then placed on the cross-price terms between each meat price and the fish group price. A likelihood ratio test was then performed to determine if the restrictions were accepted by the data. The calculated likelihood ratio, which has a chi-square distribution, was 6.20. The 5% significance level of the chi-square distribution with four restrictions is 9.48. Hence, at the means, separability between meats and fish in Japan cannot be rejected. The elasticities of the Japanese meat expenditure share system with quasi-separability imposed between each of the meats and the fish group are presented in table 2.

Testing for Perfect Substitutability among Meats

The compensated cross-price elasticities for import-quality beef in the Wagyu beef expenditure share equation and for Wagyu beef in the import-quality beef expenditure share equation are positive but not particularly large (table 2). This suggests that Wagyu and imported beef are net substitutes but not perfect substitutes. It is relatively simple to construct an asymptotic likelihood ratio test to determine whether Wagyu and import-quality beef are, in fact, perfect substitutes. To see how this might be done, consider the results that might be expected in a model of the U.S. meat system where beef was subdivided into beef from the traditional English breeds and beef from the nontraditional breeds. Although these expenditure shares need not be similar, each would be expected to react similarly to relevant price changes if, in fact, these two beef types are perfect substitutes. Also, the prices of these two types of beef would be expected to be perfectly correlated even when the relative quantity supplied of each beef type is changed. If this were not the case, consumers would refuse to purchase the higher priced of the two beef types that they consider to be identical. This implies that producers of both beef types would receive no price signals to change the relative proportions of each beef type supplied.

Table 2. Hicksian Elasticities for Separability and Perfect Substitution Tests

Type Expenditure	Unrestricted[a]	Separability Imposed	Perfect Substitution Imposed
Chi-square		6.20	391.93*[b]
Wagyu beef			
Wagyu beef	−1.78	−1.43	[c]

Note: Homogeneity and Slutsky symmetry are imposed in all cases. IQ Beef is import-quality beef.
[a] From table 1.
[b] Asterisk indicates significant at the 1% level.
[c] The Wagyu and import-quality beef shares are combined under IQ beef for the elasticity calculations.

To test the hypothesis that Wagyu and import-quality beef are perfect substitutes, therefore, the price and expenditure coefficients in the Wagyu and import-quality beef equations were restricted to be equal. The intercept terms were not restricted. With the asymptotic likelihood ratio test, the null hypothesis of perfect substitutability of Wagyu and import-quality beef can be rejected at the 1% level of confidence. This result is of particular relevance because the Japanese government has restricted beef imports to protect the Wagyu beef industry. This policy implies that the Japanese government considers Wagyu and imported beef to be close substi-

tutes. This does not seem to be so, however. Any decrease in import-quality beef prices will influence Wagyu beef demand only through the cross-price elasticity. The elasticities with perfect substitutability imposed between Wagyu and dairy beef are presented in the last column of table 2.

The elasticities for the import-quality beef and pork shares are strongly affected by this restriction. The imposition of perfect substitutability, along with homogeneity and Slutsky symmetry, results in fourteen restrictions on the twenty-eight estimated parameters. The cumulative effect of these restrictions dramatically changes some of the estimated parameters from their unrestricted values.

This test is obviously overly restrictive and is not a test of the degree of substitutability among meats. It does, however, indicate that in Japan, in contrast to most other countries, beef from different breeds cannot be considered perfectly substitutable.

Testing for Net Substitutability among Meats

An examination of the second column of table 1 indicates that import-quality beef and pork are complementary to chicken meat. Although quite common in studies of this type, this complementarity is somewhat unsettling. It is difficult to believe that consumers would react to increases in import-quality beef prices or pork prices by consuming less chicken regardless of the culture or culinary practices. In addition, if this demand system were incorporated into a model of the Japanese livestock sector, it would lead to counterintuitive policy simulation results. In this sense, the demand system is not well behaved.

A common response to this problem is to mine the data by using alternative definitions of prices or quantities or by utilizing alternative functional forms. If this sequential pretesting did not produce the desired substitutability among meats, one could impose the desired result by specifying an appropriate functional form on the utility function. Another alternative would be to explicitly impose net substitutability econometrically by specifying that the compensated cross-price elasticities must be greater than or equal to zero. When binding, this elasticity would be zero. By imposing a priori beliefs in this manner, however, the econometric approach is a compromise that neither allows the researcher to learn from the data nor produces reasonable results. In addition, zero cross-price elasticities serve to isolate the impacts of shocks to particular commodities rather than to the entire group.

Geweke has demonstrated how inequality constraints can be imposed by means of Bayesian inference. Chalfant and White have used this approach to impose curvature restrictions on a set of substitution elasticities of a translog cost function. This section demonstrates how to test and impose net substitutability among meats for an AID system using Geweke's Bayesian approach as outlined in Chalfant and White. By treating net substitutability among meats as diffuse prior information and combining this information with the sample likelihood function by using Bayes' theorem, a posterior likelihood function that is defined only over the restricted sample space is obtained. Estimates of the elasticities can then be calculated from this posterior distribution. With a quadratic loss function, the mean value of this posterior distribution is optimal. (For an excellent discussion, see Chalfant and White.)

The procedure for finding this posterior distribution is as follows. First, the demand system is estimated with or without symmetry and homogeneity imposed. The parameter vector and covariance matrix from this procedure are then used to generate a multivariate, normal distribution. The parameter vectors from this generated distribution that satisfy net substitutability become the posterior distribution. The number of replications required depends, in part, on a priori beliefs as to the number of replications that will, in fact, satisfy the restrictions. The proportion of draws that satisfy the restrictions measures the probability that the system meets the restrictions (Chalfant and White). The mean values of this posterior distribution can then be used to calculate the elasticities, which will, by construction, satisfy net substitutability.

From the equation for computing the Hicksian elasticity (8), it is clear that, for the net substitutability restriction to be satisfied ($\delta_{ij} > 0$) at the means, γ_{ij} must be greater than $-W_j * W_i$. Therefore, to impose net substitutability at the means, the value of the cross-price parameter must be restricted to be greater than the negative of the product of the expenditure shares.

With this procedure, the Japanese meat demand system with homogeneity and symmetry imposed was estimated to obtain estimates of the coefficients and corresponding covariance matrix. These coefficients were assumed to be point values taken from a multivariate normal distribution with population variances equal to those

in the variance-covariance matrix. A sample distribution of the parameter set was then constructed by using a randomly generated, multivariate normal distribution. With use of a Monte Carlo procedure with inequality restrictions, 20,000 replications were generated. Each replication was then checked to determine if net substitutability was satisfied. The percentage of draws not violating this restriction indicates whether or not the restriction holds (Chalfant and White). The mean values of those vectors that satisfy the restrictions become the estimated parameter vector. For example, when net substitutability between all meats was imposed, the percentage of observations that satisfied the restriction was 1.13%. That is, of the 20,000 multivariate replications of the parameter set, only 226 satisfied the restrictions that all meats are net substitutes. The elasticities from the mean values of those results that satisfied the restrictions are presented in the last column of table 3.

This methodology can also be used to indicate which meat may be responsible for the replications that violate the restrictions. This is achieved by dropping the inequality restrictions for one meat at a time and then observing the change in the proportion of replications for which the substitutability restrictions are accepted while maintaining both the Slutsky symmetry and homogeneity restrictions. These results are presented in the first five columns of table 3.

The first row of table 3 indicates, for example, that 3.68% of the replications satisfied the restriction that import-quality beef, pork, chicken, and fish are substitutes. When the inequality restrictions are relaxed for one meat at a time, the

[a] IQ beef is import-quality beef, which includes both imported beef and domestic dairy beef.

only consistent complementarity is between chicken and both import-quality beef and pork. At the same time, the percentage of replications satisfying the restrictions is highest when chicken is not restricted to being a substitute of the other meats. Although perhaps simply the result of the particular data set utilized, this finding may be related to the unique and diversified Japanese food consumption patterns and traditions. Further research on this point is warranted. It is also interesting to note that all cross-price elasticities are positive when no restrictions are placed on Wagyu beef. These elasticities satisfy net substitutability with fewer restrictions than elasticities with restrictions imposed upon all meats. Consequently, they may also be useful for policy analysis.

Concluding Comments

This paper presents tests of three hypotheses regarding meat-consumer behavior in Japan: (*a*) separability of meats and fish, (*b*) perfect substitutability of Wagyu and import-quality beef, and (*c*) net substitutability of meats. These hypotheses are central to the debate on the likely effects of liberalization of Japanese meat markets. The tests of these hypotheses are new and were developed for the LA/AIDS model of the Japanese meat demand system used in this study. The demand system is well behaved in that it satisfies the theoretical restrictions of homogeneity and Slutsky symmetry. The restrictions on the demand system implied by the hypotheses are relatively simple to estimate and can be imposed and tested by using commercially available software.

The first two restrictions (separability and perfect substitutability among meats) essentially focus on the choice of dependent variables. The test of each restriction merely formalizes the decision-making process that is implicitly performed in ad hoc models. Both restrictions are imposed without changing the number of equations in the system. This method provides a basis for comparison of likelihood functions. The first test can be used in various applications to determine whether a particular commodity should be included in a demand system. In developing models to analyze the likely effects of the increasing openness of Japanese meat markets, whether or not fish should be included in the meat demand system has been a controversial issue. The separability test developed in this paper suggests that an assumption of weak form separability between meats and fish in Japan is not an incorrect specification.

The second test examines the level of aggregation that can be used in a demand system. The test provides evidence as to whether two commodities are perfect substitutes and can, therefore, be treated unambiguously as a single commodity. Most analyses of Japanese beef markets and policies have treated domestic and imported beef as identical commodities (e.g., Anderson and Hayami). Other researchers, however, have claimed that this is an inappropriate procedure (e.g., Mori, Gorman, and Faminow). In this paper, the hypothesis that Wagyu and imported beef are perfect substitutes is rejected, implying that each type of beef must be treated as a separate commodity in analyzing the effects of Japanese beef import policies on the Japanese livestock industry.

The third restriction tested is much more practical, providing a theoretically plausible means of imposing prior beliefs about the degree of substitution between two commodities in a demand system. Typically, policy analysts are forced to ignore much of what the literature in demand theory has to offer because of the necessity of obtaining econometric results that conform to prior expectations. Ad hoc models are generally favored because they allow the analyst to search among an infinite variety of possible model specifications for the subsets of parameters that produce reasonable policy simulation results. The flexibility provided by ad hoc models, however, is also their major weakness because the properties and robustness of the presented results are unclear. Even though the flexibility of theoretically richer models is greatly limited because the functional relationships and, to a certain extent, the dependent variables to be used are specified, the results are much more robust. However, where the results of these analyses are to be used for policy analysis, otherwise trivial results, such as estimated complementarity between two meats, can be of great importance. In this paper, a Bayesian procedure to impose and test net substitutability among commodities in an AID system is used to derive elasticities for the Japanese meat demand system that, by construction, satisfy net substitutability. Although the procedure does not guarantee that all Marshallian cross-price elasticities will be positive, it does remove all negative Hicksian elasticities caused by net complementarity.

The Determinants of the Migration of Labor out of Agriculture in the United States, 1940–85

Andrew P. Barkley

The flow of labor out of production agriculture is analyzed using a two-sector model of occupational choice. A migration equation is specified and tested empirically using aggregate data for the United States. The economic determinants of the migration of all farm workers and farm operators are established. Farm labor is found to be responsive to changes in the returns to agricultural labor relative to nonfarm labor returns. Given this responsiveness, policies intended to increase farm income will affect the level of agricultural employment.

Key words: labor migration, occupational choice, two-sector model, U.S. agricultural labor.

The quantity of labor employed in agricultural production in the United States has diminished dramatically over the past several decades; farm employment dwindled from over nine million workers in 1940 to just over three million persons in 1985 (table 1). The flow of labor out of agriculture has been studied extensively, but occupational migration at the aggregate level has not been carefully considered since the 1960s (Greenwood). Obtaining accurate and up-to-date estimates of the determinants of occupational migration is crucial for the evaluation of agricultural policies that attempt to increase farm income and stabilize farm employment.

Early studies of off-farm migration experienced difficulties in finding empirical relationships between the flow of labor out of agriculture and economic variables that were expected to influence the quantity of labor in the farm sector (Sjaastad 1961, Bishop). Econometric research led to successful estimation of the supply of and demand for farm labor (Tyrchniewicz and Schuh, Heady and Tweeten). These models illuminated conditions in the agricultural labor market at the time of the studies but did not explain migration as a decision made by rational economic agents.

The objective of this paper is to evaluate the economic determinants of the migration of labor out of production agriculture in the United States for (*a*) all farm workers and (*b*) farm operators. The paper proceeds by first examining the theoretical aspects of the occupational migration of labor out of production agriculture. This is followed by the specification of a migration equation that is then tested empirically using aggregate time-series data.

Theoretical Considerations

The decision to migrate from production agriculture is analyzed using a model of occupational choice that builds on Sjaastad's (1962) pioneering view of migration as an investment in human capital and Todaro's study of labor migration. A two-sector approach is utilized by disaggregating the economy into a production agriculture sector and a nonfarm sector that includes all other occupations (Mundlak 1988).

Consider an individual facing given returns (wages) in two mutually exclusive occupations: the production of agricultural products ($i = 1$)

[a] *INC* is ratio of disposable incomes, nonag. to ag.; *d*, ratio of average products of labor, nonag. to ag.; *L1*, agricultural employment (1,000s); *M*, occupational migration of all farm workers [see equation (5)]; *L1S*, farm operator employment (1,000s); *S*, occupational migration of farm operators [see equation (5)]; *LAND*, index of real estate value per acre deflated by PPI (1977 = 100); *GOV*, government payments divided by gross farm product; and *U* is unemployment rate in total economy (%).

and nonfarm employment ($i = 2$). The choice of occupation is determined by comparing the discounted utility derived from each job over the career of the individual. A person enters the labor force at age G_0, and retires at age T. The optimization problem confronted by such a worker can be written as equation (1), where r is the rate of discount.

$$(1) \quad H_{ik} = \int_{G1}^{T} e^{-rt}\, U(X_{it}, L_{it})dt - \int_{G1}^{T} e^{-rt}[U(X_{jt}, L_{jt}) - C_{ijt}]dt,$$

where $X_{it} = q_{it}w_{it}L_{it}$, $X_{jt} = q_{jt}w_{jt}L_{jt}$.

Utility in period t is a function of both consumption in period t (X_{it}) and the hours of work spent at job i in period t (L_{it}). The movement of an economic agent from one occupation to another occurs when the expected lifetime utility derived from a potential profession rises above the lifetime utility expected in the current job, net of the disutility associated with the transfer between jobs. Occupation i is the current career (say agriculture) and j is some other occupation (say manufacturing); C_{ijt} indicates the costs of changing occupations from i to j. These costs may include both pecuniary and psychic costs. Occupational migration occurs when net utility is negative ($H_{ik} < 0$).

The flow of labor to higher wages does not take place instantaneously because of the probability, q_i, of obtaining a job in the high-wage sector (Todaro). Although the returns to labor may be higher in manufacturing than in farming, an agricultural worker currently engaged in a job search may discount the higher wage by the probability of obtaining employment in the industrial sector.

The model presented here regards the flow of labor out of production agriculture as the occupational choice of individuals. Here, the returns to labor are regarded as summary statistics. The enormous substitution of capital for labor and the low income elasticity of demand for farm products are structural parameters that are hypothesized to affect the migration of labor only through their impact on the relative returns to labor in the farm and nonfarm sectors. While the underlying cause of off-farm labor migration may be labor-saving technological change, the individual decision to change careers is influenced by the ability to earn a living in each occupation rather than the underlying structural conditions that determine the returns to labor.

Potential migrants must make an estimate of the probability of obtaining a job in the nonagricultural sector [q_j in equation (1)] to calculate H_{ik}. This probability is incorporated into the empirical model by the inclusion of macroeconomic variables, such as the unemployment rate and the relative size of the sectoral labor forces. Economic conditions within agriculture, such as government payments to farmers and land values, are also expected to affect the flow of labor out of agriculture.

The migration of individual k occurs if $H_{ik} < 0$. An index function f_{ik} is employed to separate migrants from nonmigrants.

$$(2) \quad H_{ik}f_{ik} \leq 0 \text{ where } f_{ik} = \begin{cases} 1 \text{ if } H_{ik} < 0 \text{ (migration occurs)} \\ 0 \text{ if } H_{ik} \geq 0 \text{ (migration does not occur)}. \end{cases}$$

This index function allows for the aggregation of individual migrants by the summation of f_{ik}. The gross rate of migration from occupation i to occupation j is denoted by M_{ij}.

$$(3) \quad M_{ij} = \sum_{k=1}^{z} f_{ik},$$

where z is persons employed in occupation i.

Some persons flow from nonfarm jobs to agricultural positions in a given time period. Here, M_{ji} represents persons who enter agriculture from the nonfarm economy, and M represents net migration out of agriculture:

$$(4) \quad M = M_{ij} - M_{ji}.$$

Specification of the Migration Equation

The migration equation developed below is an application of the empirical work of Mundlak (1979). Here, migration is limited to occupational migration at the aggregate level. Occupational migration is defined as the percentage change in agricultural employment (L_1) from one year ($t - 1$) to the next (t).

$$(5) \quad M = [L_{1(t-1)} - L_{1(t)}]/L_{1(t-1)}.$$

This definition of migration is an approximation to actual migration out of production agriculture; the definition considers only changes in the number of jobs in the farm sector. As such, the definition does not distinguish between retirements or actual movements to nonfarm positions. Part-time farming has become an important aspect of agricultural labor markets.

However, because of data limitations, this development is ignored here. This leads to an underestimate of the movement of labor out of agriculture; many of the persons that are counted as farm workers in this study are part-time farmers.[1]

Migration is expected to be a function of the returns to labor in the nonfarm sector relative to the returns to labor in agriculture. Let d be the ratio of nonfarm returns to agricultural returns.

$$(6) \qquad M = f(d), \quad f'(d) > 0.$$

The larger is the nonfarm sector relative to the farm sector, the greater is its capacity to absorb migrants from agriculture. Hence, the number of migrants is expected to depend on the relative size of the labor force in each sector, reflecting the probability of obtaining employment in each sector [i.e., the q_i of equation (4) is larger]. The relative size of the labor force is introduced into the migration equation (7) by defining $g = L_2/L_1$.

The rate of unemployment in the nonagricultural sector (U) is a measure of the probability of obtaining employment in the nonagricultural sector. Other variables that yield information concerning the expected returns to labor in agriculture are included in the vector z, and e is the stochastic component of the regression model.

$$(7) \qquad m = f(d)g^{\beta 2}U^{\beta 3}z^{\beta 4}e.$$

The model is specified in semilogarithmic form, as in (8).

$$(8) \qquad M = \beta 0 + \beta 1\log(d) + \beta 2\log(g) + \beta 3\log(U) + \beta 4\log(z) + V.$$

To avoid simultaneity, all of the independent variables are lagged one period; the change in agricultural employment between period $t - 1$ and period t is modeled as a function of the predetermined variables in period $t - 1$.

One component of the vector of exogenous variables (z) is the price of land. The owners of farmland receive income in the form of capital gains when land values increase. Thus, land prices are expected to influence the migration decision of farm operators who own part or all of their land. Potential migrants compare future streams of income in alternative occupations. One way to model a forward-looking migration decision is to invoke rational expectations. If well-functioning land markets exist, the value of land reflects the expected stream of all future returns to resources in agriculture.[2] The price of land contains all of the relevant information about the expected future of the agricultural sector, and thus it is an adequate representation of expectations that are formed rationally.

A measure of government payments is included as an exogenous variable in the migration equation to capture the effects of intervention in the market for farm labor. This variable is defined as the percent of farm income that results from government payments. Equation (8) is estimated using least-squares regression for both aggregate occupational migration (M) and farm operator migration (S).

Data

Two series of agricultural employment data are available in the United States, the U.S. Department of Agriculture (USDA) series and the Bureau of the Census series. The USDA series is derived from an establishment survey, while the Census series results from a household survey. The establishment survey of the USDA leads to double-counting because many agricultural workers hold more than one job simultaneously. The USDA data have been criticized for not reporting what they claim to measure, i.e., the amount of labor actually employed in agriculture in a given time period (Johnson and Nottenberg). For this reason, the Census data series was used in this study.

Some problems also exist with the Census series. The definition of the farm labor force was changed several times during the period of this analysis. These changes altered the series significantly in 1960, 1972, and 1978. Substantial increases in the farm labor force data series occurred in both 1942 and 1955. These expansions are anomalous; the USDA series shows a decrease of farm labor in both years.

The Bureau of the Census reports a rise of 226,000 workers between 1954 and 1955. Of these, 175,000 are reported to be female. However, there is no apparent reason why the number of female workers in agriculture should increase at this rate. Dummy variables were

[1] Hours of work are difficult to include in the empirical analysis because of data limitations. The USDA publishes hours of work, but the estimates are considered unreliable (Johnson and Nottenberg).

[2] Land values are used as a proxy for the returns to all resources engaged in production agriculture. See Melichar for a discussion of the relationship between land values and the returns to agricultural resources.

included in regression trials to account for definitional changes in the Census survey in 1960, 1972, and 1978 and for the unexplained increases in farm labor which occurred in 1942 and 1955. Two of the five dummy variables (*DUM*55 and *DUM*72) were statistically significant and thus were retained in the empirical model.

Two measures of the returns to labor are used in this research: (*a*) a measure of value added per worker and (*b*) data on income per capita. The first labor returns measure is the gross domestic agricultural product divided by the number of workers in the farm labor force.

Output data for both the farm and nonfarm sectors are in nominal terms. Nominal output measures capture the effects of relative price changes (the terms of trade) between agricultural and nonagricultural products.[3] Government price supports are included in the measure of farm output. Other government payments, such as deficiency payments, are not included (government payments are included as a separate regressor).

The second measure of aggregate labor returns employed is the series of disposable income per capita in agriculture as a percentage of disposable income per person in the nonfarm sector (USDA). Disposable income for both the farm and nonfarm population is calculated by deducting taxes from total income (which includes off-farm income for the farm population) in each sector. The sectoral disposable income is divided by an estimate of the farm and nonfarm populations, as opposed to the labor force in each sector which is used in the calculation of the average product ratio. The disposable income series was discontinued by the USDA in 1983, causing the ending year of the regression analyses to be different for the average product and the disposable income regressions.

The measure of land prices is the USDA series of real estate values (index, 1977 = 100), deflated by the producer price index for farm products.[4] The government intervention variable is derived by dividing the total amount of government payments to agriculture (USDA) by farm income to obtain the percent of income from government sources. The unemployment variable (Bureau of Labor Statistics) reflects unemployment in the entire economy.

Results

The regression results for total migration and farm operator migration are presented in table 2. A functional relationship is found between the relative returns to labor in agriculture and the level of occupational migration out of the farm sector. The remaining explanatory variables are all of the expected sign, excluding the government payments and unemployment variables, as explained below.

The regression coefficient of the ratio of labor returns variable ($\beta 2$) reports the responsiveness of a change in farm employment to changes in the relative return to agricultural labor. Elasticities are calculated at mean values. The elasticity of total farm migration with respect to the ratio of average products [$E(m, d)$] equals 4.50. This elasticity supports the hypothesis that the flow of labor out of agriculture responds to economic incentives. The results of the disposable income ratio trials are quite similar to the results of the regressions that utilize average products, indicating that the migration equation is robust to different measures of the nonfarm/farm returns ratio.

The regression results for variables that reflect macroeconomic conditions demonstrate the linkages between the farm and nonfarm sectors. The ratio of the nonfarm labor force to the farm labor force has a significant impact on the migration of labor out of agriculture. This ratio reflects the absorptive ability and the opportunity for employment of the nonfarm sector.

The government payments variable did not perform well. Government payments have divergent effects on the size of the labor force. Income assistance in the form of price supports and target prices are expected to slow the rate of migration out of agriculture. However, acreage set-asides accompany enrollment in the price support programs. Land diversion reduces the need for inputs which are complementary to land, resulting in an increase in the migration of labor out of agriculture. The government payments variable did not capture either of these anticipated effects of government policy on the agricultural sector. Perhaps the two effects offset each other and net to zero.

The benefits of government programs are expected to be capitalized into the value of farm-

[3] Real values would also reflect relative prices if the same inflation adjustment was used for both sets of data. However, the inflation rate of agricultural products differs from the inflation rate of nonfarm products. If the two different rates were used, the ratio would be purged of changes in relative prices.

[4] Although the returns ratio is left in nominal terms, the land price variable is deflated to capture changes in real land values only because this variable is not an intersectoral ratio.

Table 2. Labor Migration out of Agriculture, 1940–85

Dependent Variable: Migration of labor out of agriculture	Average Product Ratio (d) (1940–85)		Disposable Income Ratio (INC) (1940–83)

Notes: t-statistics are in parentheses. All explanatory variables are lagged once and in logarithms. See text for variable definitions. Level of significance; '***': $p \le 0.01$, '**': $p \le 0.05$, '*': $p \le 0.10$.

land (Floyd). Higher land values are found to be associated with less migration out of agriculture. The responsiveness of labor migration with respect to the price of land is large. This relationship reflects not only the technological substitution of inputs but also expectations of future returns to farming that are capitalized into the value of farmland.

Government intervention in the agricultural sector may have slowed the rate of migration from agriculture indirectly through higher land prices. However, government policies have not been successful at halting migration; farm incomes have not risen rapidly enough to keep pace with increases in nonfarm income over time, with the exception of the early 1970s.

Farm employment stabilized at around 3.4 million workers during the period from 1971 to 1983 (table 1). The regression results yield insight into the causes of this break in the trend of outmigration. The period was one of historically high relative farm returns (d) and disposable incomes (INC). The opening of international agricultural markets resulted in high expectations and high land values ($LAND$). This combination of high income levels and high expectations resulted in the retention of labor in agriculture for about a decade, but off-farm migration resumed during the "farm crisis" of the early 1980s.

Higher levels of unemployment are expected to detract potential migrants from leaving agriculture. However, the migration of farm operators increases in periods of high unemployment, holding all else constant. This unexpected result comes from high levels of both operator migration and unemployment rates in 1943. When this association is purged from the regression by excluding all periods before 1944, no relationship remains between the unemployment rate and the migration of farm operators.

Conclusions and Policy Implications

Economic growth has resulted in increasing nonfarm labor returns over the past several decades. Technological growth and rising nonfarm labor returns have been associated with decreasing agricultural employment; this is evidenced by the enormous decrease in the number of agricultural workers since 1940.

Agricultural policies have manipulated output prices in the attempt to mitigate the adverse effects of technological change on the farm sector. Output price increases result in a rightward shift in the demand curve for agricultural labor. While this strategy may partially offset the impact of technological change in the short run, the historical pattern of labor migration out of agriculture indicates that these policies have not raised output prices high enough to bring farm returns in line with nonfarm labor returns over the long run.

Farm labor is found to be mobile. Mobility is measured by the relatively high elasticities of annual changes in farm employment to changes in the relative returns to farm labor. Given a high degree of mobility, policies that attempt to raise farm income through price supports or direct payments are likely to result in lower levels of migration out of agriculture. While government payments did not influence changes in agricultural employment directly, an indirect impact may have occurred through increased land values. Land value appreciation slows the rate of labor migration out of production agriculture.

Price supports are included in the measure of relative labor return, and to the degree that value added in agriculture is increased by government programs, farm policy may have affected migration decisions over the course of this study. Macroeconomic conditions, as measured by the unemployment rate, were not associated with off-farm migration. However, the relative size of the labor force did influence off-farm migration.

This study has provided empirical evidence that (*a*) farm labor responds to economic conditions in the short run, and (*b*) the value of farmland, as a proxy for returns to resources in agriculture, is associated with the decision to migrate out of the agricultural sector. Technological change results in a leftward shift in the demand for agricultural labor. This causes either fewer workers in agriculture or lower returns to agricultural labor, or both. The responsiveness of labor to changes in labor returns determines which of these outcomes will ensue. If labor is responsive (elastic) to labor returns, then a shift in the demand for labor will manifest itself as a change in the level of agricultural employment.

The major implication of the estimated responsiveness of agricultural employment with respect to intersectoral returns is that policies intended to increase farm income through price and income support will affect both the level of farm employment and the level of farm income. For this reason, policy makers and analysts have and will experience difficulty in assessing the quantitative impact of farm policies on changes in agricultural employment and changes in farm income.

A Nonparametric Approach to Expenditure-Constrained Profit Maximization

Rolf Färe, Shawna Grosskopf, and Hyunok Lee

A nonparametric approach to expenditure-constrained profit maximization is developed. A deterministic frontier profit function is constructed with and without expenditure constraints. Foregone profit is used as dual evidence for the existence of expenditure constraints. Individual evaluations on performance and expenditure constraints are produced. Empirical analysis is based on survey data for California rice farms. Seventeen of the eighty-two surveyed farms experience profit loss as a result of expenditure constraints.

Key words: expenditure constraint, frontier technology, nonparametric approach, profit maximization.

Recently Lee and Chambers (1986) developed a short-run expenditure constrained theory of profit maximization.[1] Their theory extends the work by Shephard on indirect production theory, and it has a natural place in the analysis of credit constraints. Such constraints occur frequently in agricultural production.

In this paper we introduce a nonparametric alternative to the Lee and Chambers model and apply it to a cross section of eighty-two California rice farms. Lee and Chambers derived a parametrically testable hypothesis of expenditure constraints using a dual framework. In our nonparametric approach, constrained and unconstrained profit frontiers are constructed, and foregone profit is evaluated as dual evidence for the existence of expenditure constraints. Specifically, a deterministic frontier profit function is constructed with and without expenditure constraints using a programming approach. In spirit, this nonparametric method is closely related to that of Farrell.[2] Hence, the important distinction between our model and the Lee and Chambers model arises from the fact that our model does not presume the optimality (constrained or unconstrained) of the observed data points. Because the effectiveness of expenditure constraints is evaluated in our approach at the frontier, any inefficiency other than that resulting from binding expenditure constraints can be readily identified and isolated from effects of expenditure constraints.

Like the Lee and Chambers approach, we can model a multiple output, multiple input technology without constructing indexes; in contrast to their approach, the approach used here imposes no prespecified functional form on the data, reducing specification error. The Lee and Chambers approach was used to determine whether farms faced binding expenditure constraints at the aggregate level; the approach here yields information on the microlevel as to the expenditure constraint hypothesis. In contrast to Lee and Chambers, technology is modeled in a frontier framework, which as a byproduct yields

For an overview of various extensions of the original Farrell efficiency measures, see Färe, Grosskopf, and Lovell. An alternative approach which also uses linear programming techniques; but specifies a parametric model is due to Aigner and Chu. For an overview of parametric and nonparametric approaches to efficiency measurement (including stochastic approaches), see Lovell and Schmidt.

information on the performance of individual observations.

The Nonparametric Models

Our model is specified as a series of linear programming problems which, like the nonparametric efficiency measures to which they are related, produce individual measures of performance. These allow us to identify whether an individual farm faces binding expenditure constraints and the associated loss in profits resulting from that constraint. In addition, this method yields a measure of profits lost from deviations from profit-maximizing behavior unrelated to credit constraints.

Suppose there are $k = 1, \ldots, K$ observations of inputs x^k, where $x^k = (x_1^k, \ldots, x_n^k, \ldots, x_N^k) \in R_+^N$ and outputs $u^k = (u_1^k, \ldots, u_m^k, \ldots, u_M^k) \in R_+^M$. These observations may be for the same farm over K periods or K farms in the same period or panel. A nonparametric frontier technology formed by the observations may be written as the boundary of[3]

$$(1)\quad T = \left\{ (x, u) : \sum_{k=1}^{K} z^k u_m^k \geq u_m, \quad m = 1, \ldots, M \quad \sum_{k=1}^{K} z^k x_n^k \leq x_n, \quad n = 1, \ldots, N, \quad z \in R_+^K, \quad \sum_{k=1}^{K} z^k = 1 \right\},$$

where inputs x and outputs u are defined as above, $z = (z^1, \ldots, z^k, \ldots, z^K)$, and z^k is the intensity variable for activity k. The z variables serve to form convex combinations of the observed input and output data, which is perhaps best understood with the aid of a diagram.

In figure 1, three observations of (x, u) are labeled A, B, and C. Because the intensity (z) variables sum to one, the constraints in (1) form convex combinations of the three observed points. The inequalities in the constraints yield vertical and horizontal extensions of the original points

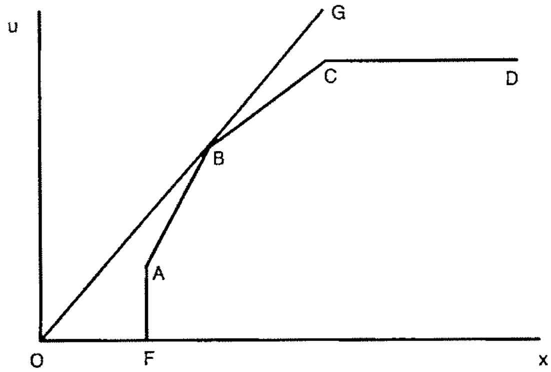

Figure 1. Frontier technology (variable and constant returns)

and their convex combinations, which allow for strong disposability of inputs and outputs.[4] The technology (1) formed by these observations is bounded by the line segments FA, AB, BC, CD, and the x-axis starting at point F.

Note that (1) allows for increasing, constant, and decreasing returns to scale. Segment AB of the technology exhibits increasing returns to scale, whereas segment BC exhibits decreasing returns to scale. If the true technology exhibits constant returns to scale, however, the restriction $\Sigma_{k=1}^{K} z^k = 1$, should be dropped. In figure 1, the new frontier technology is then bounded by OBG and the x-axis. Therefore, in the case of the variable returns-to-scale technology, point B exhibits constant returns to scale. (1) is often termed an inner approximation to the true technology, where z is the vector of intensities that shows to what extent a particular activity is employed in the production process.

To formalize the nonparametric alternative to the Lee and Chambers model, suppose that inputs can be partitioned into fixed inputs x_f and variable inputs x_v, so that each input vector $k = 1, \ldots, K$ can be written as $x^k = (x_v^k, x_f^k)$, where $x_v^k = (x_{v_1}^k, \ldots, x_{v_i}^k, \ldots, x_{v_l}^k)$ and $x_f^k = (x_{f_{l+1}}^k, \ldots, x_{f_N}^k)$. Denote output prices by $r = (r_1, \ldots, r_M) \in R_+^M$ and denote by $P_v = (P_{v_1}, \ldots, P_{v_i}, \ldots, P_{v_l})$ the price vector of variable inputs. All farms are assumed to face the same input and output prices for each output and input; therefore the k superscript is dropped for these price vectors. Short-run profit for farm k can be calculated as the solution to the linear programming problem:

[3] This technology is less restrictive than the original Farrell formulation which imposed constant returns to scale and allowed for only scaler output. Generalizations of the original Farrell piecewise linear reference technology are due to Farrell and Fieldhouse, Shephard, and Afriat, among others. A related literature provides nonparametric tests of regularity conditions in production using programming techniques, see, for example Afriat, Hanoch and Rothschild, Diewert and Parkan, and Varian for examples of this approach.

[4] (1) satisfies free disposability of inputs, i.e., if $(x, u) \in T$ and $y \geq x$, then $(y, u) \in T$, and free disposability of outputs, i.e., if $(x, u) \in T$ and $v \leq u$, then $(x, v) \in T$.

$$\text{(2)} \quad \pi_s(r, P_v, x_f^k) = \max_{u_m, x_v, z} \sum_{m=1}^{M} r_m u_m - \sum_{i=1}^{I} P_{v_i} x_{v_i}$$

s.t.

$$\sum_{k=1}^{K} z^k u_m^k \geq u_m, \quad m = 1, \ldots, M,$$

$$\sum_{k=1}^{K} z^k x_{v_i}^k \leq x_{v_i}, \quad i = 1, \ldots, I,$$

$$\sum_{k=1}^{K} z^k x_{f_i}^k \leq x_{f_i}^k, \; i = I+1, \ldots, N,$$

$$\sum_{k=1}^{K} z^k = 1, \quad z \in R_+^K.$$

In order to illustrate the programming problem in (2), consider figure 2. Suppose three observations of inputs and output are labeled A', B', and C'. The hyperplane spanned by the variable input prices and output prices is denoted by HH'. The solution to (2) is attained at C' in figure 2 (for the moment ignore EE').

Two comments on the linear programming problem (2) are in order. First, there are no constraints on the choice of the variable inputs x_v and the outputs u except the technology. Thus, this problem yields the maximal short-run profit for each observation. Second, if all inputs are variable, i.e., if $I = N$, then (2) becomes a long-run profit-maximization problem.

One of the contributions of the Lee and Chambers paper is the introduction of an expenditure constraint on the subvector of the farm's variable inputs. To introduce that type of constraint into our model, let maximum allowable expenditure be denoted as E. The corresponding

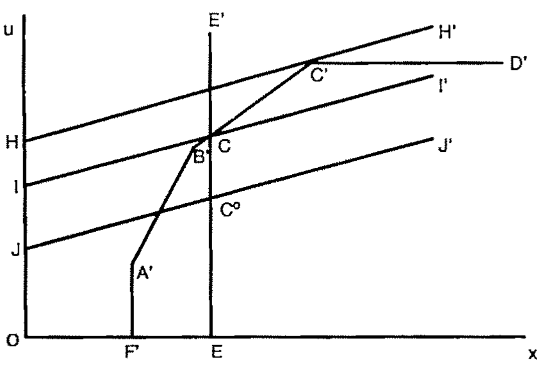

Figure 2. Expenditure-constrained profit maximization

expenditure constraint for observation k can be written as

$$\text{(3)} \qquad P_{v_1} x_{v_1}^k + \ldots + P_{v_I} x_{v_I}^k \leq E^k.$$

This constraint is illustrated in figure 2 by the area between the vertical line EE' and the output axis. From the figure it is evident that the expenditure constraint could lower profit relative to the "unconstrained" profit from (2): because the farm must choose a point like C (C' is no longer feasible), profits fall from OH to OI. Thus, if farms face binding expenditure constraints they will be losing profits.

To compute the loss in profits from the expenditure constraint, profit with the expenditure constraint (3) must be calculated. The k superscript will be dropped because the variable inputs x_v are choice variables.[5] Specifically, for farm k, expenditure constrained profit is calculated as the solution to

$$\text{(4)} \quad \pi(r, P_v, x_f^k, E^k) = \max_{u_m, x_v, z} \sum_{m=1}^{M} r_m u_m - \sum_{i=1}^{I} P_{v_i} x_{v_i}$$

s.t.

$$\sum_{k=1}^{K} z_x u_m^k \geq u_m, \quad m = 1, \ldots, M,$$

$$\sum_{k=1}^{K} z^k x_{v_i}^k \leq x_{v_i}, \quad i = 1, \ldots, I,$$

$$\sum_{k=1}^{K} z^k x_{f_i}^k \leq x_{f_i}^k, \quad i = I+1, \ldots, N,$$

$$\sum_{i=1}^{I} P_{v_i} x_{v_i} \leq E^k,$$

$$\sum_{k=1}^{K} z^k = 1, \quad z \in R_+^K.$$

A comparison of (4) and (2) shows that $\pi_s(r, P_v, x_f^k) \geq \pi(r, P_v, x_f^k, E^k)$, thus profit loss resulting from the expenditure constraint, which we call financial efficiency, can be defined as

$$\text{(5)} \qquad F^k = \pi(r, P_v, x_f^k, E^k)/\pi_s(r, P_v, x_f^k),$$

where F^k is less than or equal to one, with $F^k = 1$ if the expenditure constraint is not binding.

[5] As a practical matter the maximum allowable expenditure is calculated as observed expenditure on variable inputs, i.e., $\sum_{i=1}^{I} P_{v_i} x_{v_i}^k$ is used as a proxy for E^k.

The computation of F^k requires data on inputs, outputs, variable input prices, output prices, and expenditure. Unfortunately, the data set does not include information on quantities of inputs and outputs; rather, it includes information in value terms. Specifically, information is available on revenues, costs, and variable input expenditure. Thus, the model introduced above must be modified. We follow the basic model developed by Färe and Grosskopf.

Define the revenue associated with output m as $R_m = r_m u_m$ and the cost of variable input v_i as $C_{v_i} = P_{v_i} x_{v_i}$, and similarly for fixed inputs. The data now consist of $k = 1, \ldots, K$ observations of $R^k = (R_1^k, \ldots, R_m^k, \ldots, R_M^k)$, $C_v^k = (C_{v_1}^k, \ldots, C_{v_i}^k, \ldots, C_{v_I}^k)$, and $C_f^k = (C_{f_{I+1}}^k, \ldots, C_{f_N}^k)$. Assume that all of the farms in the sample face the same input and output prices.[6] Under this assumption, the short-run profit-maximization problem from (2) becomes

$$(6) \qquad \pi_s(C_f^k) = \max_{R_m, C_v, z} \sum_{m=1}^{M} R_m - \sum_{i=1}^{I} C_{v_i},$$

s.t.

$$\sum_{k=1}^{K} z^k R_m^k \geq R_m, \quad m = 1, \ldots, M,$$

$$\sum_{k=1}^{K} z^k C_{v_i}^k \leq C_{v_i}, \quad i = 1, \ldots, I,$$

$$\sum_{k=1}^{K} z^k C_{f_i}^k \leq C_{f_i}^k, \quad i = I+1, \ldots, N,$$

$$\sum_{k=1}^{K} z^k = 1, \quad z \in R_+^K.$$

In this modified problem, the nonparametric frontier technology is constructed from observed revenues R_m^k and observed costs $C^k = (C_v^k, C_f^k)$ rather than observed output and input quantities. To show that the two models (2) and (6) yield the same maximum under these assumptions, it is sufficient to compare their respective first constraints. From (2),

$$(7) \qquad \sum_{k=1}^{K} z^k u_m^k \geq u_m, \quad m = 1, \ldots, M.$$

The assumption that each farm faces the same prices is used to obtain

$$(8) \qquad r_m \left(\sum_{k=1}^{K} z^k u_m^k \right) \geq r_m u_m = R_m,$$

$$\sum_{k=1}^{K} z^k (r_m u_m^k) \geq R_m,$$

$$\sum_{k=1}^{K} z^k R_m^k \geq R_m.$$

This expression shows that the first constraint of problem (2) is equivalent to the same constraint of problem (6); because similar arguments can be made to show the equivalence of the rest of the constraints in each problem, we may conclude that $\pi_s(r, P_v, x_f^k) = \pi_s(C_f^k)$, given identical firm-level prices.

Following the procedure outlined above, the expenditure-constrained profit-maximization problem from (4) can be reformulated into value terms

$$(9) \qquad \pi(C_f^k, E^k) = \max_{R_m, C_v, z} \sum_{m=1}^{M} R_m - \sum_{i=1}^{I} C_{v_i}$$

s.t.

$$\sum_{k=1}^{K} z^k R_m^k \geq R_m, \quad m = 1, \ldots, M,$$

$$\sum_{k=1}^{K} z^k C_{v_i}^k \leq C_{v_i}, \quad i = 1, \ldots, I,$$

$$\sum_{k=1}^{K} z^k C_{f_i}^k \leq C_{f_i}^k, \quad i = I+1, \ldots, N,$$

$$\sum_{i=1}^{I} C_{v_i} \leq E^k,$$

$$\sum_{k=1}^{K} z^k = 1, \quad z \in R_+^K.$$

The solutions to problems (6) and (9) can be compared to obtain a measure of profit lost because of the expenditure constraint, i.e., financial efficiency,

$$(10) \qquad F^k = \pi(C_f^k, E^k) / \pi_s(C_f^k).$$

Note that $\pi(C_f^k, E^k) = \pi(r, P_v, x_f^k, E^k)$ by arguments similar to those used to prove that $\pi_s(C_f^k) = \pi_s(r, P_v, x_f^k)$. Therefore, (5) and (10) yield the same value.

Recall that the expenditure-constrained profit function is defined at the frontier technology, as

---

[6] Because expenditure data are employed under this assumption, the results should be interpreted with care. For example, if pecuniary externalities exist, the results will be biased.

is clear from (4). By introducing observed profit, π^k, $k = 1, \ldots, K$, an alternative measure of performance can be obtained by comparing the values of π^k and $\pi(C_f^k, E^k)$. Thus the actual efficiency measure denoted by A^k is defined as the ratio of actual profit to expenditure-constrained profit,

$$(11) \qquad A^k = \pi^k / \pi(C_f^k, E^k).$$

By the definition of $\pi(C_f^k, E^k)$, π^k can be at most equal to $\pi(C_f^k, E^k)$, implying that A^k is always less than or equal to one in value. When farm k is actual efficient, its observed profit will equal (maximal potential) expenditure-constrained profit, i.e., $A^k = 1$. If the farm is actual inefficient, $A^k < 1$. A^k is named "actual efficiency" because $A^k = 1$ is always achievable with existing fixed inputs and the actual level of expenditure if firm k operates efficiently. Deviation of A^k from the unit value can be interpreted as a measure of profit loss by farm k as a result of actual inefficiency evaluated at the actual expenditure level.

We have examined profit loss resulting from the expenditure constraint (financial inefficiency) and profit loss caused by failure to achieve maximal potential profit given actual expenditure levels (actual inefficiency). It is intuitively clear that these two mutually exclusive measures together comprise an overall (financial and actual) efficiency measure, which can be obtained by comparing actual profit and unconstrained, maximal potential short-run profit. The overall efficiency measure denoted by O^k is defined as

$$(12) \qquad O^k = \pi^k / \pi_s(C_f^k),$$

or equivalently,

$$(13) \qquad O^k = A^k \cdot F^k.$$

Overall efficiency is decomposed into actual efficiency and financial efficiency and is expressed as the product of these two efficiency measures. This is illustrated in figure 2. A firm operating at point C^0 with observed profits OJ would have overall efficiency of OJ/OH, where C' represents optimal choice when the firm is not expenditure constrained. Financial efficiency is measured for this firm as OI/OH, where OI is the maximum achievable profit given the expenditure constraint, EE'. Actual efficiency is equal to OJ/OI, the ratio of actual to maximal expenditure constrained profit. The decomposition is confirmed since $OJ/OH = (OJ/OI)(OI/OH)$.

The decomposition above is in the spirit of the original Farrell decomposition of overall efficiency (the ratio of observed to minimal costs) into technical (price unrelated) and allocative (price related) components. It differs, however, in several ways. First, because explicit price data are not available, price related inefficiency cannot be isolated (it is effectively assumed that there is no price-related inefficiency). Second, the framework is short run: inputs are partitioned into fixed and variable inputs, where only variable inputs are choice variables. Third, performance is evaluated with respect to (variable) inputs and outputs simultaneously, whereas Farrell's original measures take output as given and effectively calculate maximum proportional feasible reductions in inputs (and associated costs).[7] Put differently, performance is measured relative to short-run profits rather than costs (or revenues). If, however, a farm is found overall efficient here, it would be maximizing revenue (given inputs and output prices) and also minimizing short-run costs (given outputs and input prices).

Data and Results

The models developed in the previous section are applied to a sample of California rice farms. These data were obtained from the 1984 national special crop survey conducted over U.S. rice producers by the U.S. Department of Agriculture. Although the original survey was conducted at a national level, this study concentrates on the California region for which the survey contains information on eighty-two individual rice-producing farms. Concentrating on one region reduces the wide variation in characteristics of rice farming at the national level. Our method presupposes that the same technology is available to all farms; thus, differences in production methods might appear as inefficiency. Because rice production techniques are fairly homogenous within the California region, this potential source of bias should be ameliorated. Focus on one region should also reduce price variation, an important consideration given our assumption that all farms face the same prices. Again, this assumption could lead to bias if pecuniary externalities exist.

[7] Under constant returns to scale, Farrell's original measures are equivalent to taking inputs as given and maximizing outputs (and revenues) (see Färe, Grosskopf, and Lovell).

Because the primary purpose of the survey was to obtain information on costs and returns in rice production, the data on individual farms are largely in value terms rather than quantities, although these values are available at a very disaggregated level. To arrive at the variable and fixed input proxy variables, the data from the survey were aggregated into three (quasi-) fixed and six variable input cost categories.

The six variable input costs included (*a*) materials, which included expenditures on fertilizer, pesticides, and custom operations;[8] (*b*) energy, which included expenditures on fuel, oil, and electricity; (*c*) leased farm equipment expenditures; (*d*) marketing services, which included transportation expenditures; (*e*) labor; and (*f*) purchased water. The proxy of E^k was calculated as the sum of these six expenditure categories for each observation. The three (quasi-) fixed input variables included (*a*) acres of land; (*b*) capital equipment in dollar value; and (*c*) overhead expenses, which included accounting fees, legal fees, insurance, taxes, and interest.

Rice farmers also produce other crops, although the survey indicated that only wheat was produced by these farmers at a significant level. Only twenty-one of the eighty-two farms produced wheat, with average revenues of $100,751. As a result, both wheat and rice revenues were included as output proxies. To compute revenues, the output measures net of seed planted were multiplied by the harvest-month price for medium- and short-grain rice and by the three-month average of winter wheat prices. Descriptive statistics of the variables are collected in table 1.

Short-run expenditure constrained profit (9) and short-run unconstrained profit (6) were calculated for each of the eighty-two farms. This involved running these two linear programming problems for each farm. The loss in profit caused by expenditure constraints was calculated as the ratio of constrained to unconstrained profit [see (10)]. The results indicate that seventeen of the eighty-two farms faced binding expenditure constraints, i.e., F^k from (10) was less than unity. The average loss for those seventeen farms was about 8% of unconstrained profits (see table 2).

Decomposition results indicate that only thirteen out of eighty-two farms are actual efficient, while sixty-five farms are financially efficient. All actual efficient farms except one exhibit financial efficiency. This fact suggests that actual efficient farms are also financially efficient (that is they are overall efficient), but financially efficient farms are not necessarily actual efficient. This observation is consistent with out intuition that, given fixed inputs, to achieve overall efficiency financial conditions must a priori allow farmers to purchase desired levels of variable inputs. However, when actual efficiency is evaluated across expenditure-constrained versus unconstrained farms, financially constrained farms perform better on average than financially unconstrained farms. An explanation for this ap-

[8] This category consisted largely of custom-hired applications of chemicals.

Table 1. California Rice Farms: 1984 Descriptive Statistics

Variable	Mean[a]	Standard Deviation
Revenues	311574.72	378545.56
Materials	85815.79	125914.60
Energy	24908.35	30310.98
Equipment	6472.65	19144.07
Marketing	28555.37	43704.82
Labor	122844.97	158193.35
Water	19093.04	32651.78
Land	511.73	661.41
Capital	284416.05	329480.66
Overhead	110133.66	236185.98

Note: Sample size: 82.
[a] All categories except land are measured in 1984 dollars, and land is measured in acres.

Table 2. Decomposition Results: Means and Frequencies

Measure	Expenditure-Constrained Farms (17 farms)	Expenditure-Unconstrained Farms (65 farms)
Actual efficiency (A^k)	0.481 (0.331)[a]	0.416 (0.390)
Number of actually efficient farms ($A^k = 1$)	1	12
Financial efficiency (F^k)	0.921 (0.128)	1.000 (0.000)
Number of financially efficient farms ($F^k = 1$)	0	65
Overall efficiency (O^k)	0.453 (0.312)	0.416 (0.390)
Number of overall efficient farms ($O^k = 1$)	0	12

[a] Numbers in parentheses are standard deviations.

parent anomaly may come from the relatively high level of quasi-fixed inputs used by the unconstrained farms. The data show that constrained farms spent on average 30% less on capital, 47% less on overhead, and had 46% less land than financially unconstrained farms. If excess capacity with respect to fixed inputs occurs for the observation period of this study, that excess capacity would more likely occur with financially unconstrained farms and could account for their comparative inefficiency.

In contrast to Lee and Chambers, the restriction that constant returns to scale prevail was not imposed. In order to determine the effect of this specification on the degree to which expenditure constraints would be binding, we recalculated the constrained and unconstrained profit-maximization problems (9) and (6) without the constraint that the intensity variables sum to unity. As mentioned earlier, dropping that restriction imposes constant returns to scale on the technology. The resulting loss in profits from expenditure constraints was similar to the variable returns case suggesting that these rice farms are relatively scale efficient.[9]

Next, we summarize additional information concerning the results on optimal variable input usage. In the single input case, input use under a binding constraint cannot be greater than the input use under no constraint. However, with more than one input, some inputs could be used more intensively with lower expenditure. Thus, examining the optimal use of variable inputs at different expenditure levels should yield insight into the underlying technology. To do so, we first select out the expenditure-constrained farms from the sample. Then the ratio of optimal variable input usage with and without expenditure constraint is calculated to compare input use between the two expenditure levels. If the resulting ratio is less than unity, then optimal expenditure constrained input usage is less than unconstrained optimal input usage and vice versa. Table 3 summarizes these results.

The results from table 3 suggest that the optimal response by farms facing binding expenditure constraints would in general be to underutilize all of their variable inputs relative to the unconstrained optimal utilization, except for marketing, which optimally would be increased relative to unconstrained levels. The most dramatic underutilization rates are for equipment

Table 3. Analysis of Constrained Farms

Variable	Mean	St. Dev.
Ratio of optimal input use with and without constraint:		
F^*	0.92	0.13
Materials	0.73	0.18
Energy	0.75	0.23
Equipment	0.32	0.33
Marketing	1.32	0.51
Labor	0.73	0.26
Water	0.86	0.21
Ratio of constrained (observed) to unconstrained expenditure:		
$E^*/E(C_f^*)$	0.78	0.18

(on average constrained rates are roughly 30% of unconstrained optimal rates). Because the equipment variable is restricted to leased equipment, this suggests that rice farmers could substitute owned equipment when faced with credit constraints. Because credit is tied to cash flow, farmers are less likely to reduce expenditures on seed, for example, than equipment. The fact that optimal expenditure on marketing is greater when farms are credit constrained is less intuitive.

These observations suggest a need to consider the validity of the model (McCarl, Gass). A possible explanation is that the variables included do not account for all farm-specific characteristics. Unlike other inputs, marketing may be especially affected by farm-specific factors (distance to market, storage capacity, etc.) which, if not accounted for, may cause systematic bias in the results.[10] One way to test model validation is to examine the dual of the problem proposed in this study (McCarl). In other words, redefine the maximization problem as its associated dual minimization problem to check for consistency of the shadow prices and programming solutions. Nevertheless, recognizing that no model reflects all of perceived reality, the nonparametric models are subject to relatively less specification error than parametric models.

Concluding Comments

In this paper we have introduced a nonparametric alternative to the expenditure (credit) constrained model of profit maximization of Lee

[9] See Färe and Grosskopf for a discussion of scale efficiency. Detailed information concerning the disaggregated results are available upon request from the authors.

[10] Because this information is not available, one way to circumvent this problem may be to use variable input expenditure excluding marketing expenses and to use the revenue figure net of marketing expenses.

and Chambers. Among pros and cons of each approach, lack of statistical properties of the current approach is offset by the ability to evaluate whether expenditure constraints are binding for individual observations.[11] Moreover, frontier specification of the profit function also produces useful byproducts, namely, observation-specific information on performance (losses in profits) caused by expenditure constraints as well as inefficiency unrelated to credit constraints.

When expenditure constraints were evaluated for individual farms, seventeen of the eighty-two California rice farms in the sample were losing profit because of expenditure constraints. The average profit loss of the expenditure-constrained farms was roughly 8% of their unconstrained profit. Given the fact that California rice farms operate on a relatively large scale, farmers in this region may have relatively easy access to credit. In light of this, further research on other rice-producing regions may provide more insight in analyzing this issue.

The findings on expenditure constraints should be interpreted with some caution. As the *Journal* editor has pointed out, there likely are other maintained behavioral hypotheses which are not incorporated here, most importantly, risk behavior. What appear to be binding expenditure constraints could reflect the prudent use of credit to limit the odds of bankruptcy should an unexpected downturn occur. Finally, the fact that constrained farms were on average more actual efficient than unconstrained farms merits further analysis, perhaps with respect to risk as suggested above.

[11] Other advantages/disadvantages are: the parametric model estimated by Lee and Chambers is differentiable, allowing for identification of substitution possibilities, etc., and is readily estimated using aggregate time-series data but is susceptible to measurement error if the parametric form does not reflect the underlying structure of technology.

Improving on Shadow Price Information for Identifying Critical Farm Machinery

Bruce A. McCarl, D. Earl Kline, and Donald A. Bender

A method is presented for identifying critical farm machinery in a linear programming context. The method uses a technical coefficient sensitivity analysis formula that overcomes problems associated with direct use of shadow prices for critical machinery identification. Case studies show the formula identifies the benefits of altering machinery generally with less than 10% error.

Key words: farm machinery, linear programming, sensitivity analysis, shadow price, technical coefficients.

Identification of critical farm machinery bottlenecks (hereafter called critical machinery) and subsequent investigation of the net benefits obtained by adding or replacing machines is a common extension application of linear programming (McCarl et al.; Doster et al.; Krutz, Combs, and Parsons: Debertin et al.). Shadow prices play a key role in this application (Doster et al.; Krutz, Combs, and Parsons). However, shadow prices are not directly applicable because they are (*a*) indicators of the marginal effect of altering a single right-hand side, while machinery changes can alter multiple technical coefficients across multiple rows; (*b*) applicable for only a limited range of alteration; and (*c*) potentially misleading when degeneracy occurs (McCarl 1977; Paris; Gal, Kruse, and Zornig).

Fortunately, a formula which predicts the consequences of changing multiple technical coefficients is available (Mills, Freund). However, this formula is applicable to infinitesimal changes only. Further, it has not been widely applied or tested for empirical accuracy for large changes. The purposes of this article are to review the technical coefficient sensitivity analysis formula, apply this formula to machinery analysis, and report on formula reliability.

An Illustration: The Effect of Machinery Alteration

Consider a simple two-crop farm where each crop requires land preparation, planting, and harvesting. Suppose the cropping season is divided into three time periods. Both land preparation and planting can occur in the first two time periods, with land preparation preceding planting. Harvesting occurs only in the third time period. A potential linear programming (LP) formulation of this case is shown in table 1.[1] (see also table 2.) The constraints restrict the availability of land and labor in three periods, land preparation time in two periods, planting time in two planting periods, and harvest time in the harvest period. The variables reflect three timing sequences for each crop. That is, (*a*) land preparation in period 1 (*Prep*1) then planting in period 1 (*Plant*1); (*b*) land preparation in period 1 then planting in period 2; and/or (*c*) land preparation in period 2 then planting in period 2. The model also includes constraints which balance crop production and input usage with variables which depict crop sale and input purchase.

This formulation contains several simplifying assumptions regarding machinery. First, one hour

Note: The variables and parameters used in this model are defined in table 2.

Table 2. Summary of Nomenclature in Table 1

Variable	Description
W_i	Number of units of crop i sold
X_{ij}	Acres of crop i grown according to land preparation and planting combination j where: $j = 1$ for land preparation in period 1 and planting in period 1; $j = 2$ for land preparation in period 1 and planting in period 2; $j = 3$ for land preparation in period 2 and planting in period 2
Z	Number of dollars worth of miscellaneous inputs purchased

Parameters	Description
a_{ik}	Use of time (hours/acre) when doing operation k on crop i where: $k = 1$ depicts land preparation; $k = 2$ depicts planting; $k = 3$ depicts harvesting
d_i	Unit variable cost for growing one acre of crop i
s_i	Laborers required to harvest crop i for one hour
m	Laborers employed
n	Land available (acres)
p_i	Price of one unit of the output from crop i
t_j	Hours available in period j
y_{ij}	Yield of crop i when planted in period j

of labor is used per hour of nonharvesting machinery operation. Second, the working rates are independent of time period. Third, the working rates depend on the crop. Fourth, all jobs on the farm are combined into the preparation, planting, and harvesting categories, and all jobs within each of these categories are assumed to be done within a period for any acre.

To illustrate how changes in machinery affect the LP tableau, suppose the land preparation equipment complement is altered and the working rate changes. In turn, one would alter a_{11} and a_{21}, and twelve coefficients in the model would change. However, none of these would be right-hand sides (i.e., the items fundamentally associated with shadow prices). Further, the affected rows involve both land preparation and labor.

Machinery Alteration Value Estimation Using Shadow Prices

Traditionally, shadow prices are used to identify critical machinery in terms of those machines having the largest shadow prices (Krutz, Combs, and Parsons). In the LP model shown in table 1, high shadow prices on preparation time would signal the desirability of larger preparation equipment.

Consider the implications of an increase in the land preparation working rate where the hours spent per acre (a_{11} and a_{21}) are reduced by 20%. An estimate of the objective function consequences of this alteration involves the optimal solution variable values (x^*) as well as shadow prices from the preparation and labor rows. The value of the altering preparation working rate is the shadow prices on the two land preparation rows times by 20% of the right-hand side summed across the preparation rows.[2] In addition, the value of the labor alteration is found by multiplying the decrease in labor use (for period 1 this equals $a_{11}\, x_{11}^* + a_{11}\, x_{12}^* + a_{21}\, x_{21}^* + a_{21}\, x_{22}^*$ times 20%) times the shadow price. In general, this procedure involves (*a*) identification of the rows with altered resource usage by working rate changes (denote these as g such that some a_{gj}'s are altered); (*b*) computation of the change in resource use by the affected machinery in those rows ($\Sigma_j\, \Delta a_{gj} x_j^*$ where x_j^* is the optimal value of the jth variable and Δa_{gj} is the change in a_{gj}); and (*c*) valuing the working rate alteration by multiplying the sum from each affected row by its shadow price (u_g^*) and summing ($\Sigma_g\, u_g^*\, \Sigma_j\, \Delta a_{gj} x_j^*$).

Theoretical Justification

The preceding section gives an inferential process for computing the value of a machine working rate change. However, is this procedure accurate? The accuracy of such a procedure can be evaluated from both theoretical and empirical standpoints.

From a theoretical standpoint, this procedure is an application of a method developed by Mills in the early 1950s (Freund). This method starts from the linear programming model:

$$\text{(1)} \qquad \text{Maximize } Z = CX \quad AX \le B \quad X \ge 0,$$

[2] This assumes the model contains a row $ax = b$ which is altered so that $(.8)ax = b$. This implies the constraint will have $0.2b$ in extra resources. Thus, one can estimate the consequence by valuing a 20% increment in b. One could also take into account the reduction in a, but this is not consistent with Mills' formula.

which yields X^* as a column vector containing the optimal primal variable solution and U^* as a row vector containing the optimal shadow price solution. Now, suppose the A matrix is changed as follows:

$$A_{new} = A + \Delta A,$$

where A_{new} is the technical coefficient matrix after alteration and ΔA gives the technical coefficient changes. Mills' formula predicts that the consequent alteration in the optimal objective function for an infinitesimal ΔA is

$$(2) \qquad \Delta Z = -U^*\Delta AX^*.$$

This formula reflects multiplication of the vector of optimal shadow prices from the original model (U^*) times the matrix of anticipated changes in the A matrix (ΔA) times the vector of optimal variable values (X^*) to estimate the change in the objective function value.[3] This procedure parallels the inferential process outlined previously and may be explained in two parts. First, consider the part of the formula that involves the change in the A matrix (ΔA) times the optimal decision vector (X^*).

$$(3) \qquad \Delta R = -\Delta AX^* \text{ or } \Delta R_g = -\sum_j \Delta a_{gj}x_j^*.$$

The term ΔR is the anticipated savings in resource usage; it equals the sum of per unit resource usage change (ΔA) times the number of units of the decision variables (X^*) employed. For example, if one hundred acres ($X^* = 100$) are planted and a tenth of an hour ($\Delta A = -0.1$) is saved per acre, then one would anticipate saving ten hours in total ($\Delta R = 10$).

The change in the objective function is estimated by valuing the anticipated resource usage changes (ΔR) using the corresponding shadow prices:

$$(4) \qquad \Delta Z = -U^*\Delta R \text{ or } \Delta Z = -\sum_g U_g^*\Delta R_g = -\sum_g U_g^* \sum_j \Delta a_{gj}x_j^*.$$

Further, one may include the effect of any changes in the objective function coefficients by adding the term ΔCX^*, where ΔC is the vector of changes in the objective function. Thus, the final formula for estimation of the expected consequences of a change in the technical and objective function coefficients is

$$(6) \qquad \Delta Z = -U^*\Delta R - \Delta CX^* = -U^*\Delta AX^* - \Delta CX^*.$$

Thus, if ten hours are to be saved at a shadow price of \$5 per hour, then \$50 is the estimated value of the machinery change.[4]

This formula provides a method for estimating the effect of machinery alterations. Each machine in an LP model can be investigated to determine the effect of a 1% change in its working rate on the value of the objective function. The resultant information can then be presented along with the normal LP shadow prices. Furthermore, this method allows one to consider component machines within an operation. For example, in Purdue's Top Farmer model (McCarl et al.) or Kentucky's Kash Profits model (Jones, Debertin, and Moore), each machinery operation typically involves four or five different machines. In addition, the formula overcomes some of the shadow price limitations examining simultaneous changes in multiple rows which can overcome degeneracy problems (McCarl 1977).

Empirical Reliability

Before using formula (6) its reliability should be examined. Reliability is an issue because (6) predicts the consequences of infinitesimal ΔA, but machinery changes can cause large changes in A. In turn, changes in A alter the LP basis matrix and can have significant effects on the solution.[5]

Implementation

Formula (6) was included in the REPFARM farm planning package (McCarl 1982) used in the Purdue Top Farmer Extension program. The implementation required several steps: (*a*) the REPFARM input module was modified to identify the machinery used for each cropping operation; (*b*) a report writer module was included which calculates changes in the technical coefficient matrix and the consequent results of (6)

[3] The formula is relevant only for infinitesimal changes in the A matrix because the optimal primal and dual solution vectors are both functions of A.

[4] One could also develop information on the changes in the objective function by calculating the ΔR vector and restarting the LP solver with a parametric programming request.

[5] The basis matrix changes may involve either changes in elements or changes in the columns included. In either case the relationship between ΔA and the change in the objective value is nonlinear.

for user specified changes in the machine working rates; and (c) an additional report was added which contained the results of (6).

Empirical Reliability Testing

Formula reliability was investigated using two Texas case studies, one involving a farm in the High Plains region and the other in the Blacklands region. First, base models for each case were set up and validated. Then, the shadow prices were examined. Subsequently, the value of changes in individual machines were investigated using formula (6). The shadow prices for and results of this process for the second case study appear in tables 3 and 4. The table 3 shadow prices suggest machines in the planting operation and tractors are the likely machinery to change. However, because tractor use is a function of machinery working rates, then nonzero tractor shadow prices suggest that other machines may be desirable to change. Further, because multiple machines are used in the planting operation, then the individual machines to alter must be determined. The results in table 4 show the formula allows identification of machinery items which are implicit in shadow prices for other items (i.e., the baler value was implicit in the tractor shadow prices).

Reliability of the information generated using formula (6) was investigated for four of the higher valued machines in each case study. The working rates for the selected machines were altered individually and jointly between minus 50% and plus 100% in 5% increments as well as from 150% to 400% in 50% increments. The LP was rerun for each alteration. In turn, the predicted objective function value was calculated as follows:

$$Obj_{pred} = Obj_{base} + K^*\Delta Z, \tag{7}$$

where K represents the percentage change in the working rate, ΔZ is the result of (6) for a 1% change in the working rate, and Obj_{base} is the base model objective function value. Next, an actual objective function value (Obj_{act}) was obtained from the LP rerun. Finally, the relative error was computed as

$$\text{Error} = \frac{(Obj_{pred} - Obj_{act})}{Obj_{act}}. \tag{8}$$

Selected results from the two case farm studies are given in table 5. When one machine was changed at a time, the maximum error from the formula arose when the working rate was halved (−50%) and that error averaged 6.2%. When changes in working rates ranged from between −25% to +100%, the errors were less than 3.5%. When two machines were changed simultaneously within the 0% to +100% interval the results show a maximum average error of 2.7% with a maximum error of 7.3%. Simultaneous alterations in three machines resulted in small errors as working rates were increased from +5% to 100%. Largest errors were observed when all four machines were simultaneously changed.

These results suggest that formula (6) accurately predicts the benefits of changes in a set of machines. However, subsequent LP reruns should be conducted to verify machinery alterations selected for implementation. The results also show the formula is more accurate in upsizing versus downsizing situations. Fortunately upsizing is often of interest when identifying critical machinery in an extension context.

Table 3. Machinery Shadow Prices for Blacklands Case

Resource	Period	Value/hr. ($)
Large tractor time	Jun. 29–July 12	100.86
Large tractor time	July 13–July 26	100.86
Large tractor time	July 27–Aug. 9	100.86
Large tractor time	Aug. 10–Aug. 23	100.86
Large tractor time	Aug. 24–Sep. 6	100.86

Note: All errors are the absolute value of the difference between the predicted and actual divided by the actual.
[a] For the Blacklands case, the machines tested are the cultivator, disk, mower conditioner, and planter.
[b] For the High Plaines case, the machines tested are the shredder, planter, rotary hoe, and cultivator.

Concluding Comments

This paper reports on the utilization of Mills' formula for identifying critical machinery. Formula reliability was investigated using case examples. The predictions were generally within 5% of the results of LP runs for working rate increases of up to 100% involving up to four machines simultaneously. Formula performance worsens as more machines are simultaneously changed. This approach enhances the information contained in individual shadow prices making it more relevant to machinery alterations. The information also has been included in an expert system (Kline et al.).

Our experience suggests that this formula would aid evaluation of machinery changes and could easily be incorporated into the report writers of existing models.[6] However, the changes still need to be tested for practical consistency with reruns of the linear program, and machinery cost should be considered before selection decisions are made. Finally, the technical coefficient sensitivity analysis method could be used in other types of linear programming analyses where technical coefficients are altered.

[Received July 1988; final revision received October 1989.]

[6] For example, generating the estimates using the LP model in table 3 would require 12 solutions, but the formula generated the estimates from the basic solution. Similarly, the cases reported in table 5 required more than 300 runs and 24 hours of CPU time on a VAX minicomputer, but the formula generated the predictions from the base run solution data instantaneously.

Nonparametric and Semiparametric Estimation: An Analysis of Multiproduct Returns to Scale

Giancarlo Moschini

The nonparametric and semiparametric regression models based on kernel density estimation are reviewed, and they are applied to the analysis of returns to scale in dairy farms using a multioutput cost function. Semiparametric tests of constant returns to scale and homogeneity of production are developed, and their implementation show that both of these hypotheses are rejected. Kernel estimation of the local degree of multiproduct returns to scale confirms that the sample's dairy farms are characterized by a considerable degree of scale economies.

Key words: cost function, dairy, flexible functional forms, kernel estimation, scale economies, semiparametric regression.

The functional specification of econometric models is a crucial component of applied research in agricultural economics that has been the object of considerable research. Notable is the introduction of flexible functional forms, pioneered by Diewert and by Christensen, Jorgenson, and Lau. This concept (see Barnett for a concise review) centers on the local approximation properties of a Taylor-series expansion of the unknown true function. Gallant and White, however, have exposed a number of statistical drawbacks of these local approximations, which has led to the development of models, such as Gallant's Fourier functional form, that can achieve global properties by the use of nonparametric approximations. This points the way to more general, and somewhat simpler, nonparametric estimation techniques.

The usefulness of nonparametric methods in applied analysis is underscored by Afriat's analysis of the restrictions of consistent choices. This approach has been extended to the analysis of production by Varian and by Chavas and Cox. In this paper, however, the term "nonparametric" applies to the statistical method of density estimation. Using this approach one can estimate the regression function or other functionals of interest without making any parametric assumptions about the true functional form. A parametric form can sometimes be retained for a portion of the model, and this leads to semiparametric specifications that can prove useful in hypothesis testing. Unlike the Afriat-type nonparametric methods, the nonparametric approach based on density estimation that is used in this paper has a solid statistical foundation, which is appealing for empirical applications requiring formal tests of hypotheses.

The nonparametric and semiparametric approaches to econometrics have attracted considerable interest in recent years (two general surveys are Ullah 1988b and Robinson 1988b). The purpose of this paper is to review the kernel method of nonparametric estimation and to apply this method to the analysis of multiproduct returns to scale using a cost function of Ontario dairy farms. Specific attention is devoted to the formulation of tests of interest in semiparametric form. The paper is organized as follows. The kernel density estimator of the regression function is reviewed, including a discussion of implementation procedures, statistical properties, and an introduction to the semiparametric regression. A multioutput cost function model is then presented. Two semiparametric tests are developed: a test of constant returns to scale, and a test of homogeneity of production. Finally, the kernel estimator of partial derivatives is used to obtain a measure of the local degree

The author thanks an anonymous reviewer for helpful comments.

of multiproduct returns to scale in dairy farming.

Nonparametric Estimation

To introduce the nonparametric approach to estimation, consider a simple problem involving two continuous random variables Y and X, and a sample of independent realizations $\{Y_1, X_1; Y_2, X_2; \ldots; Y_N, X_N\}$ from a continuous bivariate distribution function with density $f(y, x)$. The typical problem can be formulated in terms of estimating the expectation of Y conditional on the explanatory variable X, i.e., $E(Y|X) \equiv R(X)$, where $R(X)$ can be interpreted as the regression function that underlies the model:

$$(1) \qquad Y = R(X) + U,$$

where U is an error term satisfying $E(U|X) = 0$ by construction. Usually, $R(X)$ is assumed to have a parametric form, say the linear form $R(X) = \alpha + \beta X$. Given the sample of realizations of the variables Y and X, one can estimate the parameters involved, thereby estimating the conditional expectation $R(X)$. Alternatively, one may note that the conditional expectation of Y given $X = x$ is

$$(2) \qquad E(Y|X = x) = \int_{-\infty}^{\infty} y \frac{f(y, x)}{g(x)} dy,$$

where $g(x) = \int f(y, x)dy$ is the marginal density of X. The nonparametric approach utilizes (2) to estimate $E(Y|X = x) \equiv R(x)$ by approximating the unknown density functions $f(y, x)$ and $g(x)$ given the sample of realizations of the random variables Y and X.

Silverman discusses the use of nonparametric methods for the estimation of density functions. Consider first the estimation of the univariate marginal density $g(x)$ using the sample of independently drawn realizations $X_1, \ldots, X_n$. From the definition of a probability density function, we have

$$(3) \qquad g(x) = \lim_{h \to 0} h^{-1} \Pr(x - \tfrac{1}{2}h < X < x + \tfrac{1}{2}h).$$

Because a sample-based estimate of the probability Pr(.) is given by the fraction of the sample falling in the interval $(x - \frac{1}{2}h, x + \frac{1}{2}h)$, we can choose a "small" number h and define the (naive) estimator $\tilde{g}(x)$ of the density function as

$$(4) \qquad \tilde{g}(x) = (Nh)^{-1} \sum_{n=1}^{N} I[(x - X_n)/h],$$

where $I[.]$ is an indicator function satisfying $I[w] = 1$ if $-1/2 < w < 1/2$ for $w \equiv (x - X_n)/h$, and $I[w] = 0$ otherwise. Thus, the estimator $\tilde{g}(x)$ is essentially based on the histogram constructed on the interval $x \pm \frac{1}{2}h$, where h is the window width. A significant deficiency of this estimator is that it is not smooth. Also, where the data are sparse, $\tilde{g}(x)$ could be assigned the value zero, which may be contrary to prior beliefs about the true density. The kernel estimator, introduced by Rosenblatt, overcomes these problems. This estimator is obtained by substituting a kernel function $k(w)$ for the indicator function in (4), that is,

$$(5) \qquad \hat{g}(x) = (Nh)^{-1} \sum_{n=1}^{N} k[(x - X_n)/h],$$

where the kernel function $k(w)$ typically is itself a symmetric density function, i.e., satisfying $k(w) \geq 0$, $\int k(w)dw = 1$, and $\int wk(w)dw = 0$.[1]

The kernel density estimator can be extended to the multivariate case. For instance, the joint density $f(y, x)$ is estimated by

$$(6) \qquad \hat{f}(y, x) = (Nh^2)^{-1} \sum_{n=1}^{N} k_2[(y - Y_n)/h, (x - X_n)/h],$$

where $k_2(w', w)$ is a bivariate kernel satisfying $k(w) = \int k_2(w', w)dw'$ for $w' \equiv (y - Y_n)/h$.

From (2), the kernel estimator of the regression function is obtained as

$$(7) \qquad \hat{R}(x) = \int_{-\infty}^{\infty} y \frac{\hat{f}(y, x)}{\hat{g}(x)} dy.$$

In practice it is not necessary to estimate the individual densities in (7). Using the estimators in (5) and (6) one obtains

$$(8) \qquad \hat{R}(x) = \frac{\sum_{n=1}^{N} \int y\, k_2[(y - Y_n)/h, (x - X_n)/h]\, dy}{h \sum_{l=1}^{N} k[(x - X_l)/h]},$$

or, because of the transformations $w \equiv (x - X_n)/h$ and $w' \equiv (y - Y_n)/h$,

[1] This guarantees that the estimated density is non-negative and integrates to one.

(9)
$$\hat{R}(x) = \frac{\sum_{n=1}^{N} \int (Y_n + hw')\, k_2(w', w) h\, dw'}{h \sum_{i=1}^{N} k[(x - X_i)/h]}.$$

After evaluating the integral, and noting that $\int w' k_2(w', w) dw' = 0$ for symmetric kernels, the estimated conditional mean can be rewritten as

(10) $$\hat{R}(x) = \sum_{n=1}^{N} Y_n r_n(x),$$

where

(11) $$r_n(x) = \frac{k[(x - X_n)/h]}{\sum_{i=1}^{N} k[(x - X_i)/h]}.$$

Thus, the estimator $\hat{R}(x)$ is a weighted average of the Y_n's, where the weights r_n's are sample-specific and depend on the evaluation point x, assigning the greatest weights to the observations that are closest to the evaluation point.

This regression estimator can be extended to the general case of many X variables. In the notation above, simply reinterpret x, X_n, and w as vectors of dimension M, where M is the number of X variables, and substitute $K(w)$ for $k(w)$, where $K(w)$ is a multivariate kernel function.

Sometimes the estimation of the conditional mean, or regression function, is the main point of interest of applied research, and the above will suffice. Often, however, one is interested in the derivatives of the regression function, which is typically the case if one focuses on elasticities. An obvious estimator for these derivatives is given by $\beta_j(x) \equiv \partial\hat{R}(x)/\partial x_j$. Vinod and Ullah estimate $\beta_j(x)$ using analytic derivatives of (10), whereas Rilstone and Ullah suggest the numerical derivative:

(12) $$\hat{\beta}_j(x) = [\hat{R}(x + \tfrac{1}{2}h) - \hat{R}(x - \tfrac{1}{2}h)]/h$$

where $(x + \frac{1}{2}h) = (x_1, \ldots, x_{j-1}, x_j + \frac{1}{2}h, x_{j+1}, \ldots, x_M)$, and $(x - \frac{1}{2}h)$ is similarly defined.

Implementing the Kernel Estimator

The implementation of the nonparametric estimators of the regression function and of the partial derivatives is essentially based on equation (10). This shows that $\hat{R}(x)$ is a weighted average of the Y_n's, with weights depending on the X_n's and on the evaluation point x, and as such relatively straightforward to compute. Two main choices are necessary at this stage. First, one must choose a kernel function $K(w)$. The choice of the kernel has been shown not to be crucial (Epanechnikov). A common practice is to use the multinormal density $K(w) = \Pi_{j=1}^{M} k(w_j)$, where

(13) $$k(w_j) = (2\pi)^{-1/2} \exp(-1/2w_j^2).$$

To accelerate the asymptotic bias reduction, Robinson (1988a) suggests the use of higher-order kernels, which can be constructed by linear combinations of (13), with the weights chosen such that the kernel has zero moments up to the desired order (see also Hong and Pagan).

The choice of the window width h, on the other hand, is much more important because h controls the amount of smoothing imposed on the data. Criteria that can be used range from trial-and-error with subjective choice to a variety of automatic selection methods (Marron). The point to notice is that the variance on the kernel estimator is inversely related to h, while the bias varies directly with h. Thus, if h is too large, the shape of the underlying density function is obscured (causing bias); while, if h is too small, spurious detail is introduced (causing imprecision). A viable trade-off, advocated by Ullah (1988b) and Bierens, consists in choosing

(14) $$h = c\, N^{-[1/(4+M)]},$$

where c is a proportionality constant, N is the sample size, and M is the number of nonparametric regressors involved. As in Hong and Pagan, in the empirical application that follows (14) is used and a different proportionality constant for each variable is defined, setting c_j equal to the sample standard deviation of the jth X variable.[2]

Statistical Properties

The statistical properties of the kernel estimator have been analyzed extensively; the main results are reviewed in Bierens, Prakasa Rao, and Ullah (1988b). Under certain assumptions, a crucial one being that $h \rightarrow 0$ and $Nh^M \rightarrow \infty$ as

[2] This is important to account for the possible different scale of the regressors. The procedure adopted is equivalent to putting $c =$ 1 and linearly transforming the data to have unit covariance matrix prior to the nonparametric estimation.

$N \to \infty$,[3] it is shown that the estimator $\hat{R}(x)$ is consistent and asymptotically normal, and a similar property is established for $\hat{\beta}(x)$. In particular, the variance of $\hat{\beta}_j(x)$ can be estimated by (Ullah 1988a):

$$(15) \quad V(\hat{\beta}_j) = \hat{V}(x)[Nh^{M+2}\hat{g}(x)]^{-1} \int (K')^2 \, dw,$$

where $\hat{g}(x)$ is given by (5), $K' = \partial K(w)/\partial w_j$, and $\hat{V}(x)$ estimates the conditional variance of Y given $X = x$ as

$$(16) \qquad \hat{V}(x) = \sum_{n=1}^{N} Y_n^2 r_n(x) - \hat{R}(x)^2.$$

It should be noted, however, that the rate of convergence of the nonparametric estimators is slower than the root-N rate of parametric models. The maximal rate of convergence in distribution of the kernel estimator is $(Nh^M)^{1/2}$ for the conditional mean and $(Nh^{M+2})^{1/2}$ for the response coefficients. These rates are slower than $N^{1/2}$ because of the requirement $h \to 0$ as $N \to \infty$. This feature is common to other nonparametric estimators. For example, Gallant's Fourier functional form typically does not achieve root-N consistency. When h is chosen as in (14), it is also clear that the rate of convergence of the kernel estimator is inversely related to the number of explanatory variables (the "curse of dimensionality"). For practical applications this means that large samples should be used, and that reliance on asymptotic properties for hypothesis testing may not always be appropriate. The semiparametric model can overcome the inefficiency of the nonparametric estimators and may be more useful when the main objective is hypothesis testing.

Semiparametric Regression

In the semiparametric regression model of Robinson (1988a), an unknown nonlinear form is postulated only for part of the model, which can be estimated nonparametrically, while the remaining part of the model is linear (or, more generally, parametric). Let the Z denote the variables that enter the model linearly, and X denote the remaining variables. In this case the model of interest is written as

$$(17) \qquad Y = Z\gamma + \theta(X) + U,$$

where $E(U|Z, X) = 0$. Because of the generality of $\theta(X)$, the identification conditions for this model preclude Z from having an intercept, and require that no element of Z be included in X.

In this context, interest usually centers on the estimation of γ. If $E(Z|X)$ is a well-defined operation, from (17) we can write

$$(18) \quad Y - E(Y|X) = [Z - E(Z|X)]\gamma + U.$$

The conditional expectations $E(Y|X)$ and $E(Z|X)$ in (18) can be evaluated without making unduly restrictive assumptions about $\theta(X)$ utilizing the nonparametric regression estimator described above. Given this, γ can be estimated by a no-intercept ordinary least squares (OLS). Robinson (1988a) shows that the estimator of γ obtained in this fashion achieves root-N consistency and asymptotic normality. As will be shown below, some hypotheses typically of interest in production economics can be cast in a form such as (17), thereby providing an efficient test without making any restrictive assumption about the function being estimated.

A Cost Function Model for Dairy Farms

Because the nonparametric methods described above expand on the notion of flexibility that has been the tenant of many empirical applications, they offer a new approach to typical estimation and testing problems in production economics. In this paper a multiproduct cost function of Ontario dairy farms is analyzed using a large body of farm-level data. The relatively large number of observations offers a credible application for the nonparametric estimation approach, in view of the caveats on the slow rate of convergence discussed earlier. The predominantly cross-section nature of the data means that the estimated model is more suitable for studying the long-run structure of the typical farm. The analysis focuses on the issue of scale economies, which has important implications for the long-run configuration of the dairy industry in Canada.

For the problem at hand, the optimization behavior of the farms is best described conditional on the output level, which leads to a cost function representation of the production structure. More formally, if the production technology is described by the production possibilities set T, which contains all the combinations (Q, q) of output vectors Q and input vectors q that are

[3] For example, in the univariate case this means that the window width must get smaller as N increases, but at a rate lower than N^{-1}. This guarantees that the expected number of sample points in the interval $x \pm \frac{1}{2}h$ tends to infinity as $N \to \infty$.

technically feasible, given a vector $\tilde{p}$ of nominal input prices, the cost function $\tilde{C} = C(Q, \tilde{p})$, defined as

$$(19) \qquad C(Q, \tilde{p}) \equiv \min_{q} \{\tilde{p}q : (Q, q) \in T\},$$

provides a dual representation of this technology. Under some general conditions, $C(Q, \tilde{p})$ is a continuous, nonnegative, nondecreasing function, positively linearly homogenous and concave in $\tilde{p}$ (McFadden).[4] The property of homogeneity in prices is maintained by expressing deflated costs $C \equiv \tilde{C}/\tilde{p}_1$ in terms of a vector of deflated prices $p \equiv \{1, \tilde{p}_2/\tilde{p}_1, \ldots, \tilde{p}_t/\tilde{p}_1\}$, where t is the number of inputs and the deflator is one of the prices (the first one in this case) such that $C = C(Q, p)$.

This cost function is estimated using a data set consisting of 612 farm-level observations of Ontario dairy farms spread over the six years from 1978 to 1983. Inputs are aggregated into four groups: labor, feed, other intermediate inputs, and capital, and for each group a Fisher price index was constructed. The production vector consists of three output groups: milk, livestock products, and crops. Milk output is measured in hectoliters of 3.6% fat content milk, while the other two outputs represent a collection of products aggregated via a Fisher index. All right-hand-side variables are normalized to equal 1 at the median value of the sample, and the total cost of production is measured in dollars. More details on the nature of the data, and on aggregation procedures, can be found in Moschini.

Semiparametric Test of Constant Returns to Scale

The hypothesis of constant returns to scale in production represents an important benchmark. It implies that input proportions are independent of the scale of production and are determined only by the relative price of the inputs. This has important implications for the impact on input demand of supply management and other policies that may affect output at the farm level. Also, constant returns to scale justify the use of linear programming models of the farm firm, a widespread tool of farm management analysis.

Constant returns to scale are best understood in the context of homogenous production structures. Lau generalized this case to the multiproduct case and defined the notion of almost homogeneity. According to this characterization, the production structure is almost homogenous of degree 1 and s if $(Q, q) \in T$ implies $(\lambda^s Q, \lambda q) \in T$ for $\lambda > 0$ (when all inputs are scaled by the same proportion λ, all outputs are scaled by λ^s). In this case, the multiproduct cost function is homogenous of degree $\alpha = 1/s$ in outputs (Brown, Caves, and Christensen). When $s = \alpha = 1$, we have constant returns to scale, and the cost function can be written as

$$(20) \qquad C = Q_1 C(\bar{Q}, p),$$

where $\bar{Q} \equiv \{1, Q_2/Q_1, Q_3/Q_1\}$. Thus, (20) constitutes the model of the null hypothesis. For the alternative model it is convenient to consider the class of cost functions homogenous of degree α possibly different from one, which can be represented as

$$(21) \qquad C = Q_1^{\alpha} C(\bar{Q}, p).$$

The fact that the alternative model is not the most general one does not detract from the usefulness of the test. As emphasized by Davidson and MacKinnon, what is important is that the alternative model provides the appropriate "regression direction" and not necessarily the model of choice were the null hypothesis to be rejected. Moreover, under the null hypothesis $H_0: \alpha = 1$, the model provides the most general flexible form, so that no misspecification error from that source is likely to emerge.

Taking logs of both sides of (21) yields

$$(22) \qquad \ln C = \alpha \ln Q_1 + \ln C(\bar{Q}, p).$$

The stochastic version of (22) has the structural form of the semiparametric model (17), with $\ln C \equiv Y$, $\ln Q_1 \equiv Z$, and $\ln C(\bar{Q}, p) \equiv \theta(X)$. Thus, using (22) the hypothesis of constant returns to scale can be tested without making arbitrary assumptions on the shape of the true cost function.

The coefficient α was estimated by the nonparametric regression framework, and the result is reported in table 1.[5] Two models were used,

Table 1. Tests of Constant Returns to Scale

Kernel	$\hat{\alpha}$	Standard Error	t-Ratio $H_0: \alpha = 1$
Standard normal	0.7644	0.0132	−17.92
Higher-order	0.7642	0.0129	−18.21

[4] Also, $C(Q, \tilde{p})$ is assumed twice continuously differentiable.

[5] Estimation was carried out on an IBM computer using user written programs coded in Fortran.

one using the normal kernel in (13) and the other using one of the higher-order kernels suggested by Robinson (1988b) (the fourth-order kernel based on (13) such that the first two moments of the kernel are both zero). In both cases, the hypothesis of constant returns to scale, $H_0: \alpha = 1$, is rejected at the 5% probability level.

Because α is the reciprocal of the degree of homogeneity of the production structure, it can itself be interpreted as a measure of returns to scale.[6] The fact that $\hat{\alpha} < 1$ suggests that milk production is characterized by increasing returns to scale.

Semiparametric Test of Homogeneity

Interpreting $\hat{\alpha}$ in the previous section as the degree of multioutput scale economies may be inappropriate in that this is strictly valid only if the underlying technology is indeed homogenous of some degree. To gain some insight into this issue, it is useful to consider other implications of the class of homogeneous production processes.

As with constant returns to scale, when the production structure is homogenous input proportions still are independent of the scale of production. This property is best expressed in terms of share equations. If $q_j(Q, p)$ represents the input level that solves the cost-minimization problem, then $S_j = p_j q_j(Q, p)/C$ gives the optimal cost share of the jth input, and from the derivative property $S_j = \partial \ln C/\partial \ln p_j$. If the cost function is homogenous in output, it can be written as $C = Q_1^{\alpha} C(\bar{Q}, p)$. In this case $\partial \ln C/\partial \ln p_j$ is independent of the output deflator Q_1, and we can write $S_j \equiv S_j(\bar{Q}, p)$. Thus, homogeneity in output implies that the optimal shares are independent of the scale of production.

This proposition can be tested by augmenting the share equations under homogeneity in the variable addition framework advocated by Pagan. A simple way of doing so is to write the share equations as

$$S_j = \delta_j Q_1 + S_j(\bar{Q}, p), \tag{23}$$

where the linear term $\delta_j Q_1$ allows for nonhomogenous departures in a useful regression direction, that is, one in which the scale of production does influence the input shares.

The stochastic version of (23) again takes the form of the semiparametric model (17). The null hypothesis of homogeneity requires $H_0: \delta_j = 0$, and under the null the model has the most flexible specification. Table 2 reports the estimated δ coefficients for the four input cost shares. Similar to the results in table 1, no differences due to the higher-order kernels were found, and only the results obtained from the standard normal kernel (13) are reported. In all cases the estimated δ are significantly different from zero at the 5% probability level, which leads to the conclusion that the technology of milk production is not homogenous.

The coefficients reported in table 2 also provide some insight into the scale bias in input demand. When all outputs are expanded in the same proportion, such that $\bar{Q}$ does not change but Q_1 increases, the share of labor is significantly decreased. On the other hand, the share of the other three inputs increases, especially those of intermediate inputs and capital. This is consistent with the observation that cost-reducing technologies in larger-scale dairy farming typically include labor-saving solutions such as milking parlors and automatic feeding techniques. This also suggests that results on the bias of technological change from aggregate data sets ought to be interpreted carefully because scale changes are usually obscured at the aggregate level when the industry output is relatively constant and the number of firms is declining, which is the case of the Ontario dairy industry.[7]

Nonparametric Estimation of Returns to Scale

The analysis in the previous sections showed that the cost function of Ontario dairy farms is likely

Table 2. Tests of Homogeneity

Cost Share	$\hat{\delta}_j$	Standard Error	t-Ratio $H_0: \delta_j = 0$
Labor	−0.0484	0.0039	−12.35
Feed	0.0094	0.0047	1.99
Intermediate Inputs	0.0273	0.0033	8.24
Capital	0.0117	0.0044	2.67

[6] The (local) degree of homogeneity of the production structure is usually taken as the measure of multiproduct scale economies (Panzar and Willig), while the (local) degree of homogeneity in output of the cost function is usually taken as measuring returns to size. However, at cost-minimizing points, the two measures are fully equivalent in that one is the reciprocal of the other. Because of this, for simplicity and uniformity of exposition here and in the rest of the paper, returns to scale are cited even though, strictly speaking, returns to size are being measured.

[7] This result also vindicates the contention that the alternative model need not be the most general one, as long as it explores a useful regression direction. The alternative of an homogenous structure allowed rejection of constant returns to scale, even though it is itself rejected in this section.

characterized by increasing returns to scale. Because the hypothesis of homogeneity is rejected, however, the coefficient of the semiparametric model (23) cannot be interpreted as the (constant) measure of the actual degree of scale economies. To obtain a measure of this parameter for the general cost function model, we can make use of the nonparametric estimator of partial derivatives of equation (12). Without loss of generality, the nonhomogenous cost function is rewritten with arguments in logarithmic form, i.e.:[8]

(24) $$\ln C = \phi(\ln Q, \ln p).$$

In keeping with the previous sections the local degree of homogeneity in output of the cost function is used as a measure of multiproduct returns to scale, that is $\rho = \Sigma_i \, \partial \ln C / \partial \ln Q_i = \Sigma_i \, \partial \phi / \partial \ln Q_i$. Thus, the degree of returns to scale involves a summation of first derivatives of $\phi(.)$, which can be estimated without any restrictive functional form assumptions by using the estimator (12).

This estimation was performed with the explanatory variables evaluated at the median point for the input prices, and at the 50%, 75%, 90%, and 95% points of the percentile distribution of output.[9] Only the normal kernel was used, and the results are reported in table 3. Significant increasing returns to scale are found for all the evaluation points. Thus, not even the largest Ontario dairy farms seem to have exploited the existing scale economies in milk production. This conclusion is consistent with the observation that the largest farms in this industry are typically smaller than in comparable U.S. situations, and with previous findings on the U.S. dairy industry (Matulich).[10] Note that Moschini had found locally constant returns to scale for the largest Ontario dairy farms. This difference in results is probably caused by the restrictiveness of the second-order approximation nature of the functional form used in that study (a hybrid-translog form), which underscores the desirability of the nonparametric approach.

Concluding Comments

The nonparametric kernel regression provides a way of estimating production relationships without making prior assumptions about the true shape of the function being estimated. As such, it provides an alternative to parametric flexible functional forms for econometric applications. Unlike other nonparametric methods used to study production technologies, the nonparametric and semiparametric models of this paper have a solid statistical foundation and permit hypothesis testing in a standard sense.

The application to estimating the cost function of Ontario dairy farms emphasized the derivations of simple tests of hypothesis in semiparametric form which, under the null, do not impose undue restrictions on the shape of the underlying technology. The results indicate that constant returns to scale and homogeneity of production cannot be maintained, and that the sample's dairy farms are characterized by substantial scale economies.

[Received May 1989; final revision received October 1989.]

Table 3. Estimated Returns to Scale

Percentile Evaluation Point	$\hat{\rho}$	Standard Error	t-Ratio $H_0: \rho = 1$
50	0.5489	0.0594	−7.59
75	0.6156	0.0696	−5.52
90	0.6928	0.1033	−2.97
95	0.7096	0.1352	−2.15

[8] Expressing the model in terms of logarithmic variables will change the shape of the joint density of (C, Q, p), but is inconsequential in our case because of the amorphous nature of the nonparametric estimator.

[9] Because the measure of multiproduct returns to scale used is best interpreted as relating to the slope of ray average costs (Baumol, Panzar, and Willig), the evaluation point of all three outputs is the index of milk (the most important output in this case) at the given percentile levels.

[10] For example, the 95% point of the percentile distribution of milk output for the sample used corresponds to a dairy herd of approximately 100 cows.

A Comparison of Alternative Crop Response Models

Michael D. Frank, Bruce R. Beattie, and Mary E. Embleton

Three parsimonious models are hypothesized to represent corn yield response to nitrogen and phosphorus. Each model imposes specific restrictions with regard to the elasticity of factor substitution and growth plateau. Nonnested hypothesis tests are used to evaluate the competing hypotheses. The results support the restrictions imposed by the Mitscherlich-Baule model. For these data, corn response is characterized by limited substitution between nitrogen and phosphorus and a growth plateau. Further, the cost of using optimal input levels implied by the Mitscherlich-Baule if it were not "true" is small relative to the other parsimonious forms and a translog approximation.

Key words: crop response, elasticity of factor substitution, growth plateau, nonnested hypotheses.

Agricultural economists have been interested in the specification and estimation of agronomic response functions for some time. Notable studies include Heady, Heady and Dillon, Heady and Hexem, Johnson, Perrin and Spillman. Such studies empirically investigated the characteristics imposed a priori by the functional form selected. Recently, interest has focused on a more formal evaluation of the implicit restrictions imposed by certain commonly used models. In particular, Ackello-Ogutu, Paris, and Williams (APW) in this *Journal* and Grimm, Paris, and Williams (GPW) empirically tested certain technical aspects of crop response using nontested hypothesis tests.

Both APW and GPW found that a response model based on a von Liebig function was seldom rejected in favor of a polynomial. In the latter study, the von Liebig was compared to three commonly used polynomial functions (quadratic, three-halves, and square root) for five independent data sets. Their results support a growth plateau and zero elasticity of factor substitution (σ) between water and nitrogen (right-angle isoquants). Such characteristics follow from von Liebig's "law of the minimum." These papers (APW and GPW) as well as Paris and Knapp make a strong appeal for the von Liebig model on theoretical and empirical grounds for modeling crop response to macronutrients.

The difficulty with the results of Paris and coworkers is that it is not possible to "disentangle" the separate issues of plateau growth and factor substitution. By limiting their model comparisons to the quadratic, three-halves, and/or square root versus the von Liebig, the choice was effectively limited to plateau growth and no factor substitution or nonplateau growth and substitution. The interesting possibility of plateau growth and factor substitution was precluded given the models selected for comparison.

As a practical matter, GPW found that optimal nitrogen and water levels for corn and other crops varied substantially between alternative specifications. In particular, optimal nitrogen applications implied by simple polynomials were from 12.4% to 81.4% greater than those derived from a von Liebig function. Recommendations based on an "incorrect" model could have a substantial impact on profitability, i.e., the cost of using a misspecified model could be substantial.

This paper extends previous work by comparing the quadratic and the von Liebig to a third alternative—the Mitscherlich-Baule function. Each function is relatively parsimonious and imposes certain technical characteristics on the response curve. In particular, the Mitscherlich-Baule allows for plateau growth and factor substitution ($\sigma > 0$). Thus, the function does not

Helpful comments and criticisms of two *Journal* referees are appreciated by the authors.

adhere strictly to the "law of the minimum" but (unlike a polynomial) can exhibit a growth plateau. Such comparison gives more detail and flexibility regarding technical properties embodied in alternative plant growth processes. Further, by comparing the level of profit implied by each parsimonious form to that implied by a more complicated "translog" approximation, an estimate of the cost of parsimony (and the implied technical properties) is also demonstrated.[1]

The remainder of this paper is organized as follows. First, the empirical models and methodology are briefly discussed. The general problem of testing nonnested hypotheses is not discussed because the application of such methodology has become common in the literature (Ackello-Ogutu, Paris, and Williams; Grimm, Paris, and Williams; Smith, van Ravenswaay, and Thompson; Wohlgenant and Mullen). Next, the empirical results are presented and discussed. The final sections include a discussion of the relative costs of using the three parsimonious forms and a brief summary.

Empirical Models and Methodology

Determining the technical properties of plant response is largely an empirical issue. Two important aspects are elasticity of substitution and a growth plateau. Specific hypotheses regarding both are often imposed by the algebraic form of the response function.

Historically, polynomial functions (in particular, the quadratic) have been popular specifications for estimating crop response to macronutrients. The quadratic function,

$$(1)\quad Y_i = \beta_0 + \beta_1 N_i + \beta_2 P_i + \beta_3 N_i^2 + \beta_4 P_i^2 + \beta_5 N_i P_i,$$

where y_i is corn yield (bu.), N_i is applied nitrogen (lbs.), P_i is applied phosphorous (lbs.) and the β_j are parameters, imposes $\sigma \neq 0$ and no growth plateau. That is, for β_1, $\beta_2 > 0$, and β_3, $\beta_4 < 0$ yield decreases as N_i and P_i levels become large *ceteris paribus*, so that the function exhibits diminishing marginal productivity and input substitution for all N_i and $P_i > 0$. These properties plus the fact that the function is linear in all parameters contributed to its historical popularity.

In contrast, a von Liebig function,

$$(2)\quad Y_i = \min(Y^*, \beta_1 + \beta_2 N_i, \beta_3 + \beta_4 P_i),$$

where Y^* is maximum corn yield, is consistent with the idea that nitrogen and phosphorus perform different biochemical functions in plant growth (Wild). Further, the function implies that the plant responds (in a linear fashion) only to the most limiting nutrient. After some level of application (say, N^* and P^*) the plant will no longer respond to the applied nutrients. At this point, the plant reaches maximum growth (yield) at Y^*. In this manner, the specification of a von Liebig a priori imposes both $\sigma = 0$ for all levels of inputs and a growth plateau after N^* and P^*.

It seems entirely plausible, given the broad range of plant nutrients (including water) and application/availability levels, that characteristics imposed by either the quadratic or von Liebig model are not reasonable for all plant growth situations. Indeed, there is little empirical support for yield decreases due to excessive application of many plant nutrients as implied by the quadratic specification. Further, for some data sets and plant growth situations macronutrient isoquants may not be strictly fixed proportion, contrary to the implication of a von Liebig function. In the case of nitrogen and phosphorus on corn the possibility of $\sigma > 0$ and a growth plateau has considerable intuitive appeal.

A function that allows for convex, but not necessarily right-angle isoquants and that will accommodate plateau growth is the Mitscherlich-Baule:

$$(3)\quad Y_i = \beta_0[1 - \exp(-\beta_1(\beta_2 + N_i))][1 - \exp(-\beta_3(\beta_4 + P_i))].$$

The Mitscherlich-Baule is appealing for a number of reasons. First, the function is flexible regarding the degree of isoquant convexity, accommodating cases of near perfect factor substitution ($\sigma \rightarrow \infty$) to cases of near zero factor substitution ($\sigma \rightarrow 0$).

For the Mitscherlich-Baule, the elasticity of factor substitution at the *i*th data point is

$$(4)\quad \sigma_i = \frac{Y_i[f_N N_i + f_p P_i]}{N_i P_i[2 f_N f_p + \beta_3 Y_i f_N + \beta_1 Y_i f_p]},$$

where $f_N = \beta_0\beta_1[1 - \exp(-\beta_3(\beta_4 + P_i))] \exp(-\beta_1(\beta_2 + N_i))$ and $f_p = \beta_0\beta_3[1 - \exp(-\beta_1(\beta_2 + N_i))] \exp(-\beta_3(\beta_4 + P_i))$ are first derivatives evaluated at N_i and P_i, respectively.[2] As N_i and

[1] Similar analyses have been conducted by Havlicek and Seagraves, Bay and Schoney, and Griffin et al.

[2] For the function given in equation (3), $f_{NN} = -\beta_1 f_N$, $f_{pp} = -\beta_3 f_p$, and $f_{NP} = f_N f_p / Y$. Substitution of these results into the usual formula for σ yields equation (4).

P_i get arbitrarily large, the isoquants approach the limiting case of no factor substitution (right-angle isoquants). As N_i and P_i get small, σ_i increases, suggesting greater factor substitution. Thus, the Mitscherlich-Baule has sufficient flexibility to accommodate limited factor substitution if the data and production process so suggest. Second, the Mitscherlich-Baule, like the von Liebig, imposes plateau growth. For many (although probably not all) plant nutrient response relationships, this feature has considerable appeal. Finally, as mentioned earlier, inclusion of the Mitscherlich-Baule as an option along with the quadratic and von Liebig allows the analyst a broader range of possibilities in terms of isoquant pattern and plateau versus yield decline in model evaluation.

With the addition of an additive random error, $\epsilon_i \sim nid(0, \sigma^2)$, equations (1)–(3) provide a relatively simple framework for evaluating the elasticity of substitution between nitrogen and phosphorus and the existence of a growth plateau for corn. As outlined in APW, a formal test of the implicit hypotheses must be based on nonnested hypothesis testing procedures.[3] However, various asymptotically equivalent nonnested test statistics include the J-test and P-test based on compound regression models (Davidson and MacKinnon), the N-test derived from a likelihood ratio (Cox 1961, 1962; Pesaran 1974; Pesaran and Deaton), and the "adjusted" N- and W-tests which correct for size in small samples (Godfrey and Pesaran). As a practical matter, the choice of which test statistic to use in finite samples depends largely on the nature of the problem.

Most applications of nonnested testing have involved linear models such as equation (1). With the Mitscherlich-Baule function as an alternative the nonnested test statistic must be applicable for nonlinear models. Versions of the J-test, P-test, and N-test (but not the W-test or "adjusted" N-test) have been developed explicitly for nonlinear models. Further, both the J-test and P-test may be used to evaluate more than one (possibly nonlinear) alternative jointly, e.g., the quadratic versus the von Liebig and Mitscherlich-Baule. The latter joint tests are more powerful than pairwise comparisons with more than two competing hypotheses (Davidson and MacKinnon, Wisley and Johnson).

In finite samples inferences based on the J-test, P-test and N-test could conflict because the tests are equivalent only asymptotically. Although not explicitly for nonlinear alternatives, Pesaran found that the N-test performed satisfactorily for samples of 100 observations. The J-test and P-test may still lack power even in such moderately sized samples. However, comparing the results across versions indicates the robustness of the three nonlinear tests. This approach was taken in the following application.

Empirical Results

The estimated models corresponding to equations (1)–(3) are presented in the first three sections of table 1.[4] Parameter estimation was based on data from an agronomic experiment involving the yield response of corn to application of nitrogen and phosphorus (Heady, Pesek, and Brown). The sample data contain 114 observations.

In general, the estimated regression coefficients are statistically significant at the 5% level with few exceptions. The R^2 statistics are relatively high and comparable in magnitude. However, the quadratic does not appear to fit the data as well as the von Liebig or the Mitscherlich-Baule. Further, the signs and relative magnitudes of the estimated coefficients suggest that each curve fulfills the usual regularity conditions.

As noted above, both the von Liebig and Mitscherlich-Baule impose a growth plateau. Moreover, estimated growth plateaus for the Mitscherlich-Baule and the von Liebig exhibit little discrepancy. This plateau is estimated as 127.631 bushels for the Mitscherlich-Baule and 124.610 bushels for the von Liebig. Agreement between the estimated plateaus and the superior fit of the plateau models when compared to the polynomial suggest that, for this data set, corn response to nitrogen and phosphorus displays a growth plateau. However, such an analysis does not give much insight about the degree of factor substitution. Further analysis requires a more formal comparison of the models.

[3] Simply put, nonnested hypotheses result in regression models when no model of interest is more general than all potential alternatives. In the nested case, the restrictions implied by the null hypothesis can be imposed on the more general model and evaluated using the usual Neyman-Pearson approach. When there is no such general model of interest (a nonnested case) the procedure outlined by Cox (1961), where each model is temporarily held as the null and compared to all alternatives is appropriate. Unlike the nested case, such an approach can result in rejection or acceptance of all hypotheses.

[4] Estimation of the parameters for the von Liebig model is outlined in Paris and Knapp. A more theoretical discussion of such segmented regression models is given in Feder.

Table 1. Production Function Estimates and Related Statistics

Quadratic:

$$Y_i = -7.509 + .584N_i + .664P_i - .00158N_i^2 - .00180P_i^2 + .000811N_iP_i$$

(6.637) (.0635) (.0635) (.000177) (.000177) (.000155)

d.f. = 108 $R^2 = 0.832$ SSE = 40728.9

von Liebig:

$$Y_i = \min(124.610);\ 29.041 + .960N_i;\ 20.020 + 1.222P_i)$$

(1.893) (3.308) (.0728) (3.153) (.0779)

d.f. = 109 $R^2 = 0.912$ SSE = 21256.3

Mitscherlich-Baule:

$$Y_i = 127.631[1 - \exp(-.0191(N_i + 13.361))][(1 - \exp(-.0275(P_i + 5.603))]$$

(2.423) (.00220) (2.580) (.00322) (1.436)

d.f. = 109 $R^2 = .924$ SSE = 18551.8

"Translog" approximation:

$$Y_i = .0412(N_i + 24.380)^{2.554}(P_i + 2.0877)^{.304} \exp[.123\log(N_i + 24.380)\log(P_i + 2.0877)$$

(.105) (9.340)(.949) (1.729)(.355) (.0366) (9.340) (1.729)

$$- .292(\log(N_i + 24.380))^2 - .0845(\log(P_i + 2.0877))^2]$$

(.0915) (9.340) (.0356) (1.729)

d.f. = 106 $R^2 = 0.935$ SSE = 15847.3

Note: Statistics in parentheses are standard errors.

The nonnested hypothesis test results are presented in table 2. Because there is no "true" null hypothesis, the tests are performed by temporarily holding each hypothesis as null and testing in a pairwise fashion with each temporary alternative. In some cases, the alternative is comprised of several hypotheses. Such comparison produces a matrix of results (table 2). In this matrix, each group of three rows corresponds to the comparison of the null models against each alternative. The first element in each group is the value of the N-test, the second element is the value of the P-test, and the third element is the value of the J-test. The final group of statistics corresponds to the test against both alternatives jointly. With only one alternative, each test statistic is distributed as a standard normal under the null. In the joint case, the test statistic is distributed under the null as a chi-square random variable with degrees of freedom equal to the number of hypotheses in the alternative.

The results in table 2 illustrate several characteristics of nonnested tests. First, when the temporarily held null hypothesis is linear in all parameters the J-test and P-test are equivalent. Hence, the values in the last two rows of each group are equal when the quadratic is the null (the first column). Second, the relative values of the test statistics support a tendency of the "pairwise" J-test and P-test to overreject the null even with a moderately sized sample. In partic-

Table 2. Nonnested Hypothesis Test Results

Alternative Hypothesis	Null Hypothesis[a]		
	Quadratic	von Liebig	Mitscherlich-Baule
Quadratic		−2.823**	−1.673
		2.565*	1.982*
		3.464**	2.572*
von Liebig	−13.645**		−0.442
	10.403**		1.684
	10.403**		1.807
Mitscherlich-Baule	−18.062**	−4.840**	
	12.254**	4.460**	
	12.254**	2.535*	
Both[b]	96.506**	18.888**	7.441*

[a] The statistics in each group are the respective values of the N-test, P-test and J-test. Under the null, each statistic is distributed as standard normal. A single asterisk indicates statistical significance at the 5% level. Two asterisks correspond to significance at a 1% level.

[b] Comparison of the null hypothesis to both alternatives jointly. Under the null, the statistic is distributed as chi-square with two degrees of freedom.

ular, the temporary null is often rejected so that the restrictions of neither model in a particular comparison are supported. Only in the Mitscherlich-Baule versus the von Liebig comparison is the result conclusive at a 5% significance level. Finally, the implications of the J-test and P-test are seldom transitive, e.g., at a 5% significance level the Mitscherlich-Baule is favored over the von Liebig, but neither the Mitscherlich-Baule nor the von Liebig can be favored over the quadratic.

Because of the shortcomings of the "pairwise" J-test and P-test, inferences from the N-test and "joint" P-test are probably more reliable.[5] The results of these tests suggest that the Mitscherlich-Baule is favored over both the quadratic and the von Liebig. Specifically, N-test values of -18.061 and -1.673 imply that the temporary null of quadratic may be rejected in favor of the Mitscherlich-Baule and that the Mitscherlich-Baule (when null) is not rejected when compared to the quadratic. The Mitscherlich-Baule is also favored when compared to the von Liebig. Finally, when the Mitscherlich-Baule is compared to the quadratic and von Liebig jointly, the null hypothesis cannot be rejected at a 1% significance level.

Thus, these data lend support for the Mitscherlich-Baule, suggesting plateau growth but nonzero elasticity of factor substitution. The isoquant pattern for the estimated Mitscherlich-Baule function is presented in figure 1. While the isoquants have a rectangular-like shape, they do not exhibit fixed proportions. Empirical σ values range from 0.114 at $N = 40$ and $P = 320$ to 0.732 at $N = P = 40$. Of course as either N or P is allowed to get large, σ approaches zero (the flat or vertical portions of the isoquants) implying no factor substitution. This result supports the "law of the minimum" for excessive levels of nutrient when the other is limiting. However, the fact that the isoquants are not everywhere vertical or horizontal suggests some substitution possibilities even if over a narrow range.

Cost of Mispecification

The results of the preceding analysis suggest that, for these data, corn yield displays a nonzero elasticity of substitution and a growth plateau.

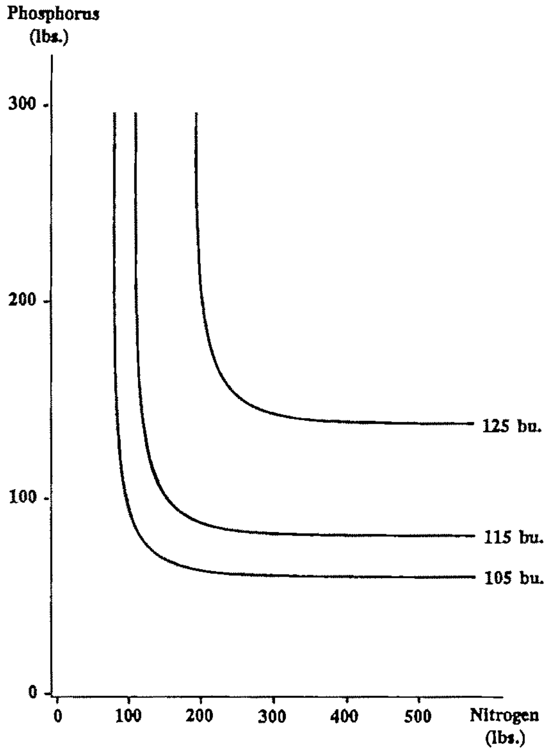

Figure 1. Isoquant pattern for Mitscherlich-Baule

However, as a practical matter, it is important to know the cost of imposing an elasticity of substitution equal to zero or no growth plateau. It is also important to determine the cost of using a model that is parsimonious in parameters but imposes certain technical characteristics a priori on the production process. In either case, this cost is the loss in profits of using the "wrong" production model to derive optimal (profit maximizing) inputs levels.

A demonstration of the relative costs of parsimony or model misspecification is presented in table 3. Using 1988 prices, the implied profit-maximizing levels of nitrogen and phosphorus and corresponding net returns were determined for each function. The optimal values differ considerably among the parsimonious forms. The quadratic implies relatively large input levels when compared to the von Liebig and the Mitscherlich-Baule. However, the difference is much more pronounced between the von Liebig and the quadratic.

The cost of incorrectly specifying one of the parsimonious forms is quantified by comparing net returns given that one of the functions is the true function. For instance, if the true response

[5] Although the J-test may be used for joint comparison, it is difficult to determine when the null is nonlinear. For this reason, it was not calculated.

Table 3. Optimal Values and Relative Cost of Misspecification

"True" Function	Optimal[a] Values	Cost of Applying Optimal Levels Based on[b] Quadratic	von Liebig	Mitscherlich-Baule	"Translog"
		($/ac.)			
Quadratic	209.50 lbs. N 205.02 lbs. P 232.85 net $	0.00	77.39	28.40	23.63
von Liebig	99.54 lbs. N 85.60 lbs. P 244.12 net $	48.26	0.00	20.34	21.96
Mitscherlich-Baule	159.00 lbs. N 124.00 lbs. P 211.96 net $	14.21	15.38	0.00	0.38
"Translog"	155.00 lbs. N 135.00 lbs. P 215.07 net *	9.68	12.65	0.34	0.00

[a] Optimal levels of nitrogen (lbs.), phosphorus (lbs.) and net returns ($) assuming a corn price of $2.27 per bu., a nitrogen price of $0.20 per lb. and phosphorus price of $0.22 per lb.
[b] The decrease in net returns (return over fertilizer costs) by applying the input levels implied by an "incorrect" function. For example, if the "true" function is quadratic net returns from applying 209.50 lbs. N and 205.02 lbs. P is $232.85 per acre. However, if the von Liebig optimal input levels (99.54 lbs. N and 85.90 lbs. P) were applied instead, net returns would be reduced by $77.39 per acre.

was characterized by $\sigma = 0$ and an asymptotic growth plateau, i.e., the von Liebig was "true," using the input levels implied by the quadratic would decrease return over fertilizer costs $48.26 per acre. Further, if the Mitscherlich-Baule was true ($\sigma > 0$ and growth plateau), net returns would be decreased by $14.21 per acre by using the quadratic input levels.

Notice (table 3) that the restriction of a nonzero elasticity of substitution and a growth plateau is the least costly among the parsimonious forms for these data and prices. Specifically, if the Mitscherlich-Baule is specified and the "true" function is the von Liebig or the quadratic, the decrease in net returns is small relative to the other misspecifications.

Optimal levels were also determined using a "translog" approximation which appears to fit the data better than any of the parsimonious forms but at the expense of three additional parameters when compared to the von Liebig and Mitscherlich-Baule and two more when compared to the quadratic.[6] Such additional parameters allow for a more flexible approximation of the response surface; however, because of this flexibility, both a concise interpretation of the parameter values and calculation of optimal input values is difficult. Comparing the cost of using the more parsimonious forms when the "translog" is assumed correct illustrates the impact of using such restrictive forms.

If the "translog" is the appropriate approximation for the underlying response curve, the cost of specifying either a von Liebig or quadratic is substantial (table 3). However, the implicit cost of using the Mitscherlich-Baule is relatively small. Thus, the cost of imposing either zero elasticity of substitution and a growth plateau or nonzero elasticity of substitution and no plateau can be substantial.

Concluding Comments

Both statistical analysis and comparison of the costs of misspecification suggest that for this data set corn response is characterized by a nonzero elasticity of substitution and a growth plateau. This result is relatively robust among the various nonnested test statistics used. It was further shown that the cost (in terms of foregone profit resulting from incorrect optimal input levels) from specifying the response function as either quadratic or von Liebig could be substantial for these data.

In comparison to the findings of Paris and his

[6] Experience with this "translog" function suggests that it may not be a viable approximation for all data configurations. However, because the function was included only for comparison, a search for a more robust approximation was not attempted. Two possible alternatives are the augmented Fourier transformation (Gallant) and cubic splines (Poirier). Each require estimation of a large number of parameters but could be used for comparison as the "translog" approximation was used in this study.

co-workers, our results support the idea of plateau growth; however, the hypothesis of no input substitution over the entire input space was not supported. Indeed there may be agronomic applications (e.g., the application of nitrogen under dryland farming conditions) where the idea of plateau growth also is questionable. There are no doubt many applied situations where the "law of the minimum" is an appropriate specification; but just as a polynomial specification should not be assumed a priori, neither should a von Liebig model.

Optimal Strategies for Marketing Calves and Yearlings from Rangeland

Lee Garoian, James W. Mjelde, and J. Richard Conner

Many of the problems encountered in ranching stem from the uncertainty associated with forage availability and the relatively stable forage requirements of the traditional cow-calf operation. This results in underutilization of forage during forage surpluses and costly overutilization during shortages. Smaller cow herds combined with the possibility of carrying calves over to the following spring and/or fall allows forage requirements to be manipulated in response to forage availability. Dynamic programming results suggest that smaller cow-calf-yearling operations have potential to increase expected net returns over a larger cow-calf operation.

Key words: calf and yearling marketing, dynamic programming, forage utilization.

Stochastic weather conditions result in considerable variation in range forage availability. Many of the management decisions made by ranchers are reactions to current range conditions. The most common reaction at the onset of adverse range conditions is supplemental feeding. More dramatic responses, such as reducing herd size, are usually reserved for extended periods of severe forage shortages. On the other hand, when range conditions are good, forage is often underutilized. This inefficient use of the forage resource contributes to the low returns associated with cow-calf operations.

Increased efficiency and reduced risk could possibly be achieved through smaller breeding herds and utilization of flexible marketing strategies. A smaller breeding herd would result in less required feeding during routine forage shortages and lower probability of having to reduce breeding stock numbers during prolonged shortages. The reduced revenue associated with the smaller herd could potentially be offset by retaining weaned calves during periods of excess forage and selling them as yearlings. Excess forage would be converted to weight gain by the calves, leading to a possible increase in revenues. The effect of this type of operation is that livestock forage demands are inexpensively manipulated in response to forage production.

Another advantage of this strategy is that it may be possible to take advantage of seasonal price fluctuations (Faminow and Gum). During the fall, when supply of calves is highest, calf prices are usually at their lowest yearly price. Carrying weaned calves over the winter and spring would permit ranchers to benefit from the seasonally higher spring and summer prices. While prices of heavier calves are traditionally discounted relative to lighter animals, capturing seasonal price fluctuations could potentially offset this loss (Rodriguez and Taylor).

Decision rules for marketing cattle have been determined by comparing expected value of weight gains with expected costs (Bullock and Logan; Fisher; Kennedy; Rodriguez and Taylor; Clark and Kumar; Yager, Greer, and Burt). Strategies developed in these studies utilized deterministic weight gains and stochastic livestock prices in establishing the benefits of retaining livestock. In feedlot situations, costs were considered deterministic because feed requirements can be estimated relatively accurately for any given level of weight gain. In rangeland situations, however, costs were considered stochastic because uncertainty associated with feed purchases is considerably greater. Stochastic livestock prices and range conditions have been considered separately in rangeland models

(Fisher, Lambert, Rodriguez and Taylor). However, both sources of uncertainty are relevant in determining optimal management strategies.

The objective of this paper is to determine potential economic benefits of smaller cow herds using flexible marketing strategies. To accomplish this objective, a dynamic programming model which includes both stochastic prices and range condition is developed. Conventional cow-calf operation is contrasted to the more flexible cow-calf-yearling marketing strategy.

The Planning Environment

The model is developed for a 3,000-acre pasture at the Texas Experimental Ranch at Throckmorton. The climate is highly variable, with annual rainfall ranging from 18 to 33 inches (VanTassell, Heitschmidt, and Conner). The existing spring calving cow-calf operation is stocked with 325 cows producing an annual average of 260 weaned calves weighing 537 pounds. Current operations are contrasted with a cow-calf-yearling operation based on a light to moderate stocking rate of 275 cows. In comparing the two operations, it is assumed that when forage shortages occur, the rancher provides supplemental feed to maintain desired animal performance. Therefore, weaning percentages and weights are assumed to be the same for the two operations. Further, it is assumed that the quantity of forage demand for each class of cattle is known for each month of the year and that supplemental feed can be directly substituted for forage.

In October, the ranch manager of a cow-calf-yearling operation considers the number of weaned calves to sell or, inversely, the number of calves to retain until spring. The major factors influencing this decision are current forage availability and calf prices. Current forage availability is the primary indicator of the quantity of forage that will be available over the winter; therefore, it is an indicator of the feed costs associated with carrying a given number of cows and yearlings over the winter.

The current price for calves influences the sell decision because price in conjunction with weight determines the current value of each calf. In response to low prices, the manager may carry livestock forward in expectation of higher prices. Alternatively, high prices may induce the sale of livestock in the current period.

The expected returns from retaining livestock and selling them in the future is a function of expected future prices and livestock weight. In this analysis, livestock weights are the average of those expected from retaining equal numbers of steer and heifer calves. That is, the decision on the proportion of steer and heifers to retain is not considered in this analysis.

May is selected as the second decision point during the year. Most forage is produced in the early spring, and by late May a rancher will have a good indication of the amount of forage that will be available for the remainder of the production year. The rancher, in a manner similar to the October decision, determines the number of short yearlings to sell, and the process moves to the October decision point again where all long yearlings (any calves retained from last year's calf crop) are sold. The decision process then begins again with the current year's calf crop. This two-stage decision process is repeated for each year of the planning horizon.

Dynamic Programming Model

Specification of the cow-calf-yearling dynamic programming (DP) model requires one deterministic state variable, inventory of yearlings on hand (I), and two stochastic state variables, amount of forage available [standing crop (SC)] and nominal cattle prices (P). Two decision points or stages within the year are considered, May and October. The inventory state variable represents the number of short yearlings in May and the number of long yearlings in October. Standing crop represents the amount of forage the rancher anticipates being available from the current stage to the next. In October, the price state variable represents calf prices, whereas in May it represents short yearling prices. Control of the system is exerted by selecting the number of calves to sell in October and the number of yearlings to sell in May (D). This decision influences the inventory state variable directly and the standing crop state variable indirectly through forage demand.

Quantification of standing crop and price is achieved by approximating discrete intervals for these continuous variables. Eight equally spaced intervals between 0 and 2,856 pounds per acre are modeled for standing crop. Cattle prices, which range between \$30 per hundredweight and \$85 per hundredweight, are subdivided into eleven intervals of equal width. Both standing crop and price state variable intervals are represented by the interval midpoints. The decision variable and the livestock inventory state vari-

able are represented by eleven values starting at 0 and increasing by increments of 10% of the weaned calf crop.

The assumed objective is to maximize the expected present value of net returns associated with the cow-calf-yearling operation over a ten-year planning horizon. This leads to the general recursive equation:

$$(1) \quad F_n(I, SC, P) = \max_D \{R_n(I, SC, P, D) + \beta_n E_p E_{SC} F_{n-1}(I, SC, P)\},$$

where $F_n(I, P, SC)$ is the expected present value of net returns from following an optimal policy with n stages remaining in the planning horizon given I, P, and SC at stage n; $R_n(I, P, SC, D)$ is the immediate net returns associated with decision D given I, P, and SC at stage n; β_n is the one-period discount factor; E_p and E_{SC} are the expectation operators taken over price and standing crop; max is the maximization operator; and I, P, and SC are as defined earlier. For compactness, subscripts for the current stage are suppressed on the state variables in equation (1). Further, equation (1) follows the convention of numbering stages according to the number of stages remaining in the planning horizon, that is backwards numbering of stages.

Various components make up the immediate net returns function, $R(I, SC, P, D)$. The most obvious component is returns from the sale of calves or yearlings. These returns are calculated as price multiplied by an assumed weight minus an $8.00 per head commission charge. Weaned calves in October are assumed to weigh 5.37 hundredweight, whereas short yearlings in May weigh 7.05 hundredweight. Within the model, any remaining calves from last year's crop (long yearlings) are sold in October. Returns from the sale of long yearlings is calculated in an identical fashion as returns from calves or short yearlings with the following exception. Recall that the price state variable in October is the price of calves. In order to reduce the dimensionality of the model, a relationship between calf prices and long yearling prices is included. By using this relationship, a state variable representing long yearling prices is not necessary. The following relationship was estimated using auction report data (Texas Department of Agriculture) on October calf prices and October prices for livestock weighing the same as the long yearlings for the years 1975–88,

$$(2) \quad \underset{(1.667)}{DIF = -4.2917} + \underset{(.0308)}{.12833P}, \quad \bar{R}^2 = .57,$$

where DIF is the difference between calf and long yearling prices, P is the price of calves, and standard errors are in parentheses. This relation is used to reduce the price received for long yearlings as a function of calf prices. Long yearlings are assumed to weight 7.95 hundredweight.

A second component of $R_n(I, SC, P, D)$ is variable costs associated with the operation. Each October, a variable cost of $114.83 per cow is imposed on the immediate returns function. A per head charge for retaining yearlings of $27.05 is imposed in May and $48.26 in October. For all livestock classes these costs include labor, salt, minerals, veterinary services and medicine, repairs, fuel, machinery, and equipment. These costs and the commission charge were obtained from livestock enterprise budgets developed by the Texas Agricultural Extension Service. An index of production items, interest, taxes, and wage rates for the years 1977–87 showed an average yearly increase of 4.6% (USDA). Variable costs and commissions were inflated at this annual rate.

The final major component in $R_n(I, SC, P, D)$ is supplemental feed costs. When livestock forage demands are greater than available standing crop, the difference is made up by feeding range cubes to maintain desired animal performance. The cost of feeding range cubes is based on the National Research Council guidelines that range cubes are substituted at 44% of the range forage shortage. This cost is calculated as

$$(3) \quad FC_n(SC, I_{n-1}) = .08(.44)\,(TFD_n(I_{n-1}) - TSC_n(SC)),$$

where $TFD_n(I_{n-1})$ is total forage demand of all livestock, $TSC(SC)$ is total standing crop, and .08 represents the cost of range cubes in dollars per pound. Forage demand is based on weighted average requirements of 24.4 pounds per day and 14.0 pounds per day during the October to May grazing period for cows and short yearlings. During the May to October period, forage requirements are 31.1 pounds per day and 24.7 pounds per day for cows and long yearlings (Reichers, Conner, and Heitschmidt). Total standing crop is the product of standing crop yield (lb./ac.), number of acres and utilization rate. Utilization rates of 57% and 33% indicate the weighted average percent of standing crop that may be grazed during the October to May and May to October periods (Reichers, Conner, and Heitschmidt). Feed costs are assumed to remain constant as no price trends were detected in protein supplements.

The discount rate is based on annual nominal inflation rate of 9%, which represents the yield on ten-year government bonds. The terminal value of the process is given by the liquidation of all nonbreeding stock. That is, both the current year's calf crop and all long yearlings are sold, as the terminal stage is assumed to occur in October.

Markovian Relationships

Equation (1) is numerically solved by backward enumeration subject to transition equations for the state variables. The deterministic inventory transition is

$$(4)\qquad I_{n-1} = .8\,(CW) - D \quad \text{if } n-1 \text{ represents May, and} \qquad = I_n - D \quad \text{if } n-1 \text{ represents October,}$$

where CW is the number of brood cows, .8 is the calving rate, and I and D are as defined earlier.

A modified version of a simulation model developed for the Texas Experimental Ranch is the basis for determining the standing crop transition equations (Reichers, Conner, Heitschmidt). Ranch weather data from 1950 through 1985 were used to simulate thirty-six years of standing crop, for October and May, for six levels of brood cows, from 250 to 325 cows by increments of 25 cows, and each of the eleven inventory levels of yearlings associated with a particular herd size. The effect of cows and yearlings on available forage was assumed directly proportional to forage deficits or surpluses in the simulation model (Heitschmidt, Dowhower, and Walker). Standing crop data for October was regressed on May standing crop, the number of breeding cows, and the number of yearlings retained. May standing crop was estimated using October standing crop and livestock numbers. These estimated equation are

$$(5)\qquad SC_{\text{Oct}} = \underset{(56.763)}{1553.7} + \underset{(.01031)}{.28532}SC_{\text{May}} - \underset{(.08418)}{1.1513}LYRLS - \underset{(.15970)}{1.9267}CW + e_1, \qquad \bar{R}^2 = .45 \quad \hat{\sigma} = 349.53, \text{ and}$$

$$(6)\qquad SC_{\text{May}} = \underset{(98.288)}{845.65} + \underset{(.02433)}{.68762}SC_{\text{Oct}} - \underset{(.13261)}{.80138}SYRLS - \underset{(.25132)}{1.3718}CW + e_2 \qquad \bar{R}^2 = .39 \quad \hat{\sigma} = 538.50,$$

where $LYRLS$ is the number of long yearlings, and $SYRLS$ is the number of short yearlings (standard errors in parentheses). Although statistical relationships when using simulated data are meaningless, the two standing crop equations appear to show a strong Markovian relationship.

Recall that the price state variable represents calf prices in October and short yearling prices in May. Therefore, the average monthly price of short yearlings in May was used to predict October calf prices, and average monthly October calf prices were used to predict May short yearling prices. The estimated price equations based on Amarillo auction data for the years 1975–88 are

$$(7)\qquad \ln(P_c) = \underset{(.35697)}{-.67919} + \underset{(.091055)}{1.1753}\ln(P_{sy}) + e_3 \qquad \bar{R}^2 = .93 \quad \hat{\sigma} = .08, \text{ and}$$

$$(8)\qquad \ln(P_{sy}) = \underset{(.48127)}{1.4354} + \underset{(.12244)}{.64735}\ln(P_c) + e_4 \qquad \bar{R}^2 = .70 \quad \hat{\sigma} = .14,$$

where P_c is the price of calves, P_{sy} is the price of short yearlings, and ln is the natural logarithm (standard errors are in parentheses). Equations (7) and (8) indicate the existence of a strong Markovian relationship between the price variables.

Stochastic transitions for prices and standing crop are developed by fitting four different cumulative distribution functions for the error terms associated with equations (5) through (8). The approach, which utilizes a hyperbolic tangent function to estimate the distributions (Taylor 1984), allows conditional probabilities to be generated (Taylor 1986). Maximum likelihood estimates of the cumulative distribution for standardized error terms associated with equations (5) through (8) are as follows:

$$(9)\qquad F(e_1) = .5 + .5\,\text{Tanh}\,(\underset{(.018)}{.040836} + \underset{(.015)}{.801909}\,e_1),$$

$$(10)\qquad F(e_2) = .5 + .5\,\text{Tanh}\,(\underset{(.018)}{.096422} + \underset{(.016)}{.864450}\,e_2),$$

$$(11)\qquad F(e_3) = .5 + .5\,\text{Tanh}\,(\underset{(.227)}{-.0154} + \underset{(.200)}{.9281}\,e_3),$$

$$(12)\qquad F(e_4) = .5 + .5\,\text{Tanh}\,(\underset{(.238)}{-.0209} + \underset{(.195)}{.9003}\,e_4),$$

(standard errors in parenthesis). These four functions represent the stochastic nature within the model. The stochastic transitions are assumed independent of each other.

Results

Several types of results are presented to compare a cow-calf-yearling operation to a cow-calf operation. First, convergent decision rules are presented for the cow-calf-yearling operation with 275 brood cows. Convergent decision rules for this application have the following property: the decision rule in May for year t is the same as the decision rule for May in year $t + 1$, and similarly for the October decision rule. Second, the present values of expected net returns associated with different initial conditions are presented for a ten-year planning horizon. These net returns are then contrasted with those of a cow-calf operation with 325 brood cows by decomposing the difference in expected net returns between the two operations into a herd size and marketing effect.

Convergent Decision Rules

Optimal decisions converged after five years. Convergent decision rules reduce the difficulty of presenting optimal decisions considerably. It is possible to present the October convergent decisions succinctly because the solution is invariant to the inventory state variable. Recall that all long yearlings must be sold; therefore, a state variable representing the number of long yearlings sold in October has no effect on the current decision.

The convergent October decisions (number of calves sold) for a herd size of 275 cows for each range condition and price state are presented in table 1. Standing crop and price effects are evident in the convergent decision rules with standing crop exerting the strongest influence. A threshold standing crop level is apparent between 536 pounds per acre and 893 pounds per acre. This threshold indicates the amount of forage necessary to support the cow herd without supplementation. Below this level all calves are sold. The decision rule illustrates the economic infeasibility of supplementing calves through the October to May grazing season. A second threshold occurs between the 893 pounds per acre and 1,250 pounds per acre levels. This threshold indicates that at the 1,250 pounds per acre level there is enough forage to support the cow herd and all calves. At the 893 pounds per acre level there is enough forage to support only a few calves.

At the 893 pounds per acre level the first price effect occurs. Prices above \$57.50 induce the sale of all calves. At these prices net returns from selling are greater than discounted expected net returns from retaining calves. As standing crop levels increase, price must increase before calves are sold. Good range conditions in this period allow calves to be retained without supplementation. Prices must increase before the returns from selling calves are greater than the expected net returns from selling them as yearlings.

May convergent decisions vary with respect to the inventory state, but because of the consistency of the optimal convergent decisions a complete presentation is possible. Decision rules are to sell all short yearlings when prices are below \$67.50 per hundredweight and above \$72.50 per hundredweight, regardless of the

Table 1. Convergent Decision Rules Indicating the Number of Calves Sold in October for Cow-Calf-Yearling Operation with 275 Cows

Calf Price (\$/cwt)	Standing Crop (lb/ac)							
	179	536	893	1,250	1,607	1,964	2,321	2,678
32.50	220	220	198	0	0	0	0	0
37.50	220	220	198	0	0	0	0	0
42.50	220	220	198	0	0	0	0	0
47.50	220	220	198	0	0	0	0	0
52.50	220	220	198	0	0	0	0	0
57.50	220	220	198	0	0	0	0	0
62.50	220	220	220	110	0	0	0	0
67.50	220	220	220	220	154	0	0	0
72.50	220	220	220	220	220	66	0	0
77.50	220	220	220	220	220	220	220	220
82.50	220	220	220	220	220	220	220	220

standing crop and inventory states. Factors contributing to these sell decisions are low weight gains during the summer and the discount for heavier livestock in October. Examining the price transition probability distributions showed that the expected difference between short yearling prices and long yearling price is smallest when short yearling prices are $67.50 per hundredweight and $72.50 per hundredweight. The expected value of the modest summer weight gains is not enough to compensate for the reduced value of previous weight increases. Further, all short yearlings are sold if standing crop is below 1,607 pounds per acre, regardless of price and inventory states. Short yearlings are retained only within the small remaining state space defined by prices of $67.50 per hundredweight and $72.50 per hundredweight with standing crop levels of 1,607 pounds per acre, 1,964 pounds per acre, 2,321 pounds per acre, and 2,678 pounds per acre.

Following the optimal decision rules given in table 1 for October results in six possible short yearling inventory levels in May. The six inventory levels are 0, 22, 66, 110, 154, and 220, associated with selling 220, 198, 154, 110, 66, or 0 calves. Optimal convergent May decisions for these six inventory levels and the two price levels which result in the retention of short yearlings are given in table 2. Within a given inventory level, the number of livestock sold decreases as the standing crop level or price increases. Inventory permitting, the number of livestock retained tends to a constant number of short yearlings being retained for each standing crop level and price level. Livestock prices of $67.50 and standing crops of 1,607 pounds per acre, 1,964 pounds per acre, 2,321 pounds per acre, and 2,678 pounds per acre result in 0, 44, 88, and 154 short yearlings being retained. Similarly the number of short yearlings retained with a price of $72.50 and standing crop levels of 1,707 pounds per acre, 1,964 pounds per acre, 2,321 pounds per acre, and 2,678 pounds per acre are 44, 88, 154, and 198, respectively.

Table 2. Convergent Decision Rules Indicating the Number of Short Yearlings Sold in May for the State Space Where Yearlings Are Retained

Inventory Short Yearlings	Short Yearling Price ($/cwt)	Standing Crop (lb/ac) 1,607	1,964	2,321	2,678

220	72.50	176	132	66	22

Present Value of Expected Net Returns

Expected present values of net returns generated from following an optimal policy for the ten-year planning horizon given different initial conditions are presented in table 3. These values assume that no yearlings are on hand at the start of the planning horizon. Net returns range from

$68,322 for the lowest initial price and standing crop to $300,951 under the highest initial price and standing crop states. The largest portion of this range is caused by price differences. Within the lowest standing crop level net returns are expected to increase by $160,367 if the initial price is $82.50 per hundredweight instead of $32.50 per hundredweight. Incremental initial price increases improve net returns between $11,000 to $20,000 within a given initial standing crop level.

The benefit of an initial standing crop level of 2,678 pounds per acre instead of 179 pounds per acre is $72,262 within the $82.50 price state. The largest share of this improvement occurs between the two poorest standing crop levels. Incremental increases between 179 and 536 pounds per acre result in an increase of $31,246, whereas an initial standing crop of 893 pounds per acre instead of 536 pounds per acre results in an increased net return of $26,870. These improvements illustrate the cost of feeding livestock during initial periods of insufficient forage. Another critical forage level is between 893 pounds per acre and 1,250 pounds per acre, where net returns increase $6,246. At the 1,250 pounds per acre level, there is enough forage to initially carry calves through the October to May grazing season. Further increases in net returns resulting from improved standing crop levels are attributed to the lower probability of transition to poor range condition associated with the better initial range conditions.

Herd and Marketing Effects

The expected net returns from the cow-calf-yearling operation are contrasted with those of a conventional cow-calf operation. The cow-calf operation is modeled by constraining the dynamic programming model to sell all calves in October. As noted earlier, the cow-calf operation is based on the current stocking rate of 325 cows. Table 4 presents the differences in expected present values between the two livestock operations. Adoption of the smaller cow-calf-yearling operation produces substantial benefits given poor initial standing crop and low initial prices. Benefits decline as initial price and range conditions improve, culminating in negative benefits with initially high prices and standing crops. Negative values reflect the better performance of the cow-calf operation given these initial states.

Increased insight concerning the cause of these benefits is achieved by decomposing the values in table 4 into a herd and flexible marketing effect. The herd effect is obtained by calculating the differences in expected present value of net returns between conventional cow-calf operations with 325 cows and 275 cows. Expected gains from operating a smaller herd given different initial conditions are shown in table 5. A disadvantage of the larger herd is the increased probability of having to feed. At initial low prices and poor standing crop levels, the cost of feeding the larger herd completely overshadows the revenues from increased calf sales. With initial poor range conditions and high prices the differences are still large, but higher prices partially compensate for large feeding costs. Even with good initial standing crop, the smaller herd performs better under low prices. Only at initially high prices and good range conditions do the net returns from the larger herd exceed those of the smaller herd. Although these results are

measured in terms of returns net of specified variable cost, the smaller herd would also result in lower annual capital costs due to the smaller investment in the cow herd.

Marketing effects are determined by comparing a 275-head cow-calf-yearling operation to a 275-head cow-calf operation. The expected gains in the net present values from adoption of the flexible marketing strategies given different initial conditions are shown in table 6. These gains result from more efficient utilization of forage and capturing seasonal price differences. Flexible marketing benefits are greatest when initial forage is abundant and price is low. Under high initial prices, differences are relatively low because all or most of the calves are sold in October under both systems. It is somewhat surprising that the benefits are so large under poor standing crop conditions and low prices because both operations initially sell all calves. Over time, as standing crop improves, the flexible marketing approach benefits from excess forage and seasonally high prices. The only benefit of increased standing crop production for the conventional operation is reduced feed costs.

Alternative Stocking Rates

Benefits from adoption of a cow-calf-yearling operation consist of a marketing and a herd effect. The herd effect represents the change in expected present value of net returns from operating with a smaller breeding herd. The herd effect is negative only when initial standing crop levels are good to high and initial prices are high. This suggests that ranchers could gain from smaller herds under conditions of either initial low prices or low standing crop levels.

Determination of the optimal herd size re-

quires calculating the expected value of the convergent stage returns. However, the difficulty of manipulating two different matrixes of dimension 968 by 968 (11 inventory states × 11 price states × 8 standing crop states) and four vectors of dimension 1 by 968 makes determination of optimal herd sizes impractical.

The marketing effect represents increased returns resulting from selling heavier livestock at higher prices during the summer. As expected, the marketing effect is positive for all initial combinations of state variable levels. This suggests that adoption of a flexible marketing strategy regardless of the herd size chosen will provide increased net returns.

Convergent optimal decision rules are obtained from the DP model for six herd sizes ranging in size from 250 to 375 brood cows. Generally, the convergent decisions are robust with respect to the number of brood cows. The optimal October decision is to sell all calves when standing crop levels are insufficient to support the brood cows. Disregarding price effects, the October decision rule is to keep all calves that the October standing crop levels will support. This rule is modified as higher prices increase the net returns from immediate sale above the expected net returns from retaining livestock. As herd size increases, calves are sold at progressively lower price levels. Larger herds result in lower expected standing crop levels and higher feeding costs in subsequent periods. The expected cost of feeding retained livestock dominates the expected value of weight gain as herd size increases. This influence is evident in the convergent May decisions, where livestock are retained only under very limited conditions and small herd sizes. Larger herds reduce the probability of being able to carry yearlings through the May to October grazing period without supplemental feeding.

Concluding Comments

Results suggest that using smaller cow herds and retaining calves in the fall to sell as short or long yearlings can increase net returns over larger conventional cow-calf operations. The benefits of adopting a flexible marketing plan and decreasing herd sizes can be decomposed into a marketing effect and a herd effect. For a given herd size, the marketing effect is always positive. This is expected because the flexible marketing strategy is a more general strategy that encompasses a conventional marketing plan. The benefits of flexible marketing plans are more efficient use of the forage resource and the potential ability to capture seasonal price fluctuations. For conventional marketing of calves the herd size effect may be positive or negative depending on initial conditions.

Although the specific results reported herein apply only to the Texas Experimental Ranch, they provide guidelines for other areas and operations. Because the largest benefits of cow-calf-yearling operations occur under lower initial standing crop levels, ranchers in more arid and/or more variable rainfall regions would be expected to benefit relatively more from the alternative marketing practices. However, because livestock weight gains, costs, and seasonal forage production would vary between regions and to some extent between ranches within regions, optimal decision rules for other specific ranch situations must be obtained by parameterizing the model for each specific operation.

The Impact of Information on Environmental Commodity Valuation Decisions

John C. Bergstrom, John R. Stoll, and Alan Randall

A conceptual model is developed which provides insight into how information affects willingness to pay for environmental commodities. A refutable hypothesis of the effects of a specific information type on the magnitude of willingness to pay for an environmental commodity is developed. This hypothesis is tested using a contingent valuation method experiment. Results indicate that information affects willingness to pay in a theoretically plausible manner. The results support the contention that information is important for accurate environmental commodity consumer valuations.

Key words: consumer valuation, contingent valuation, environmental commodities, information effects, welfare measures.

Much progress has been made in the past two decades in the development of techniques for measuring the economic value of environmental commodities (Freeman; Mendelsohn and Brown; Randall, Hoehn, and Brookshire; Ward and Loomis). However, fundamental questions remain concerning the process by which consumers formulate environmental commodity valuations. An especially challenging question is: "What impact does information have on the value consumers place upon environmental commodities?"

A number of previous empirical studies have detected statistically significant changes in environmental commodity valuations induced by changes in the information presented to consumers. Such effects are usually labeled "information biases" (Cummings, Brookshire, and Schulze). Most previous studies, however, do not provide a conceptual model of information effects. Hence, it is difficult to judge whether or not observed information effects induce undesirable biases.

In the next section of this paper, a theoretical model of the effects of a specific type of information on willingness to pay for a change in a rationed environmental commodity is developed. The model focuses upon the effects of information on the marginal utility of an environmental commodity, the perceived utility levels with and without the environmental commodity, and consumer expenditures. An empirical test of a specific information effect hypothesis which arises from the model is then discussed. The results suggest that information influences willingness to pay. The paper ends with a brief summary and conclusions.

Information and Willingness to Pay

This paper focuses upon the impact of "service information" on willingness to pay (*WTP*) for a change in a rationed environmental commodity. Service information (*SI*) describes the possible uses of a commodity. Possible uses can be subjective in nature (e.g., aesthetic enjoyment). *WTP* for increments or decrements in a rational environmental commodity are measured by Hicksian welfare measures (Brookshire, Randall, and Stoll; Randall and Stoll). *WTP* can be derived

This paper was based on research supported in part by the U.S. Army Corps of Engineers, the U.S. Environmental Protection Agency, and the Georgia, Texas, and Ohio agricultural experiment stations under the W-133 Regional Project.

Special acknowledgement and thanks are extended from the authors to Douglas Larson, University of California, Davis, who suggested the formal mathematical framework for the conceptual model of information effects and provided many helpful comments on the empirical modeling. Helpful suggestions on the empirical modeling were also provided by Christopher McIntosh, University of Georgia. Comments and suggestions from anonymous *Journal* reviewers are also gratefully acknowledged.

by first specifying an income compensation function.

$$(1) \qquad h[P, Q, V(P, Q, M|SI)],$$

where P is a nonrationed commodity price vector, Q is a rationed environmental commodity, $V(.)$ is an indirect utility function, and M is money income.

The indirect utility function in (1) indicates that utility derived from P, Q, and M is dependent upon available service information denoted by SI. Given (1), WTP is defined by

$$\begin{aligned}(2) \quad WTP &= h[P, Q^c, V(P, Q^c, M^o|SI)] \\ &\quad -h[P, Q^c, V,(P, Q^r, M^o|SI)] \\ &= h[P, Q^c, V^c]-h[P, Q^c, V^r] \\ &= M^o - M^1,\end{aligned}$$

where Q^c is the post-payment quantity of a rationed environmental commodity, Q^r is a reference quantity of a rationed environmental commodity, M^o is the initial income level, M^1 is the post-payment or subsequent income level; V^c is an indirect utility level given Q^c, P, and M^o (post-payment utility level); and V^r is an indirect utility level given Q^r, P, and M^o (reference utility level).

Assume $Q^c - Q^r$ represents an increment in a rationed environmental commodity from an initial quantity, Q^o, to a subsequent quantity, Q^1. In this case $Q^c = Q^1$ and $Q^r = Q^o$, and (2) measures a Hicksian compensating welfare measure associated with the increment. Next, assume $Q^c - Q^r$ represents a decrement in a rationed environmental commodity from an intitial quantity, Q^o, to a subsequent quantity, Q^1. In this case $Q^c = Q^o$ and $Q^r = Q^1$, and (2) measures a Hicksian equivalent welfare measure associated with the decrement.

The impact of information on WTP for an increment or decrement in a rationed environmental commodity is calculated by the partial derivative,

$$\begin{aligned}(3) \qquad \frac{\partial WTP}{\partial SI} &= \frac{\partial h}{\partial V^c}\frac{\partial V^c}{\partial SI} - \frac{\partial h}{\partial V^r}\frac{\partial V^r}{\partial SI} \\ &= g^c\frac{\partial V^c}{\partial SI} - g^r\frac{\partial V^r}{\partial SI},\end{aligned}$$

where g^c is the marginal cost of utility given Q^c and g^r is the marginal cost of utility given Q^r. The terms g^c and g^r are essentially inverses of the marginal utility of money. Equation (3), which assumes SI is variable, indicates that the impact of a change in SI on WTP depends on the differential effect of information on the reference and post-payment utility levels. Assessment of this differential effect is facilitated by expressing WTP as

$$\begin{aligned}(4) \quad WTP &= \int_{Q^o}^{Q^1} - \left[\frac{dh}{dQ}\right] dQ \\ &= \int_{Q^o}^{Q^1} - \left[\frac{\partial h}{\partial Q} + \frac{\partial h}{\partial V}\frac{\partial V}{\partial Q}\right] dQ \\ &= -\int_{Q^o}^{Q^1} [h_Q + g(SI)V_Q(SI)]dQ,\end{aligned}$$

where $g(SI)$ is the marginal cost of utility given SI and $V_Q(SI)$ is the marginal utility of the rationed environmental commodity given SI.

The impact of a change in SI on WTP is then determined by the partial derivative:

$$(5) \quad \frac{\partial WTP}{\partial SI} = -\int_{Q^o}^{Q^1}\left[\frac{\partial g(SI)}{\partial SI}V_Q(SI) + g(SI)\frac{\partial V_Q(SI)}{\partial SI}\right]dQ,$$

where $\partial h_Q/\partial SI$ is assumed to equal zero because SI affects perceptions of only the possible uses of Q, not the actual, objective level of Q. The first term in (5) accounts for the impact of SI on the marginal cost of utility. The second term in (5) accounts for the impact of SI on the marginal utility of the rationed environmental commodity. Hence, the differential effect of a change in SI on the initial and subsequent utility levels is caused by changes in $g(SI)$ and $V_Q(SI)$ which are caused by changes in service information. Because different service information may have different effects on $g(SI)$ and $V_Q(SI)$, predicting the final impact of a change in SI on WTP for a change in a rationed environmental commodity is problematic and must generally proceed on a case by case basis.

A Case Study

A study was conducted to test for the impact of service information on WTP for wetlands protection. The particular wetland area considered is a large section of Louisiana's coastal wetlands. Louisiana contains over 40% of the nation's wetlands resources. The wetlands area considered in this study encompasses approximately 3.2 million acres and represents an important national resource.

Louisiana coastal wetlands are used for recreational activities, such as waterfowl hunting,

saltwater fishing, freshwater fishing, recreational shrimping, and recreational crabbing. These activities are "produced" by individuals or households by combining nonrationed, market commodities (e.g., bait, tackle, boats) and rationed, environmental commodities (e.g., wetlands) (Bockstael and McConnell).

Because of a combination of factors, wetlands in the study area are decreasing at a rapid annual rate. There is much concern over the loss of these national resources among public officials and private recreationists. The welfare impact on recreators of wetlands loss can be measured by their *WTP* to prevent the loss. This *WTP*, which represents a Hicksian equivalent welfare measure, is calculated by (2) where $Q^c = Q^o$ = initial (pre-loss) quantity of wetlands $Q^r = Q^1$ = subsequent (post-loss) quantity of wetlands. In the study, *WTP* for wetlands protection was elicited directly from recreationists using the contingent valuation method (CVM).

Information Effect Hypothesis

A recent survey indicates that consumption services or attributes supported by wetlands in the study area which are most highly valued by recreationists include hunting or fishing success, wildlife encounters or sightings, natural scenery, and remoteness or isolation (U.S. Army Corps of Engineers). In a CVM exercise, recreationists may fail to consider all of these services or attributes when formulating and stating *WTP* to prevent a decrement in wetlands from Q^o to Q^1. This incomplete information processing is supported by Hoehn and Randall's model of valuation decisions in contingent markets. Consideration of these services or attributes may be enhanced by providing CVM participants with service information (*SI*). In the present case study, *SI* represents information which describes consumption services or attributes associated with recreational trips to the wetlands study area.

By helping consumers to recognize or recall desirable consumption services or attributes, it is conjectured that *SI* affects the perceived marginal utility of a given rationed quantity of wetlands. *SI*, it is assumed, does not change perceptions of objective characteristics of the wetlands commodity itself (e.g., total acres). Thus, with or without additional *SI*, CVM participants always valued the same environmental commodity, denoted by Q in (1)–(5). *SI*, however, was assumed to affect perceived consumption services or attributes supported by Q.[1]

If CVM participants do not consider all beneficial consumption services or attributes supported by wetlands, they may underestimate the marginal utility of protected wetlands. That is, they may underestimate the change in total utility or satisfaction that would result from a change in wetlands if they fail to consider all types of benefits. Under these conditions, it is conjectured that additional *SI* that points out the beneficial consumption services or attributes may induce an upward revision in the marginal utility of protected wetlands. In this case, $\partial V_Q(SI)/\partial SI$ in (5) will have a positive sign. Hence, the second term in (5) will be positive since $g(SI)$ is assumed to be positive.

Thus, one hypothesized impact of additional *SI* is to increase *WTP* for wetlands protection by increasing the marginal utility of Q, or $V_Q(SI)$. This increase in *WTP* results from an upward revision in the post-payment utility level relative to the revision in the reference utility level. That is, with additional *SI* a CVM participant perceives himself or herself as gaining more utility from paying to increase wetlands from Q^1 to Q^o. By (3), a relative increase in the post-payment utility level increases *WTP*.

Additional *SI* may also impact the first term in (5). With additional *SI* about generally desirable consumption services or attributes, recreationists may perceive that more utility can be derived from current expenditures. Thus, $g(SI)$ would decrease since an additional unit of utility could be gained with less expenditures. This decrease in $g(SI)$ implies that $\partial g(SI)/\partial SI$ in (5) is negative. The first term in (5) would therefore be negative since $V_Q(SI)$ is assumed to be positive. A negative first term in (5) indicates that additional *SI* will also have the impact of reducing *WTP* for wetlands protection. Such a reduction in *WTP* would result from an upward revision in the reference utility level relative to the post-payment utility level which must occur

[1] Following Lancaster, environmental commodity characteristics are elements of the commodity which "make up" the commodity and are objectively measurable and observable (e.g., size, location). Following household production theory, consumers combine environmental commodity characteristics with other nonrationed market commodities to "produce" consumption activities (e.g., recreational trips). Services or attributes associated with these activities generate utility (Becker, Stigler and Becker, Michael and Becker, Stoll). Unlike commodity characteristics, consumption services or attributes can be subjective and difficult to measure and observe (e.g., aesthetic enjoyment).

so that the reference income level (M^o) remains exhausted. By (3), if the reference utility levels increase, *WTP* decreases.

Hence, the direction of the final expected impact of *SI* on *WTP* for wetlands protection depends on the strength of the differential effect on the reference and post-payment utility levels. That is, the final impact of *SI* on *WTP* depends on how additional *SI* affects recreationists' valuation of the rationed commodity interval given by $Q^o - Q^1$. The experimental hypothesis is therefore a two-tailed test and is stated in alternative form as

$$H^0: WTP(SI^1) = WTP(SI^2)$$
$$H^1: WTP(SI^1) \neq WTP(SI^2),$$

where $SI^1 > SI^2$. H^1 assumed that Grether and Wilde's notion of strong information overload is not a problem. Strong information overload is defined as the emergence of confused or dysfunctional consumer behavior caused by increased information.

Hypothesis Test Methodology

A CVM field survey experiment was conducted to test H^1. The experiment involved bid elicitation using mail questionnaires with different levels of *SI*, bid function estimation, and statistical hypothesis testing.

Survey design and procedures. In the survey questionnaire, a participant was asked to state a maximum acceptable income reduction each year to protect wetlands in the study area. Each participant submitted three bids for wetlands protection. The three bids corresponded to the following three scenarios—*WTP* for wetlands protection assuming: (*a*) current bag and catch levels could be maintained, (*b*) bag and catch levels could be maintained at 50% of current levels, and (*c*) bag and catch levels could be maintained at 25% of current levels.

Two different versions of the contingent market were employed (see appendix). Each version elicited bids under the three-bag scenarios. In each contingent market, the quantity of all types of information except for *SI* were held constant. The *SI* presented in version A did not explicitly remind recreationists of the beneficial consumption services or attributes supported by wetlands. Version B explicitly reminded recreationists of four beneficial consumption services or attributes supported by wetlands; daily bag or catch, wildlife encounters, natural scenery, and isolation or remoteness. Thus, Version B contained a greater level of *SI* than Version A.

Both versions of the questionnaire presented identical characteristic information (CI) which described wetlands in the study area (e.g., location, size, vegetation, water salinity). This information helped ensure that participants receiving both questionnaires perceived and valued the same environmental commodity, *Q*. A cross check, however, was not conducted to ensure that perceptions of the wetland area were uniform across participants because participants were randomly selected and were highly familiar with the wetlands study area. Most respondents indicated that they had been participating in outdoor recreation in the study area for over ten years. Thus, even without the CI provided in the questionnaire, perceptions of the wetlands study area and its characteristics were expected to be highly uniform across CVM participants.

In sum, the different information presented across Versions A and B is assumed not to have changed characteristics of the actual environmental commodity recreationists valued; namely, wetlands in the study area. The different information presented across Versions A and B was intended only to change perceptions of consumption services or attributes associated with wetlands-based recreational trips. The higher level of *SI* presented in Version B suggested that its valuations would be different from valuations elicited by Version A. This expectation was reinforced by the conjecture that as catch and bag were reduced, other consumption services or attributes such as wildlife encounters would become relatively more important.

The two questionnaire versions were randomly assigned across a sample of recreationists. The sample was drawn from a list of recreational users of the study area compiled by the Waterways Experiment Station, U.S. Army Corps of Engineers. The questionnaires were mailed to sample individuals in the summer of 1986. The initial mailing packet included a questionnaire, cover letter, and postage-paid return envelope. One week after mailing the initial mailing packet, a postcard reminder was sent to all sample individuals. Questionnaires were mailed to a total of 230 recreationists. Six of these questionnaires were returned because of insufficient or improper addresses. Thus, the effective sample size was reduced to 224. Of these

224 questionnaires, 139 were returned for a response rate of 62%.

Bid function specification. Economic theory suggests that *WTP* and changes in recreation quantity and quality variables are related in a nonlinear manner. Preference indicator variables such as income and other socioeconomic variables may also be related to *WTP* in a nonlinear manner (Brookshire, Randall, and Stoll; Crocker; Hammack and Brown; Weber). Previous studies also suggest that information may be related to preferences in a nonlinear manner. Grether and Wilde, for example, argue that the effects of information on preferences diminish at successively higher information levels, a phenomenon called weak information overload. A bid function with these properties is specified in general form as

$$(6) \quad WTP = \exp(a_o + a_1{*}k_1 + \ldots + a_N{*}k_N) \cdot \sum_{i=1}^{I} R_i^{bi} = z{*} \sum_{i=1}^{I} R_i^{bi}$$

where a_n is the nth preference indicator or information variable, $n = 1, \ldots, N$; R_i is the change in the ith recreation quantity or quality variable, $i = 1, \ldots, I$; z is a composite constant term; and $a_o, a_1, \ldots, a_N$; $b_i, \ldots, b_I$ are parameters to be estimated. An additional feature of (6) is that the effects of preference indicator and information variables can be collapsed into one constant term, denoted by z. This feature allows dichotomous preference indicator and information variables to contribute to a nonlinear effect on *WTP*.

In order to test H^1, a linear transformation of (6) was specified as

$$(7) \quad LWTP = a_o + a_1{*}INCOME + a_2{*}RECDAY + a_3{*}YEARS + a_4{*}CAMP + a_5{*}SUB + a_6{*}INFORM + b_1{*}LTWFBAG + b_2{*}LTFFCAT + b_3{*}LTSFCAT + b_4{*}LENCOUNT + b_5{*}LBOAT + b_6{*}LPOLL,$$

where *LWTP* is natural log of *WTP* to protect wetlands. The preference indicator variables are as follows: *INCOME* is individual income reported in the survey (continuous group estimates); *RECDAY* is days of all types of outdoor recreation per month; *YEARS* is average years of participation in waterfowl hunting, freshwater fishing, and saltwater fishing; *CAMP* is an indicator variable for hunting or fishing camp ownership (1 = yes, 0 = no). The recreation quantity and quality variables are as follows: *LTWFBAG* is the natural log of annual waterfowl bag (annual waterfowl hunting days × average daily bag); *LTFFCAT* is the natural log of annual freshwater fish catch (annual freshwater fishing days × average daily catch); *LTSFCAT* is the natural log of annual saltwater fish catch (annual saltwater fishing days × average daily catch); *LENCOUNT* is the natural log of daily wildlife encounters (e.g., sightings); *LBOAT* is the natural log of daily nonrecreational boat sightings; and *LPOLL* is the natural log of daily environmental pollution (e.g., litter). Finally, the information variable is *INFORM*, which is an indicator variable for the level of service information (1 = high level; 0 = low level).

Estimation and hypothesis test results. Equation (7) was estimated by pooling bids for the three-bag/catch scenarios and employing regression analysis. The specification of the *INFORM* variable (7) allowed for a test of the hypothesis, H^1. Equation (7) was first estimated by ordinary least squares (OLS). The condition number for this model was twenty-five, which suggests that multicollinearity is not a major concern (Belsey, Kuh, and Welsh; Judge et al., pp. 620–24).

Homoskedasticity tests suggested by Glesjer, however, indicated the presence of heteroskedasticity with respect to two of the bag/catch variables (*LTWFBAG*, *LTSFCAT*). Each of these variables was negatively related to the error variance. These negative relationships are conceptually plausible because as annual bag/catch increases (which accounts for both the quantity and quality of recreation), the effects of extraneous factors on recreation valuation behavior may diminish.

In (6), heteroskedasticity between *WTP* and the bag/catch and recreation day variables was assumed to be reinforcing and of the general multiplicative form; $\sigma_i^2 = \sigma^2{*}TWFBAG^{c1}{*}TSFCAT^{c2}$. This equation was estimated by the transformation, $\ln(e_i^2) = c_o + c_1{*}LTWFBAG + c_2{*}LTSFCAT$. The predicted values of this equation were then used to weight (7) to correct for heteroskedasticity caused by multiple variables as suggested by Kmenta (pp. 285–87). Further homoskedasticity testing failed to reject the hypothesis that the error variance was constant with

respect to *LTWFBAG* or *LTSFCAT* at the .01 level.[2]

The weighted least squares (WLS) estimates for (7) are presented in table 1. Out of the preference indicator variables, *INCOME*, *RECDAY*, *SUB*, and *YEARS* have positive signs. *INCOME* and *YEARS*, however, are not statistically significant (statistical significance levels are indicated in table 1). *CAMP* is statistically significant with a negative sign. *LTWFBAG*, *LTSFCAT*, and *LENCOUNT* have positive signs. Each of these variables was also statistically significant, which suggest they are important determinants of *WTP* for wetlands protection. *LTFFCAT* was statistically significant with a negative sign. *LPOLL* has a positive sign but is not statistically significant. *LBOAT* is statistically significant with a positive sign.

The specification of the *INFORM* variable tests the hypothesis (H^1) of no statistically significant effect of increased *SI* on the magnitude of *WTP*. As indicated in table 1, however, the *INFORM* variable was statistically significant at the .01 level of significance. Thus, the hypothesis of no statistically significant effect is rejected. Moreover, the sign of the regression coefficient is positive. This positive sign suggests that additional *SI* increased *WTP*.

SI Test Implications

The results of the CVM field survey experiment indicate that additional service information (*SI*) induces recreationists to increase *WTP* for wetlands protection. The additional *SI* apparently had a stronger positive impact on the post-payment utility level which, by (3), increases *WTP*. Is this effect of *SI* desirable? This question is difficult to answer. First, if additional *SI* is false

Table 1. WLS Estimates for Wetlands Protection Bid Function

Parameter Estimates (Standard Error)

Note: Single asterisk indicates significant at the .05 level; double asterisk indicates significant at the .01 level; $\bar{R}^2$ is adjusted R^2.

[2] It is possible that information also may impact the variance of *WTP*. For example, increased *SI* may increase the uniformity of service or attribute perceptions across respondents and therefore decrease the variance of *WTP*. On the other hand, because respondents' preferences for the additional services or attributes described by *SI* may vary considerably, increased *SI* may increase the variance of *WTP*. The specification of (6) imposes the restriction that if *SI* increases (decreases) *WTP*, it must also increase (decrease) the variance of *WTP*. Hence, the hypotheses about the effect of *SI* on the variance of *WTP* cannot be tested. The homoskedasticity tests on (7) indicated a negative relationship between *SI* and the variance of *LWTP*. This negative relationship disappeared when (7) was estimated by weighted least squares.

It was thought that the nonlinear specification of (6) would provide a stronger test of the effect of information on the magnitude of *WTP*, which was the focus of this study. Further research designed specifically to test for the effects of information and other variables on the variance of *WTP* using less structured bid functions is encouraged.

or misleading, changes in valuations induced by that information are not desirable. For example, if additional *SI* describes nonexistent beneficial consumption services or attributes supported by wetlands, or distorts existing beneficial consumption services or attributes in a positive direction, recreationists may be induced to overstate *WTP* for wetlands protection. Such overvaluation may lead to excess wetlands protection from a benefit-cost or potential Pareto-efficiency standpoint.

Another issue relates to the completeness of information and the certainty of consumer valuation processes. When consumers value a change in a commodity with a positive marginal utility, Hoehn and Randall argue that uncertain valuation processes result in undervaluation of the change. One cause of uncertain consumer valuation processes may be incomplete information.

For example, in the present study it was conjectured that recreationists may not automatically consider all of the beneficial consumption services or attributes supported by wetlands when valuing wetlands protection. Thus, as Hoehn and Randall suggest, CVM participants not given additional *SI* may have undervalued wetlands protection. Such undervaluation may result in underprovision of wetlands from a benefit-cost or potential Pareto-efficiency standpoint. Increased wetlands valuation resulting from more complete and certain consumer valuation processes may be a desirable effect of additional *SI*.

The results of the *SI* experiment, although consistent with previous studies, must be cautiously interpreted. The additional *SI* presented to recreationists described beneficial consumption services or attributes (as indicated by responses to an on-site preference survey). Wetlands also support consumption services or attributes such as exposure to insects, poisonous snakes, and hungry alligators, which some recreationists may perceive negatively. Additional *SI* which describes negative consumption services or attributes may induce reductions in *WTP* for wetlands protection. Thus, the results of the *SI* experiment do not imply that additional *SI* will always increase *WTP* for an environmental commodity.

Conclusions

Information may be an inportant determinant of perceived values that consumers place upon environmental commodities. Information is also a critical component of contingent valuation studies, but the effects of potential "information biases" are poorly understood. In this paper, a theoretical model of the effects of service information on rationed environmental commodity valuations was developed. *SI* describes consumption services or attributes which can be derived from a given environmental commodity with fixed, objectively measurable characteristics.

The theoretical model was applied to develop a testable hypothesis concerning the effect of *SI* on the magnitude of willingness to pay (*WTP*) for wetlands protection. This hypothesis was tested using a contingent valuation method (CVM) field survey experiment. The results indicate that *SI* increased *WTP* for wetlands protection. This information effect is argued not to be an undesirable bias. Rather, it is contended that *SI* increased the completeness and accuracy of wetlands protection valuations and therefore induced a desirable information effect. The results, in general, support the argument that information is an important input into consumer valuation decisions.

The *SI* presented to CVM participants described only beneficial consumption services or attributes supported by wetlands. The results may not generalize to situations where additional *SI* may also describe consumption services of attributes that consumers value negatively. A more complete understanding of the effects of specific types of information on consumer valuation decisions requires additional research.

Appendix

Service Information in Alternative Questionnaire Versions

Version A (No Explicit Service Information)
In the study wetland area, however, management programs could be carried out to reduce the rate of marsh loss. By reducing marsh loss, such programs would help to preserve populations of waterfowl, freshwater fish, saltwater fish, shrimp, and crabs in the study wetland area.
Version B (Explicit Service Information)
In the study wetland area, however, management programs could be carried out to reduce the rate of marsh loss. By reducing marsh loss, such programs would help to preserve populations of waterfowl, freshwater fish, saltwater fish, shrimp, and crabs in the study wetland area. Preservation of waterfowl, freshwater fish, saltwater fish, shrimp, and crab populations would help to protect your bag or catch of these species. Reduced marsh loss would also help to preserve other attributes of wetlands which you may value; for example: opportunities for viewing wildlife, marsh scenery, and isolated or remote areas where you can experience the outdoors.[a]

[a] To simplify and reduce wording, the phrase "attributes of wetlands" was used to represent consumption services or attributes associated with consumption activities produced from wetlands (e.g., recreational trips). The use of this phrase is consistent with the conceptual model, and it is argued that the meaning of the wording was clear to respondents from the context of the paragraph. Respondents were asked to provide feedback on the clarity of the questionnaire wording. None indicated problems understanding the questionnaire, including the service information.

Relative Agricultural Prices and Monetary Policy

John S. Lapp

An imperfect information, rational expectations model of relative price determination is presented. This model provides an econometric specification for testing for a causal relationship between money and the relative prices of agricultural commodities. Test results indicate that variations in the growth rate of the nominal money supply (whether anticipated or unanticipated) have not been an important influence on the average level of prices received by farmers relative to other prices in the economy over the period 1951–85.

Key words: commodity prices, monetary policy, relative prices.

At least since Schuh's 1974 article, interest has continued in the possible effects of monetary policy on agricultural markets. The issue is important because policies to stabilize agricultural markets must consider the sources of volatility in the industry. This paper explores this issue by studying the relationship between the growth rate of the nominal money supply and the relative price of agricultural commodities (defined as the "Index of Prices Received by Farmers" deflated by an aggregate price index). The focus is on relative agricultural prices because theory relates this price variable to issues involving supply, demand, and welfare. Unlike earlier work on this topic, the paper employs a model of the type introduced by Lucas and Barro which assumes market clearing equilibrium and imperfect information about aggregate prices. This model implies that unexpected money growth, but not anticipated money growth, may affect relative agricultural prices.

Empirical evidence indicates that nominal agricultural prices are affected by monetary events (Chambers and Just, Rausser et al., Orden (1986b, Starleaf). This implies short-run relative price effects if prices are sticky in other markets but flexible in agriculture.[1] However, Pauls has shown that relative prices in several supposedly sticky price industries behave as if prices were generally flexible. See Chambers (1984, 1985) for a discussion of the crucial role of the sticky prices assumption in this literature. Explicit tests for monetary effects on relative agricultural prices yield mixed results. Orden (1986b); Starleaf, Meyers, and Womack; and Devadoss and Meyers find evidence for effects on relative agricultural prices.[2] Belongia found small effects of unanticipated inflation on relative agricultural prices. Bessler, Gardner, and Grennes and Lapp, on the other hand, find that relative agricultural prices are not affected by nominal macroeconomic variables.

This paper is organized as follows. The next section develops a model of relative prices and monetary shocks which leads to an empirical specification for hypothesis testing. The third section sets out a strategy for testing for a relationship between money growth and relative agricultural prices. The empirical results are presented in the fourth section. Conclusions are discussed in a final section.

Model

The logic of the model is summarized as follows.[3] Buyers and sellers enter any product market with knowledge of supply and demand con-

John S. Lapp is an associate professor, Department of Economics and Business, North Carolina State University.

The author thanks Michael Belongia, John Dutton, Thomas Grennes, Paul Johnson, Michael McElroy, Douglas Pearce, Vincent Smith, Walter Thurman, and two anonymous reviewers for their helpful criticisms and suggestions. Any remaining errors and shortcomings are the responsibility of the author.

[1] This result derives from the fix price-flex price models discussed by Okun. See Bordo for an application to relative prices. Frankel has formally modeled this for agricultural markets by applying the overshooting phenomenon.

[2] Chambers (1984) finds evidence that money affects a set of three variables including relative agricultural prices, but does not report results for the individual variables.

[3] The following derivation generally follows Hercowitz but incorporates intertemporal substitution, as suggested by Pauls.

ditions and an expectation of the general price level. This implies an expected nominal price for the product. The actual nominal price will generally differ from the expected value due to real and monetary shocks. Because these shocks cannot be individually observed, the monetary shocks may be mistaken for real shocks. If so, the monetary shocks will affect the actual relative price.

Assume that supply and demand conditions in market i are given by

$$(1)\quad y(i)_t^s = \alpha(i)^s[P(i)_t - E(P_t)] + \beta(i)^s E[P(i)_{t+1} - P_{t+1}] + \epsilon(i)_t^s, \text{ and}$$

$$(2)\quad y(i)_t^d = \alpha(i)^d[P(i)_t - E(P_t)] + [M_t - E(P_t)] + \beta(i)^d \cdot E[P(i)_{t+1} - P_{t+1}] + \epsilon(i)_t^d,$$

where $y(i)$ is the quantity sold in market i, $P(i)$ is the market i price, P is the aggregate price level, M is the nominal money supply, E is the expectations operator and $\epsilon(i)^s$ and $\epsilon(i)^d$ are normal, i.i.d. disturbances. All variables are expressed in natural logarithms.

Supply and demand depend on current and expected, future relative prices, reflecting the opportunity for intertemporal substitution. Suppliers can wait until the following period to sell output, or sell from stocks, depending on their relative price expectations. Similarly, demanders can defer or accelerate purchases. The opportunities for intertemporal substitution may be more limited in agriculture than in some other industries. Nonetheless, choices about the timing of slaughter and storage permit some intertemporal substitution on both sides of the market.[4] Thus, $\alpha(i)^s > 0$, $\alpha(i)^d < 0$, $\beta(i)^s < 0$ and $\beta(i)^d > 0$ are assumed. The effects of interest rates and storage costs are not considered. Demand shifts with the real money supply, evaluated at the expected price level, as changes in the real money supply affect aggregate demand and, therefore, the demand for agricultural commodities. This includes exchange rate influences on agricultural markets caused by changes in the real money supply. The unit elasticity for expected real money balances is imposed to facilitate the analysis.

Market participants are assumed to know the nominal price of the commodity, but are uncertain of the aggregate price level. Hence, the relative price is uncertain.

The nominal money supply is represented as

$$(3)\quad M_t = M_{t-1} + g_t + m_t,$$

where g_t is expected, and m_t is unexpected, money growth; m_t is normally distributed with zero mean and variance σ_m^2 and is serially independent.[5]

Solving (1) and (2) for $P(i)_t - E(P_t)$, using the market clearing condition, yields

$$(4)\quad P(i)_t - E(P_t) = \tau(i)\{M_t - E(P_t) + \beta(i)E[P(i)_{t+1} - P_{t+1}] + \epsilon(i)_t\},$$

where $\tau(i) = 1/[\alpha(i)^s - \alpha(i)^d]$, $\beta(i) = \beta(i)^d - \beta(i)^s$, and $\epsilon(i)_t = \epsilon(i)_t^d - \epsilon(i)_t^s$ and is distributed as $N(0, \sigma_i^2)$. Then,

$$(5)\quad P(i)_t = [1 - \tau(i)]E(P_t) + \tau(i)(M_t + \epsilon(i)_t) + \tau(i)\beta(i)E[P(i)_{t+1} - P_{t+1}].$$

Equation (5) is usefully rewritten, using (3), as

$$(5')\quad P(i)_t = [1 - \tau(i)]E(P_t) + \tau(i)(M_{t-1} + g_t + m_t + \epsilon(i)_t) + \tau(i)\beta(i)E[P(i)_{t+1} - P_{t+1}].$$

Market participants are assumed to know the terms in (5′) except for m_t and $\epsilon(i)_t$. Therefore, the observation of $P(i)_t$ permits market participants to deduce $(m_t + \epsilon(i)_t)$, but not m_t or $\epsilon(i)_t$ individually. If sufficient information were available, market participants would only react to $\epsilon(i)_t$. Since $\epsilon(i)_t$ cannot be identified, market participants may erroneously react to m_t as if it were a real shock.

This process is modeled as a revision of $E(P_t)$ conditional on the observed $P(i)_t$. The value of the observed nominal price relative to the conditional expectation of the aggregate price level is the current, expected relative price in (1) and (2). The revision of $E(P_t)$ is based on the portion of $(\epsilon(i)_t + m_t)$ that is attributed to m_t. Since the portion of $(\epsilon(i)_t + m_t)$ that is due to each component is unknown, statistical methods are used to apportion the observed joint shock between the two components. The optimal expectation of m_t, i.e., the mean of the distribution conditional on the observed $P(i)_t$, is

$$(6)\quad E(m_t) = [\sigma_m^2/(\sigma_m^2 + \sigma_i^2)](m_t + \epsilon(i)_t).$$

[4] This model reflects the time at which produce is sold. Therefore, the nominal market price is observable. An alternative viewpoint would be earlier in the production process when the nominal price is not observable. Decisions made at the earlier time have implications for the supply and demand equations assumed here. However, these implications are not treated in this paper.

[5] For the current problem the process generating g_t and m_t need not be specified. Assuming that economic agents enter each period with an expectation of money growth, g_t, is sufficient. Empirical proxies for g_t and m_t are presented below.

As the uncertainity associated with money (σ_m^2) is larger relative to σ_i^2, more of $(\epsilon(i)_t + m_t)$ is attributed to a money growth shock and less to a real shock.

Market participants are assumed to know σ_m^2, σ_i^2 and $(m_t + \epsilon(i)_t)$ and to use this information to revise the expectation of P_t. It is a straightforward, but lengthy, matter to show (see Hercowitz, pp. 333–34) that

$$(7) \quad E(P_t) = M_{t-1} + g_t + [\sigma_m^2/(\sigma_m^2 + (1/\tau)\sigma_i^2)](m_t + \epsilon(i)_t),$$

where τ is the average value of $\tau(i)$ across all markets. Then, using (7) and (5′),

$$(8) \quad P(i)_t = M_{t-1} + g_t + \{[1 - \tau(i)]\Theta(i) + \tau(i)\} \cdot (m_t + \epsilon(i)_t) + \tau(i)\beta(i)E[P(i)_{t+1} - P_{t+1}],$$

where $\Theta(i) = [\sigma_m^2/(\sigma_m^2 + (1/\tau)\sigma_i^2)]$.

Averaging (8) across all markets yields the aggregate price level,

$$(9) \quad P_t = M_{t-1} + g_t + [(1 - \tau)\Theta + \tau]m_t,$$

where Θ is the average, value of $\Theta(i)$ across all markets.[6]

Equations (8) and (9) give the equilibrium values of $P(i)_t$ and P_t that are observed, *ex post*. Subtracting (9) from (8) yields the observed, equilibrium relative price of commodity i,

$$(10) \quad P(i)_t - P_t = \tau(i)\beta(i)E[P(i)_{t+1} - P_{t+1}] + (1 - \Theta(i))[\tau(i) - \tau]m_t + \{[1 - \tau(i)]\Theta(i) + \tau(i)\}\epsilon(i)_t.$$

In general, the relative price in market i depends on the current money growth shock. The sign on m_t is unknown because $[\tau(i) - \tau]$ depends on market-specific supply and demand elasticities. The sign must vary across markets because all relative prices cannot move in the same direction.

The remaining issue is to develop a proxy for $E[P(i)_{t+1} - P_{t+1}]$. Presumably, economic agents base this expectation on industry-specific knowledge that is not observable to the analyst. Pauls provides the necessary proxy by assuming that

$$(11) \quad E[P(i)_{t+1} - P_{t+1}] = A_1(L)[y(i)_{t-1} - y_{t-1}] + A_2(L)[P(i)_{t-1} - P_{t-1}],$$

where $y(i)$ and y are output in market i and in the aggregate, respectively, and $A_1(L)$ and $A_2(L)$ are polynomials in the lag operator. The real factors affecting any market in a given period will be reflected in the relative price and quantity in that market. If these real factors or their effects are serially correlated, the relative prices and quantities in one period contain information that is relevant for predicting relative prices in later periods. Moreover, anticipated future supply and demand factors will affect relative prices and quantities in the periods when those anticipations are formed. Based on these relationships, lagged values of relative prices and quantities reflect information that is the basis for expectations of future relative prices. Including quantities in (11) adds information that is not captured by relative prices alone since, in principle, including quantities would allow demand and supply shifters to be identified. Quantities are expressed relative to aggregate output to correct for scale effects over time. Pauls cites the Hansen and Sargent modeling of dynamics in a rational expectations framework in support of this approach.

Substituting (11) into (10) and setting $i = a$ to specify the market for agricultural commodities, yields the following equation for the relative price of agricultural commodities

$$(12) \quad P(a)_t - P_t = \tau(a)\beta(a)\{A_1(L) \cdot [y(a)_{t-1} - y_{t-1}] + A_2(L)[P(a)_{t-1} - P_{t-1}]\} + (1 - \Theta(a))[\tau(a) - \tau]m_t + \{[1 - \tau(a)]\,\Theta(a) + \tau(a)\}\epsilon(a)_t.$$

Equation (12) implies that the relative price of agricultural commodities may be correlated with the contemporaneous monetary shocks, m_t if $[\tau(a) - \tau]$ is nonzero. If supply and demand in agricultural markets are less elastic than average, as is usually expected, the sign of $(1 - \Theta(a))[\tau(a) - \tau]$ will be positive.[7] This equation also implies that relative agricultural prices are independent of past monetary growth rates and the anticipated component of money growth. These factors are not mistaken for real shocks and, therefore, do not affect supply or demand.

From the definition of $\Theta(a)$, the coefficient on m_t is related to the variance of unexpected money growth, σ_m^2, because greater uncertainty about money growth decreases the extent to which real market shocks are inferred from observations on nominal market prices.

[6] $\epsilon(i)_t$ drops out of (8) since its average value, across all markets, is zero. The last term of (8) disappears since the average $P(i)$, for any period, is P.

[7] The author is indebted to a reviewer for this insight. The estimated coefficients for m_t reported below are positive.

Empirical Tests

The empirical sections of this paper present tests for a statistically significant relationship between money growth and relative agricultural prices.[8] The form of the equations to be estimated is given by (12), rewritten as

$$(13)\quad P(a)_t - P_t = a_0 + \sum_{k=1}^{N} [a_k(P(a) - P)_{t-k} + b_k(y(a) - y)_{t-k}] + \sum_{j=0}^{T} [c_j\mu_{t-j} + d_j\mu_{t-j}\sigma_{\mu t-j}] + \epsilon_t.$$

The variable μ represents actual money growth or any of three alternative measures of anticipated and unanticipated money growth as defined below. The standard deviation of unanticipated money growth is σ_μ. Initially the d_j were constrained to zero.

These equations were estimated using quarterly data for the period 1951–85. The relative prices of agricultural commodities were measured by the "Index of Prices Received by Farmers" deflated by (*a*) the consumer price index (CPI), and (*b*) the producer price index (PPI). The relative output of agricultural commodities was measured by real GDP for the farm sector relative to total real GDP. The *M*1 definition of the money supply was used.

Expected and unexpected money growth must be defined. Since there is no way to know if an appropriate measure of anticipated money growth has been used, three different definitions were employed, each derived by a different method. It is assumed that expectations of money growth are formed for one quarter ahead and that expectations with a longer horizon are not formed.

The money growth variables used for estimation are as follows: *MU*, The actual, annualized, quarterly growth rate; *MUS*1, The residual from an estimated Box-Jenkins "Airline Model" ARMA process (which includes AR terms at the seasonal lags) for the quarterly growth rate of the money supply;[9] *MUX*1, *MU* minus *MUS*1; *MUS*2, the difference between the actual money growth rate and the bond-equivalent yield on 3-month treasury bills maturing at the end of the quarter;[10] *MUX*2, *MU* minus *MUS*2; *MUS*3, The residual from a regression of *MU* on lagged value of *MU*, lagged inflation rates and lagged unemployment rates;[11] *MUX*3, *MU* minus *MUS*3. *MUS*1, *MUS*2, and *MUS*3 are alternative measures of unexpected money growth shocks. *MUX*1, *MUX*2 and *MUX*3 are the corresponding measures of expected money growth.[12] The *MUS*1 and *MUS*3 measures meet the requirement of being white noise residuals. The theory predicts that any relationship between relative prices and money growth will be found in the variables *MUS*1, *MUS*2, or *MUS*3, not in *MUX*1, *MUX*2, or *MUX*3. *MU* was included among the specifications for generality.

Equation (13) does not directly control for real factors affecting agricultural markets. However, to the extent that these factors or their effects are serially correlated, they are captured in the lagged values of relative prices and quantities. Otherwise, they constitute the error term.

The theory applies to contemporaneous money growth shocks but cannot determine the length of the contemporaneous period. Because the appropriate length of a period may be longer than a quarter, a variety of lag lengths were considered. Short lags on *MUS*1, *MUS*2, or *MUS*3 would be consistent with the model; long lags would not. The lag lengths are defined in (13) by the parameters *N* and *T*. Because these tests can be sensitive to lag lengths (Saunders), they were based on the values 4, 8, and 12 for *N* and 0, 1, 2, 3, 4, 8, and 12 for *T*. The results for $N = 8$ and $N = 12$ are the same as the results for $N = 4$ except that the significance levels are lower. Only the results for $N = 4$ are reported below. Tests based on $T = 8$ and $T = 12$ never showed significant results and are not reported below.[13]

The relative prices of agricultural commodities have a distinct downward trend over the

[8] All data are from CITIBASE except for the nominal money supply for 1947: 1-1958:4, which is from the Federal Reserve Bank of St. Louis and the "Index of Prices Received by Farmers" prior to 1965:1, which are from *Agricultural Prices, Annual Summary*, various years, USDA, Washington DC. Estimates were computed using SHAZAM (White).

[9] This measure of unanticipated money growth is based on the assumption that economic agents try to extrapolate past patterns of money growth in forming expectations of future money growth.

[10] This market-based measure of unexpected money growth requires a constant trend rate of growth of the velocity of money (Levi and Shapiro). Hence, the sample period was terminated at 1981:4 for tests involving this measure.

[11] This measure assumes that economic agents predict money growth on the basis of the Fed's likely reaction to important macroeconomic variables. The lag length was nine quarters, which minimized the Akaike final prediction error.

[12] Tests based on a two-step estimation procedure have been criticized as inefficient (Mishkin). However, joint estimation is not practical here because the moving standard deviation of unexpected money growth is used as a measure of $\sigma\mu$. Therefore, *MUS*2 was used as an alternative measure.

[13] Results for $N = 8$, 12 and $T = 8$, 12 are available from the author.

sample period. Consequently, the variables were first differenced for stationarity. A dummy variable, equal to 1 for each quarter in 1973 and 0 otherwise, was included to control for the atypical volatility in 1973.

The tests in this paper are t- and F-tests of the hypotheses that the c_j and d_j of (13) are individually or jointly zero. To use the t- and F-tests the disturbances must have a normal distribution and serial independence. Therefore, the regression residuals were subjected to the Jarque-Bera Lagrange Multiplier test for normality and Durbin's h, Durbin's m, and the Box-Pierce-Ljung Q tests for serial correlation.[14] Estimation of (13) using the full period as a single sample did not pass these tests for either normality or serial independence. However, when the sample was split after 1972:4, equations with well-behaved residuals were estimated separately for each subperiod. This break point was based on a plot of the dependent variable. A disruption in commodity markets, the emergence of OPEC, a change in the operation of price supports in agriculture and the general conversion to floating exchange rates all occurred in 1973. Thus, the period beginning in 1973 differed substantially from the preceding period.

F-tests showed that seasonal factors were important in the earlier period, but not for the later period. Hence, seasonal dummy variables were included in regressions for the earlier period.

Empirical Results

Table 1 reports results for tests of serial correlation, normality, and goodness-of-fit for $T = 0$, $N = 4$. The results indicate that the model explains about 30% and, in some cases more, of the variation in the relative price of agricultural commodities (first differenced). The residuals are well-behaved and the F-ratios are generally significant.[15]

Table 2 presents the results of testing for monetary effects for alternative money growth variables, alternative values of T and both price deflators for $N = 4$. The entries are F-ratios for

the hypothesis $c_0 = \ldots = c_T = 0$ in (13). None of the F-ratios in these tables indicate a significant relationship between relative agricultural prices and actual money growth or any of the measures of expected money growth. A statistically significant relationship between relative agricultural prices (using either definition) and unanticipated money growth is suggested for $MUS1$, but not $MUS2$ or $MUS3$, in the first period for the short lag lengths. There is no evidence of a significant relationship between any of the money growth variables and the dependent variables for the second period.

Table 3 shows the coefficient estimates and their t-ratios for contemporaneous and lagged $MUS1$ for the significant specifications in table 2. These estimates show that an unexpected money growth shock had a positive effect on the relative price of agricultural commodities for the period before 1973. This direct effect appears to have persisted for two quarters. Given the lagged values of the dependent variable on the right-hand side, monetary shocks had persistent indirect effects. Based on the Akaike final prediction error criterion the optimal lag length for lagged relative prices was four quarters. The sums of the estimated coefficients on lagged relative prices are less than 0.3. Hence, the indirect effects of money growth shocks are small and die out quickly.

The economic significance of these effects can be considered in two ways: (a) by considering the estimated effect of a representative money growth shock on relative agricultural prices, and (b) by considering the effects of money growth shocks on the explanatory power of the regression equations. Using the coefficient estimates from the first row of table 3, consider a positive money growth shock equal to one standard deviation of $MUS1$. The direct effect of the shock would cause the relative price of agricultural commodities (using the CPI as the deflator) to be increased by 0.0027 in the quarter in which the shock occurred and by 0.0036 in the following quarter. This compares to an average value during this period of 0.6075 and a standard deviation of 0.0838. That is, the response to a money growth shock equal to one standard deviation of unexpected money growth is less than one-tenth of the standard deviation of relative agricultural prices.

Table 4 presents adjusted R^2 values for those specifications in table 2 with significant F-ratios and for specifications containing no money growth variables. The inclusion of contemporaneous and lagged $MUS1$ provides a modest, yet statistically significant, increase in the explained variation in the relative prices of agricultural commodities. However, money growth shocks account for a negligible fraction of the variation in the relative prices of agricultural commodities.

Equation (13) was estimated without constraining the d_j to zero to consider the effect of the variability of money growth. Moving stan-

Table 4. Adjusted R-Squared Values for Specifications with Significant F-Ratios in Table 2 and for Specifications without Money Growth

dard deviations were calculated as measures of σ_μ for each of the measures of unexpected money growth. F-tests of the hypothesis $c_0 = c_1 = d_0$ $d_1 = 0$ were computed for $N = 4$ and $T = 1$ for each definition of relative prices and each time period. All of the F-ratios were insignificant.

Conclusions

According to the empirical results in this paper, monetary policy has not been a quantitatively important determinant of relative agricultural prices. A statistically significant relationship between money growth and relative agricultural prices was found only for one of three measures of unexpected money growth and only for the period before 1973. No significant relationship was found for actual money growth, for expected money growth, or for the standard deviation of unexpected money growth.

The single significant relationship indicated a transitory, positive impact of unexpected money growth on the relative price of agricultural commodities. The estimated effect is quantitatively small and does not explain an economically meaningful portion of the variation in the relative price of agricultural commodities.

For the period after 1972, no relationship is indicated. The finding of independence of relative agricultural prices from monetary disturbances is consistent with recent findings by Kretzmer. He reports finding real effects from money shocks in a variety of industries, but not in the agriculture, forestry, and fisheries industry.

A Policy Preference Function for Government Intervention in the U.S. Wheat Market

James F. Oehmke and Xianbin Yao

This paper estimates a policy preference function that explains the government's choices of target prices, government held wheat stocks, and public wheat research funding. The policy preference function depends on producers' surplus, consumers' surplus, and budget expenditures. An important innovation in this paper is the inclusion of interactions between public research expenditures and other public policy variables. Results indicate that the government places a premium of 25% to 45% on the welfare of wheat producers of relative to budget expenditures, while wheat consumers' welfare is discounted as much as 50% relative to budget expenditures.

Key words: agricultural research, policy preference function, wheat.

The purpose of this paper is to provide an explanation of government commodity programs, stock accumulations, and research expenditures in the U.S. wheat sector. The explanation is based on a policy preference function (PPF) that depends on producers' surplus, consumers' surplus, and budget expenditures. It is assumed that target prices, reductions in (or additions to) government stocks, and public research expenditures are chosen to maximize the policy preference function. The central contribution of the paper is the estimation of a function that is consistent with the observed government interventions in the U.S. wheat market. That is, the paper explains the observed target prices, government sales, and public research expenditures as rational behavior by a government which seeks to maximize the estimated policy preference function.

The approach in this paper is based on the political interest group theories of Peltzman and Becker. Applications of these ideas to agriculture include Rausser and Freebairn's description of the beef industry, Gardner's (1985) analysis of commodity price programs and his simulation of optimal agricultural research expenditures (Gardner 1987), Pashigian's explanation of futures trading restrictions, and Chou's international political interest group model. The major innovation here is the explicit modeling of interactions between research and other government interventions in a simple dynamic framework. Previous explanations of research support have generally ignored the effects of nonresearch government policy (e.g., Evenson, Waggoner, and Ruttan; Ruttan; Oehmke).

The remainder of the paper is organized as follows. The next three sections describe the rationale behind the policy preference function, specify the functional form of the PPF, and introduce the policy instruments of public research funding, commodity programs, and changes in government stocks. The effects of these instruments on market variables and on the components of the government PPF are analyzed. The model then is applied to the U.S. wheat sector.

The Political Decision-Making Process

Peltzman and Becker (1983, 1974) model the political decision process as a set of interactions between the actors affected by potential government policies and the administering agencies.

James F. Oehmke is an assistant professor and Xianbin Yao is a graduate student, Department of Agricultural Economics, Michigan State University.

Acknowledgement is given to the Michigan Agricultural Experiment Station for their support.

The authors would like to thank Robert Evenson, Bruce Gardner, Robert Myers, two anonymous referees, and participants in workshops at Michigan State University, the University of California at Berkeley, University of California, Davis, the University of Chicago, and the University of Maine for helpful comments and discussions. The authors are responsible for any errors.

We call the administering agencies "the government," and the other agents are called "interest groups" (IGs). The interactions between the government and the IGs result in a particular set of policies. The set of policies is determined by the pressures of various IGs and the government's responses to these pressures. These pressures and responses will be determined in part by the size of the group, the transactions costs within the group, total benefits per member from the potential policy, the distribution of benefits within the group, and the costs of influencing the government. The relationships among the IGs will also be important: individuals may be members of more than one IG, e.g., farmers and consumers; interest groups may have complementary purposes, e.g., corn producers and soybean producers; the groups may directly oppose each other, e.g., dairy and beef producers on the dairy termination program; or groups with similar interests may have trouble working together, e.g., California and Minnesota dairy producers on the regulation of bovine somatatropin.

The result of these interest group and government interactions is a set of policies that may provide a positive net payoff to some IGs and a negative net payoff to others. Naturally, each interest group desires to receive a positive net payoff but may find it too costly to influence the government effectively. When inefficiencies occur in the transmission of benefits from one group to another, this policy formation process can be thought of as a negative sum game. That is, if government policies have associated deadweight losses, then society faces an overall net decline in economic efficiency (also see the literature on DUPs; e.g., Bhagwati, or Bhagwati and Srinivasan). If part of the transfer is motivated by altruism (Becker 1983, 1974) and if the government makes the transfer efficiently, then the policy formation process can be a positive sum game (Bullock).

The Peltzman-Becker theory of regulation and interest groups leads to empirical models in which the policy instruments and/or the degree of intervention are dependent variables. An important class of models (policy preference function models) focuses on the government agencies making the policy decisions. The PPF models assume that the interest group pressure forces the government to consider a set of criteria that roughly correspond to the desires of the various interest groups; these criteria are then arguments in the government's PPF. Examples of possible criteria are consumers' surplus, producers' surplus, net farm income, net exports, and government budget expenditures. In a PPF model the government chooses the types and degrees of intervention to maximize an objective function dependent on these multiple criteria. The resulting empirical formulation is an equation where the types and degrees of intervention are the dependent variables, and the set of criteria is the set of explanatory variables.

The Policy Preference Function

The policy preference function for the government is

$$V = \sum_{t=0}^{\infty} \beta^t V_t(\Delta CS, \Delta PS, \Delta G), \tag{1}$$

where ΔCS is the change in consumers' surplus, ΔPS is the change in producers' surplus, and ΔG is the change in budget expenditures attributable to the government intervention; V_t is the instantaneous value function representing the governments's preferences at time t; and β is a discount factor. (For a similar but static formulation, see Gardner 1983.) The first two arguments in the objective function are the constituents of any increase in social surplus ($SS = CS + PS$ in an undistorted market), which is a relevant measure of economic efficiency (Currie, Murphy and Schmitz). Consumers' surplus and producers' surplus are treated separately in (1) because the distribution of benefits between consumers and producers may be important to the government. Traditionally, the United States has been willing to redistribute income to farm producers. Equation (1) can capture this objective by placing a relatively high weight on producers' surplus.[1] The third argument in (1) is government expenditures. These are politically and economically important: the economic aspect will be discussed in greater detail below. It is assumed that $\partial V/\partial(\Delta PS) > 0$, $\partial V/\partial(\Delta CS) > 0$, and $\partial V/\partial\ (\Delta G) < 0$. In the special case when $V = \Delta PS + \Delta CS - \Delta G$, the value function approach is equivalent to the standard benefit-cost analysis of public policies (Harberger, Gittinger, Akino and Hayami).

The government's policy instruments are expressed in a commodity program that includes a target price, P_t, changes in government-owned

[1] Formally, we would expect that $\partial V/\partial(\Delta PS) > \partial V/\partial(\Delta CS)$ in a neighborhood of the no-intervention equilibrium.

stocks, Z_t, and a public research program with expenditures of R_t. These policy instruments affect CS, PS, and G. The choices of P_t, Z_t, and R_t are made to maximize V. Other types of government interventions such as lump-sum transfers or export subsidies that were infrequently used during the sample period (1978–85) are not considered.[2]

The solutions to (1) are referred to as the "policy optimal" target price, changes in government stocks, and public research funding levels. This nomenclature will distinguish these levels from the economically efficient levels, which the literature often refers to as the "optimal" levels.

The Policy Tools

This section presents a partial equilibrium model of a competitive, international market for a single agricultural good that is affected by the policy tools of publicly sponsored research, target prices, and sales from government stocks (for similar models, see Carter or Rodgers).

The agricultural markets are depicted in figure 1. Panel *a* represents the U.S. market for the agricultural output and panel *b* represents the world market. In panel *a* curves *D* and *S* are the domestic demand and supply curves that would occur without government intervention. In the world market the *ES* curve is the difference between the U.S. supply and demand curves; it represents the excess supply in the United States or, equivalently, it represents the supply of exports from the U.S. private sector to the rest of the world (ROW). The *ED* curve represents the excess demand by the ROW. In the absence of government intervention, the equilibrium will occur at the world price P_{w0} satisfying $ED(P_{w0}) = ES(P_{w0})$.

These supply and demand curves represent an intermediate-run scenario. The supply curve is considered a preplanting supply curve: the farmer still must make this year's production decisions, but available land, buildings, and to some extent equipment, are fixed.

The first policy instrument is a publicly funded research program that reduces production costs throughout the relevant range. The second policy instrument is a commodity program that includes a target price with a subsidiary loan rate set at or below the market price and an acreage set-aside requirement for participation in the

[2] For a discussion of the choice of policy instruments see Paarlberg (1984, 1985), Gardner (1983, 1985) and Orden.

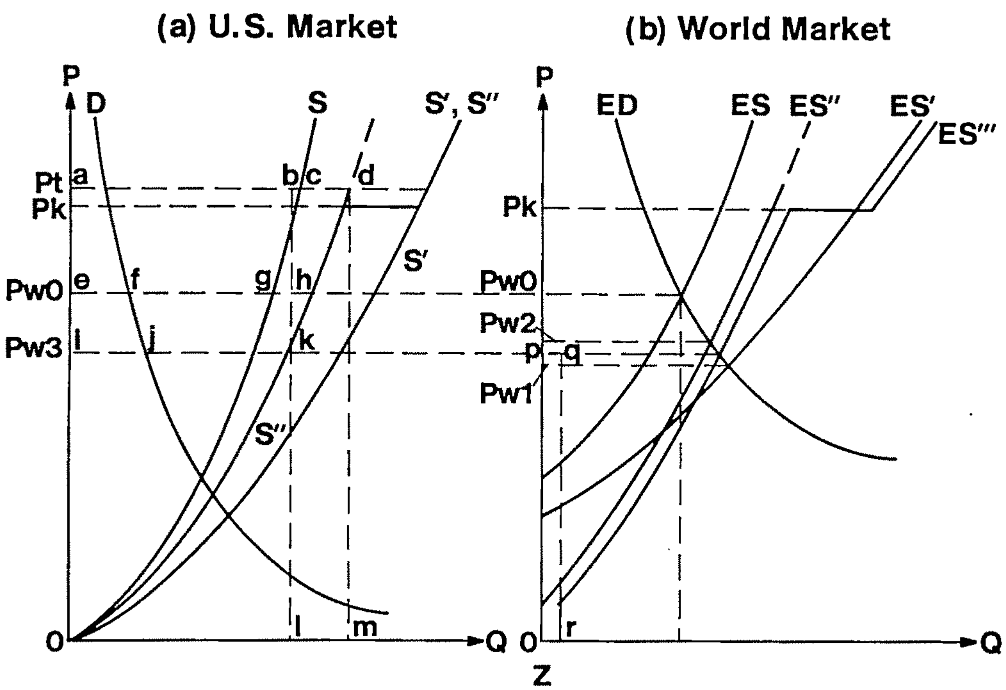

Figure 1. The effects of interventions on the agricultural markets

program. The target price in effect guarantees to domestic producers an amount equal to the target price for each unit produced on program acreage. Farmers are assumed to sell first to the market at the world price and then to the government at the loan rate. The government then makes up, through deficiency payments, any difference between the market price or loan rate and the target price. The cost of the commodity program includes the cost of the loans made to farmers plus the deficiency payments. The government can choose to reduce the stocks accumulated through the commodity program by selling grain on the world market. The third government policy instrument is the sale of grain from stocks.

Public research reduces production costs so that the supply curve S shifts to S'. The excess supply schedule ES' is derived by subtracting the demand curve from the shifted supply curve: $ES'(P) = S'(P) - D(P)$, and consequently ES' shifts to the right as S' does. The equilibrium world price falls from P_{w0} to P_{w1}.

The acreage set-aside requirement reduces output at all prices less than P_k by a proportion h. For these prices the supply curve S shifts back to the left, as represented by the supply curve S''. Figure 1 represents a net government intervention effect in which the supply curve shifts to the right, from S to S'', representing a decrease in production costs (the research effect dominates). Thus, world price P_{w2} is lower than P_{w0}.

The target price supports U.S. producer prices at level P_t. For market prices sufficiently below P_t, domestic supply will always equal the quantity $S''(P_t)$ because P_t is the price relevant to the farmers' decisions. At some market price near P_t, say P_k, farmers (with perfect foresight) will not enroll in the commodity program and thus will not be subject to acreage restrictions. These considerations lead to a kink in the supply curve S'' at P_k, as farmers shift from the acreage-constrained production to the unconstrained production represented by the supply curve S'. In figure 1 this kink is depicted by the horizontal segment of S'' at price P_k. At prices above P_k, the curves S' and S'' coincide. The corresponding kink in the excess supply schedule ES'' is depicted by a horizontal segment at price P_k, and for prices above P_k the ES' and ES'' curves coincide.

Government sales from stocks of amount Z augment the excess supply arising in the private sector. In figure 1 the augmented excess supply curve is represented by $ES''' = ES'' + Z$. Thus, the net effect of all the policy interventions is to shift domestic supply from S to S'', excess supply from ES to ES''', and to change the world price from P_{w0} to P_{w3}.

The effect of government policies on the value of the PPF is explored by examining the effect of the policies on the components of the PPF: consumers' surplus, producers' surplus, and budget expenditures. Domestic consumers' surplus increases due to the lower world price. The amount of the increase is represented by the area *efji*. Producers' surplus increases because of the shift in the supply curve from S to S'' and the higher (target) price received by producers. In figure 1 area *acge* represents increases solely because of the target price program, area *Ogh* represents increases resulting only from supply shifts, and area *cdhg* represents increases attributable to interactions between the supply shifts and the target prices.

Government budget outlays equal the sum of target price and loan and research expenditures less revenues from reduction of grain stocks. Expenditures on target prices and loan rates include payments of $P_t - P_{w3}$ on the amount $S''(P_{w3})$ of grain supplied to the market plus the loan and deficiency payment costs of the excess production $S''(P_t) - S(P_{w3})$. These two costs are represented in figure 1 by the areas *abki* and *bdml*, respectively. Public research expenditures of amount R_0 are not depicted in figure 1; however, they could be inferred from the size of the supply shift and the research production function. Revenues from the reduction of government stocks are represented by area *Opqr* in panel *b* of figure 1.

U.S. Intervention in the Wheat Market

This section illustrates a possible PPF based on U.S. wheat production. It is not an attempt to provide a detailed model of the wheat market: several such models already exist (e.g., Salathe and Langely). Nor is it an attempt to estimate rates of return to research. Only a crude approximation to the dynamics necessary for such an endeavor is used. However, the model sheds light on the political preference function, illustrates the value that the government places on increases in producers' surplus relative to budget expenditures and consumers' surplus, and allows for an informative examination of the interaction between policy instruments.

Assume two periods, 1977 and 1985, and that V has the linear form

$$(2) \quad V = w_1 \cdot \Delta CS_0 + w_2 \cdot \Delta PS_0 - w_3 \cdot \Delta G_0 + w_4 \cdot \Delta CS_1 + w_5 \cdot \Delta PS_1 - w_6 \cdot \Delta G_1.$$

The eight-year difference between the two time periods is chosen because this is an appropriate time lag between the funding of the research budget and the resulting shift in the supply curve (Zentner and Peterson, Norton). The w's represent the weights placed on each policy criterion.

The government is assumed to behave as if it maximizes the *PPF* (2) by choosing research expenditures R_0, target prices P_0 and P_1, and sales from government stocks Z_0 and Z_1. This assumption does not imply that the government is a single actor with underlying, structural preferences represented by (2); rather, it implies that the complex interactions between and among the government agencies and interest groups lead to a reduced-form representation similar to that derived from maximizing (2). For the two period model the relevant first-order conditions are

$$(3) \quad \partial V/\partial P_{t0} = 0 \quad \partial V/\partial P_{t1} = 0$$
$$\partial V/\partial Z_0 = 0 \quad \partial V/\partial Z_1 = 0$$
$$\partial V/\partial R_0 = 0.$$

Because the government knows the weights w_i, it acts as if it solves (3) to determine the optimal levels of policy intervention.

The econometrician's job is to use *ex post* observations on actual government behavior to infer the values of the government weights. For this exercise it is important to note that only relative weights matter, and hence the w's can be normalized by

$$(4) \quad w_3 = 1.$$

This indicates that the weight on 1977 expenditures is the *numèraire,* so that the values of the w_i for $i \neq 3$ represent the weight that the government places on group i relative to the weight it places on budget expenditures. Because the econometrician has observations on actual values of target prices, government sales, and research expenditures, (3) and (4) can be viewed as a system of six equations in the six unknowns $w_1, \ldots, w_6$. Under the usual regularity conditions the implicit function theorem applies, and the system (3) and (4) can be inverted to obtain

$$(5) \quad w_i = w_i(P_{t0}, P_{t1}, Z_0, Z_1, R_0; \text{Market Parameters}).$$

In (5) the phrase "market parameters" refers to the parameters determining the domestic and international supply and demand conditions. The remainder of the paper specifies these parameters and numerically estimates (5).

Assume that the excess demand curve is represented by a constant elasticity equation:

$$(6) \quad ED(P) = kP^{-i}.$$

This specification is consistent with much of the empirical work done on U.S. export elasticities. Based on these studies we specify the value $i = 1.0$. While studies of individual countries usually find much lower absolute elasticities (Abbott, Coffin, Chase-Wilde et al.), one would expect an aggregate absolute elasticity greater than 1 (Bredahl and Gallagher). Schuh suggests that the long-run value may be as high as 2, although this is probably too large (Salathe and Langley).

In the United States, the supply and demand curves are assumed to have constant price elasticity:

$$(7) \quad S(P) = aP^{s}; \quad D(P) = zP^{-e}.$$

It is assumed that $s = 0.4$ and that $e = 0.5$. The value for s is in the middle of the previously estimated elasticities (Salathe and Langley). The estimate for the demand elasticity is a compromise between the relatively low elasticities of food demand and the relatively high elasticities of feed demand (Salathe and Langley). Values for a and z are computed from supply and disappearance quantities, domestic market prices, and target prices; data are found in USDA.

Rewriting *ES* in terms of domestic supply and demand, in the absence of any government intervention the equilibrium condition $ES(P) = ED(P)$ becomes

$$(8) \quad aP_w^{s} - zP_w^{-e} = kP_w^{-i},$$

where P_w is the equilibrium world price.

Research is assumed to shift the parameter a, and the size of the shift is quantified by

$$(9) \quad a = gR^{r},$$

where r is the constant elasticity of supply with respect to research expenditures. While the choice of a functional form for the relationship between supply and research can influence welfare calculations (Lindner and Jarrett), this formulation is consistent with recent empirical work on North

American wheat research (Zentner and Peterson, Norton).[3] We use an elasticity of the supply shift with respect to research of 0.09, which is consistent with Norton's estimates for U.S. cash grain research. However, Norton specifies different lengths of lags between the time that the research is undertaken and the shift in the cost function, with the lags lasting from 0 to 7 years. These lags are shorter than usually found in the literature (Evenson). For example, Zentner and Peterson estimate functional forms that have seven-, eight-, and nine-year lags. Hence, we specify an eight-year lag between the research appropriation and the resulting supply shift.

Equations (6) through (9) specify the market parameters mentioned in equation (5): these market parameters are the parameters of the supply, demand, and research production functions. Exogenous shifts are allowed in the scale parameters a, z, k, and g in order to accommodate the eight-year difference between the two time periods. The magnitude of these shifts is determined from the data (USDA). Parameter values and the imputed values for the exogenous shifts are given in table 1.

Since the equations (6)–(9) specify the relevant market parameters, equation (5) now can be used to infer the government weights.

Results

The estimation results show that wheat producers were weighted more highly than taxpayers, who were weighted more highly than wheat consumers (table 2).[4] The value of 0.46 for w_1 indicates that in 1977 the government was willing to spend a tax dollar to help wheat consumers only if the dollar generated an increase of at least $\$1/0.46 = \$2.17$ in consumers' surplus. However, an investment that generated an increase in producers' surplus of only $\$1/w_2 = \$0.70$ per tax dollar spent was treated as a favorable investment. The weights w_4, w_5, and w_6 estimated for 1985 are slightly less than 1% of the 1977 weights. A pessimist could argue that 1977 policy makers were unconcerned with the future well-being of the population. One explanation is that policy makers were responsive to the desires of their 1977 constituents, who were looking for solutions to immediate problems. Alternatively, one could argue that the administration anticipated at least one and possibly more major pieces of farm legislation between 1977 and 1985, so that the 1985 population would not be greatly affected by the 1977 decisions. This explanation is consistent with the four- to five-year expected duration of most farm bills, in-

[3] These studies use a log-linear cost function in the estimation; this is consistent with a log-linear production function. See Takayama for details.

[4] The weight w_3 is a weight on government expenditures, which could be adjusted by the welfare cost of revenue generation to apply directly to taxpayers. Such an adjustment does not affect the interpretation of the results.

Table 1. Parameter Values Used in Estimation

Items	Notation	Units	1977	1985
Target price	P_t	1977$/bu	2.90	3.66
World price	P_w	1977$/bu	2.33	2.7
Wheat supply at P_t	$S(P_t)$	Million bu	3,160.6	2,834.0

[a] The figures for shifters are computed from the data in the table; and finally, the figures for elasticities and productivity of research are assumed consistent with the empirical findings in the literature.

[b] The 1985 supply shifter is inclusive of research effects.

Table 2. Estimates of Policy Preference Function Weights, 1977, 1985

w_1	w_2	w_3	w_4	w_5	w_6
0.46	1.43	1.00	0.35×10^{-2}	0.54×10^{-2}	0.42×10^{-2}
			w_4/w_6	w_5/w_6	
			0.81	1.26	

Note: The estimated weights are those values such that the actual research expenditures, target prices and government sales maximize the policy preference function (2).

cluding the Food and Agriculture Act of 1977, which was replaced four years later by the Agriculture and Food Act of 1981.

The relative values w_4/w_6 and w_5/w_6 can be compared to w_1 and w_2 as indicators of changes in the importance of producer or consumer groups from 1977 to 1985. These relative weights are not much different from the 1977 weights, indicating a degree of program consistency over time. However, there are some small changes in the relative weights: the ratios of w_4/w_6 = 0.81 and w_4/w_6 = 1.26 indicate that consumers became more important relative to taxpayers, while the relative importance of producers fell. These changes are consistent with claims that agricultural producer groups lost political power relative to consumer groups during the late 1970s and early 1980s (Hopkins).

The robustness of these results is examined in a sensitivity analysis showing the sensitivity of the estimated PPF weights to the value of the model parameters. The elasticities of the PPF weights with respect to the parameters are presented in table 3. For 1977, the weight on consumers' surplus, w_1, is mildly sensitive to the domestic and international demand parameters e and i. The value of -1.62 for the elasticity with respect to i indicates that a 1% decrease in the elasticity of international demand will lead to a 1.62% increase in the estimated value of w_1. This magnitude is not large enough to change the qualitative results. For example, if the value of i were to fall from 1.0 to 0.8, then the estimated value of w_1 would rise 32% from 0.46 to 0.61, still significantly below the values of w_3 and w_4. The 1985 weights are most sensitive to the parameter h representing the effect of the 1985 land set-aside requirement on the supply curve, probably because that parameter has a huge influence on the budget costs of the target price program (the 1977 wheat program did not have a land diversion clause). The largest elasticity shown in table 3 is that of the weight on producers' surplus in 1985 with respect to h, with a value of 1.81. Nonetheless, this elasticity is not large enough to affect the qualitative results. For example, if the set aside reduced output by only 5% rather than 15%, then the estimate on w_5 would rise from 0.54×10^{-2} to 0.56×10^{-2}. The ratio w_4/w_6 would exhibit the largest change, falling 25% from 0.81 to 0.61. This movement does not affect the qualitative results, nor is it of an unreasonably large magnitude. Thus, the sensitivity analysis presented in table 3 indicates that the estimated weights are reasonably robust to changes in the parameter values.

As a second type of sensitivity analysis, weights were estimated for a 1985 PPF in a one-

Table 3. Elasticities of Weights with Respect to Model Parameters

	Weight[a]				
Parameter	w_1	w_2	w_4	w_5	w_6
s	−0.07	0.03	−0.24	0.19	0.08
e	−1.17	0.00	−0.01	0.63	0.63
i	−1.62	0.00	−0.01	−0.60	0.60
h	−0.00	0.00	−1.39	1.81	1.20
c	0.22	0.02	−0.02	0.08	0.14

Note: w_1 is the weight on consumers' surplus in 1977; w_2 is the weight on producers' surplus in 1977; w_4 is the weight on consumers' surplus in 1985; w_5 is the weight on producers' surplus in 1985; w_6 is the weight on budget expenditures in 1985.
[a] Due to normalization w_3 = 1, the elasticity of this weight is not computed.

period (1985) model, taking previous policy as given. The estimated values maintain the qualitative relationships found in the two-period estimation: producers are weighted more highly than taxpayers, who are weighted more highly than consumers. The weight of consumers relative to taxpayers is approximately the same in 1985 as it was in 1977, but the relative weight on producers declined to 1.25. This weight suggests that $1 spent on producers would have to generate at least an $0.80 increase in producers' surplus in order for the government to find the expenditure worthwhile. These changes correspond to those found between the 1977 and 1985 weights in the two-period estimation. Moreover, the consistency of the relative weights across time suggests that the PPF (2) may be a stable reduced-form representation of the government's decision-making process.

A third sensitivity analysis considers how the government's use of policy instruments changes if the PPF weights change. Because the focus is on how public research expenditures change in response to different government preferences, we utilize the year 1985 in which 1977 research affects production costs. Consider a government which is unwilling to see farmers harmed by policy, including research policy that ultimately leads to a decline in farm prices. This concern can be represented by the constraint $\Delta PS \geq 0$. We then consider the policy preference function,

$$(10) \quad V = w_4 \cdot \Delta CS_{1985} - w_6 \cdot \Delta G_{1985} \quad \text{s.t. } \Delta PS_{1985} \geq 0,$$

and impose the normalization that $w_6 = 1$. The policy-optimal government choices then are determined with respect to the PPF (10).

For the specified values $w_4 = 1.00$ and $w_4 = 0.75$ the results of optimizing (10) are presented in table 4. When the elasticity of supply with respect to research is low ($r = 0.01$) target prices are set 10%–15% higher than the world market price in order to guarantee that $\Delta PS \geq 0$. For $w_4 = 0.75$ policy-optimal research expenditures are $\$20 \times 10^6$, which is approximately equal to the actual expenditures in 1977. The policy-optimal target price is $4.02 per bushel, which is higher than the actual 1985 target price. When the value of the weight w_4 increases to 1.00, the policy-optimal amount of research expenditures increases almost tenfold. This suggests that the policy-optimal amount of research expenditures may be very sensitive to the weight given to future consumers.

When the elasticity of supply with respect to research is relatively high ($r = 0.9$) the policy-optimal research expenditure is around $0.5 billion for either value of w_4. This indicates a sensitivity of research expenditures to the structural, research production parameter r, as would be expected. In this case the size of the supply shift is so great that no target prices are needed to maintain producers' surplus at or above the no-intervention level. This is in part because under this scenario U.S. wheat production has such a huge cost advantage that the U.S. becomes a strongly dominant exporter of wheat on the world market.

If the true research productivity parameter is $r = 0.01$, then the PPF (10) with $w_4 = 0.75$ provides an alternative, rational explanation of government behavior. That is, the policy-opti-

Table 4. Simulated Policy Responses to PPF Weight Changes

	Parameter Values			
	$w_4 = 1.0$		$w_4 = 0.75$	
Variables	$r = 0.9$	$r = 0.01$	$r = 0.9$	$r = 0.01$
Objective function ($\$ \times 10^6$)	3,025	−2,491	2,118	−2,500
World price ($/MT)	23	124.0	26	130.0
Target price ($/MT)	N.A.	141.4	N.A.	148.8
Research expenditures ($R \times 10^6$)	581	190	454	20
Program expenditures ($\$ \times 10^6$)	0	2,010	0	2,063
Total government expenditures ($\$ \times 10^6$)	581	2,201	454	2,083

Note: Modified value function is

$$V = w_4 \cdot \Delta CS - w_6 \Delta G \text{ s.t. } \Delta PS \geq 0.$$

Additional parameter values are $i = 1.5$, $\sigma = 0.6$, $\epsilon = 0.5$. Under both weighting scenarios the commodity program is not necessary to maintain the 1977 level of producers' surplus when $r = 0.9$, so that target prices are not used.

mal target prices and research expenditures under this scenario approximately match observed values.

All of the sensitivity tests indicate that, at least qualitatively, the policy preference function places a high weight on producers' surplus relative to consumers' surplus and budget costs. These results are intuitively plausible and contribute to the validity of the estimated weights.

A detailed examination of the results provides a possible explanation of the observed underfunding of public agricultural research. The literature on agricultural research defines underfunding as a level of support lower than that which maximizes economic efficiency. The model shows that the main beneficiaries of successful research are consumers. The estimation of the weights for the PPF specification (2) indicates that the government places a relatively low value on consumer benefits, lower than is consistent with efficiency maximization. Hence the government will provide a level of consumer benefits lower than is economically efficient, which implies that the level of research funding will be lower than the efficient level. But this is exactly the underfunding that the literature on agricultural research seeks to explain. That is, the results presented here show that if the government places a relatively low value on consumers' surplus, and if the effects of research on the target price program and on government stocks are taken into account, then the policy-optimal level of public research support will remain below the economically efficient level of support.

Conclusions

The major contribution of this paper is the estimation of a policy preference function that explains the observed levels of public research funding, target prices, and sales from government stocks for the U.S. wheat sector. The estimated PPF places an 80% premium on wheat producers' surplus relative to wheat consumers' surplus, and the results indicate that the government values consumers' surplus at approximately 50% of the value of budget savings. With these relative values, the current levels of target prices and public research expenditures maximize the government's policy objective function. The government provides positive levels of research funds mainly because they increase consumers' surplus (benefit to producers are quite small). The funds are limited relative to economically efficient levels because successful research increases the cost of the target price program, and because the increase in consumers' surplus is valued less than budget savings.

Future work in PPF modeling could be directed toward including longer time periods and more commodities in the model. This will allow for more accurate description of policies and policy effects. It will cause the number of first-order conditions to exceed the number of policy instrument choices, bringing the estimation of PPF functions within the traditional econometric framework for analysis of overdetermined systems. The econometrician can then perform standard tests of hypotheses about political behavior.

Political Preference Functions and Public Policy Reform

Gordon C. Rausser and William E. Foster

A model of policy making is developed where governments seek to maximize support from social groups through the combination of both PERT (social-welfare-increasing) and PERT (welfare-transferring) policies. The implicit weights of a political preference function shift with a change in the relative cost of interest group organizing. Attention is paid to the degree of wealth transfers as total social welfare increases because of PERT policy changes. The model demonstrates that, in the case of two competing groups, the weight given to one group in the allocation of social surplus will increase as total social welfare increases with a bias toward the other group. The relative weights placed on consumers and producers based on PEST policies alone are misleading indicators of the political influence of groups. A number of general implications of this political economic analysis for the reform of public policies are investigated.

Key words: agricultural policy, policy reform, preference functions, welfare.

Most analyses of policy reform, (e.g., Gardner, Stoeckel and Breckling), focus only on political economic-seeking transfer policies (PESTs). These policies are meant to redistribute wealth from one social group to another and are not directly concerned with efficiency. Other types of policies are PERTs, or political economic resource transaction policies (Rausser). These policies reduce transactions costs in the private sector by, for example, correcting market failures or providing public goods; they are ostensibly neutral with respect to their distributional effects. The distinction between the types of policies is briefly summarized by the popular metaphor of an economy as a pie: PERTs expand the size of the pie, and PESTs allocate the portions served.

The joint product approach to public policy involving both PESTs and PERTs avoids the extreme views found in the literature that focus either on government failures (rent seeking, directly unproductive profit-seeking activities, etc.) associated with the names of Buchanan and Tullock, Bhagwati, etc., or on market failures corrected by benign governments. We take the perspective in this paper that these extreme views only set the bounds on actual government behavior.

An analytical framework for jointly selecting PEST and PERT policies can be motivated by an example. Consider a public good that potentially can make both producers and consumers better off if there is some actual sharing of benefits. The market-exchange effects of this PERT in equilibrium, however, are such as to make producers worse off than without its dissemination. Specifically, total wealth increases (the economic pie expands) but, due to an inelastic demand, the distribution of benefits changes to the detriment of producers. Producers acting as a coalition may obstruct the implementation of the public good or PERT unless they are compensated in some form. One form of compensation is to introduce a PEST which transfers some wealth resulting from the new PERT equilibrium to producers. This transfer of wealth, the PEST, may actually be a means of securing the welfare-increasing policy even though it may appear as an inefficient rent-seeking based policy. As a result, the wealth transfer may be a crucial and Pareto-improving component of general policy. Under these circumstances, one major implication is that the social costs of PESTs should not be judged in isolation. The benefit of what may nominally be a PEST may lie in

the PERTs which it allows to exist. Correspondingly, the benefits of a PERT may be less than those observed directly. To assure the PERT's political viability, some social costs may be incurred in the implementation of inefficient transfer schemes.

In the above setting, selected policies in a world of rational decision makers reflect an optimization game that can be modeled as a maximization of a reduced-form political preference function (*PPF*). Policies are in place, in part, because they serve the interest of those with relative political power and influence. The rational process generates a portfolio or mixture of PERT and PEST policies. There is a wide scope of possibilities to interchange the use of PESTs and PERTs so as to acquire, balance, and secure political power. The PERT/PEST integrated framework emphasizes transactions costs and provides the foundation for meaningful prescription. The framework has three major dimensions: the level of PEST intervention, the level of PERT intervention, and the choice of the policy instrument mix.

To illustrate the importance of the choice of the policy instrument mix, consider the U.S. proposal for agricultural reform tabled in Geneva on 25 October 1989. This proposal focuses on market access (tarrification and phase reductions), export competition (eliminates all export subsidies and export prohibition), internal support (phase out most trade-distorting policies, discipline less trade-distorting policies, and allow all minimally trade-distorting policies), and sanitary and phytosanitary provisions (promote harmonization and establish an international process for food safety, animal health and plant health trade disputes). All of these policies and their proposed adjustments represent different alternative policy instrument mixes. For example, the internal support component of the U.S. proposal involves changing the policy instrument mix by phasing out coupled PEST policies (e.g., administered price policies, income-support policies linked to production or marketing, transportation subsidies, etc.) and permitting or, in fact, substituting PERT policies (e.g., environmental and conservation programs, research extension, education, resource retirement programs, bona fide domestic food aid) and decoupled or neutral PEST policies (income support policies not linked to production or marketing). At any point in time, the selection of a particular configuration of instruments represents the choice of the policy mix.

This paper presents a new perspective on the political economy of policy reform. A straightforward model of policy making is developed where governments seek to maximize support from different social groups through the judicious combination of both PERT and PEST policies (Rausser). Particular attention is paid to the degree of wealth transfers (accomplished by the PEST) as total social welfare increases (accomplished by the PERT). The model demonstrates that, in the case of competing interest of two groups, the influence given to one group in the allocation of economic surpluses will increase as total social welfare increases with a bias toward the other group. PEST policies, while typically thought of as welfare transferring and efficiency decreasing, can be welfare increasing when combined with PERT policies which, by themselves, may be impossible to implement. The impossibility of implementation is due to their potentially detrimental effect on sufficiently powerful interest groups. The essential result is simply that the policies accomplishing the wealth transfers cannot be isolated from policies providing public goods. Practically speaking, what may appear to be socially wasteful and incoherent agricultural programs may actually be rationally designed schemes of compensation for larger, longer-term policies which expand total societal welfare.

Public Choice

Implications of recognizing that governments choose a mixture of PESTs and PERTs are drawn from a concrete model. This concrete model incorporates government behavior and the strategic behavior of various interest groups. To simplify the presentation, and without loss of generality, only two interest groups will be analyzed here—producers and consumers. The structural framework embraces the objectives and decision rules of the government as well as the two interest groups. Current policies represent equilibrium outcomes (perhaps short run) in political economic markets. In essence, observed policies can be treated as the result of the structural framework or, equivalently, as the outcome of maximizing the reduced-form political preference function (Rausser and de Gorter). This function does not necessarily represent the public interest or a social welfare function (Rausser and Freebairn). Arguments appearing in this preference function represent the performance measures (e.g., welfare surpluses, profits, etc.) that reflect the well being of each interest group.

The parameters of this preference function or the marginal effect of its arguments have been referred to in the literature as the preference weights (Rausser and Freebairn). If we fix the level of the PERT, these parameters (or equivalently, these weights) are "local." In the revealed preference and empirical analyses that have been conducted by economists, only such local weights have been estimated.

The formulated model presumes that the well being of each interest group can be accurately measured by consumer and producer surpluses (Gardner). In the political preference function, the implicit weights placed on consumer and producer surpluses in government decisions are shown to result from the degree to which those surpluses affect political support. The weights on a sum of consumer and producer surpluses reflect the degree of relative wealth transfers from one group to another, equal weights implying no transfers (Rausser and de Gorter). We demonstrate that these weights shift with a change in the cost of interest group organizing due to, say, an institutional change. More precisely, the relative weight on each group in the *PPF* is determined by an index of relative costs of political organization.

A decrease in a group's organizing costs relative to the other group's costs increases its responsiveness to changes in its collective welfare (i.e., the cost decrease leads to an increase in its marginal political power). Such a cost decrease would shift wealth transfers in its favor and, in this way, the weight changes on that group in *PPF*.[1] Policy reform, therefore, entails the alteration of the *PPF* through changes in the underlying costs to each group determining political support. Such changes in costs may ultimately be related to institutional reform or more simply to the subsidization of political activity.

The framework also demonstrates that judging the relative weights placed on consumers and producers based on PEST policies alone may be misleading. These weights are local in the sense that they reflect constrained government tradeoffs of group welfare for a given set of PERT policies. The implicit weights based on wealth transfers alone may favor one group, but the implicit weights based on the mixture of both PESTs and PERTs may indicate just the opposite.

[1] In our model, here, it is the marginal rate of political support with respect to a change in a group's welfare that is important in choice, not the absolute level.

Government Behavior

Consider a government in which politicians institute policies and programs in order to maximize the popular support from two groups, consumers and producers. The government realizes that its actions affect the two groups' economic welfare and that their welfare is directly related to their political support. A group's welfare is measured by its economic surplus—C or F, representing consumer and producer surplus measures, respectively. Given government actions, the levels of these surpluses are determined by the group's individual members acting in a decentralized way, consuming and producing in response to both market incentives and government policies. The government's policies have differential effects on the two groups, some combinations of programs benefiting both and some benefiting one while harming the other. The government, therefore, must make a decision on the configuration of policy that optimally trades off consumer and producer support through manipulation of their welfare.

The government's choice problem is simply reflected through the effects of its actions on a government support function, $S = S[S_c, S_f]$, where S_c represents support from consumers and S_f from producers. It is also hypothesized that informed organizations represent each group's interests. Their political activities on behalf of their collectives' welfare affect the responsiveness of the groups' supports to changes in the welfare measures. These organizations set the political environment, as it were, in which the government allocates society's total welfare between consumers and producers.

As noted above, PERT and PEST policies are available to the government in maximizing its support function through manipulation of consumer and producer welfare. The choice of both types of policies is constrained by the current state of technology, the state of managerial ability of politicians, and the state of theoretical and conceptual foundations on which to build policy. We assume that these realistic constraints on the set of feasible government actions lead to limits on the total available economic surplus possible and to a social cost of transfers between groups.

PERT policies are not neutral with respect to the benefits accruing to each group. Indeed, as noted above, PERTs may be sometimes consumer harming and sometimes producer harming. We reflect the choice of a PERT by the level of an index, E, such that as this index in-

creases the total surplus available increases. For any given PERT (i.e., for any given level of E), the general design of the PEST will be chosen to attain any particular level of surplus or, more generally, welfare transfer between groups with the least cost.[2] The government recognizes that, through its design of the PEST (e.g., the level of a price floor in combination with a level of import restrictions), it is setting both consumer and producer surplus levels.

There is in effect a surplus possibility frontier for every PERT policy that describes the highest possible level of the consumer group's economic welfare, C, for a given level of the producer group's welfare, F; i.e., $C = C(F|E)$. This surplus possibility frontier is represented in figure 1. The surplus frontier incorporates both the market structure of consumer and producer behavior as well as the available technology of welfare transfer.[3] Two conditions on this surplus transformation frontier are assumed to hold: over the relevant range, the welfare of one group decreases at an increasing rate with an increase in the welfare of the other (i.e., $\partial C/\partial F < 0$ and $\partial^2 C/\partial F^2 < 0$).

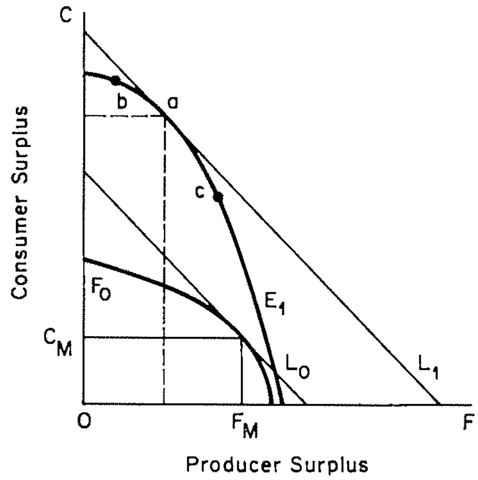

Figure 1. Surplus possibility frontiers under alternative PERTs

The surplus transformation frontiers for two levels of E are labeled E_0 and E_1, representing the movement from a lower level of total available surplus to a higher level due to the institution of a PERT and are graphically illustrated in figure 1. Without a PEST (without any transfers) the resulting equilibrium levels of consumer and producer surpluses occur at the point (C_M, F_M) where the surplus transformation curve has a negative slope of unity; that dollar from one group to another would be represented by the lines L_0 and L_1 passing through the free-market equilibrium combinations on E_0 and E_1. As the transformation frontiers are drawn, the implementation of the PERT causes the free-market combination of surpluses to move to point a in figure 1 where the free-market level of producer surplus has decreased. For example, such a producer-harming PERT would be the government's dissemination of a new supply-expanding technology that decentralized producers would adopt individually but which, in the presence of an inelastic demand, causes harm to the collective group.

Although the government's PERT and PEST decision is joint, the problem may be viewed in two stages. This is done for convenience purposes only; there is joint interaction and feedback between the stages regardless of how they might be structured. Because separability does not exist in the selection of the best mix of PERTs and PESTs, it makes little difference how the two stages are ordered. Here, the problem will be structured as one of determining the optimal

[2] We wish to emphasize that, in its most general form, our conceptual model can admit the possibility of government strategizing over the selection of the particular PEST instruments. We will set aside for the current discussion, however, the possibility that the government might purposefully introduce a degree of waste into surplus transfers for strategic ends. Such additional waste may result from the usefulness of a more wasteful transfer mechanism to (a) differentiate between decentralized decision makers and, thus, more cheaply counter political opposition by dividing and conquering and (b) encourage further rent-seeking activities of interest groups and, thus, perhaps to increase the government's political support. The first possibility is discussed and analyzed in Foster and Rausser.

Models of political competition between groups typically represent the government as a conduit of group pressure and the transfer scheme (the PEST) as a mechanism for rewarding or penalizing a group's relative political power. Heuristically, in such models the transfer mechanism implemented by the government would tend to be the most efficient. In the sense of minimizing deadweight losses, all groups can share in an efficiency gain. For example, Becker notes that competition among pressure groups favors efficient methods of taxation and sometimes (not necessarily always) efficient methods of subsidization (p. 386). Gardner uses this notion of efficient redistribution to explain why different forms of subsidization prevail over others under different market conditions. The methods of tax and subsidy in most models of political pressure serve the single purpose of allocating surpluses and, thus, these models suggest that the choice of PEST would not needlessly dissipate rents that could otherwise be enjoyed by at least one group. Closer to reality, however, the form of the PEST may also serve the other purposes of exploiting imperfect information or encouraging further rent seeking. The government may, in fact, weigh the relative inefficiency of a transfer scheme against, for example, its ability to hide its own inefficiency.

[3] Here, we are abstracting from the implementation costs of the transfer scheme and which group bears these costs. It is reasonable to assume that all groups share in these costs in the proportion that their memberships have in the total population. Thus, we assume that the group's shares of the implementation costs are not subject to strategic behavior and that they may be incorporated into the surplus transformation curve.

PESTs for each alternative level of a PERT. Once this has been determined, we then proceed to the best PERT policy conditioned upon the optimal (conditional) selection of the PEST. These two stages are offered as a simple way of interpreting the joint interactive algorithm that must be employed to determine the optimal instrument mix of PESTs and PERTs.

First, for a PERT (a level of E), the government chooses a constrained support-optimizing level of consumer and producer surpluses such that those levels lie on the surplus transformation curve. Its allocation of surpluses is dependent on the degree of rewards (increases in support) and penalties (decreases in support) offered by each group, and each group offers both greater rewards and penalties as it becomes more sensitive (or responsive) to changes in its collective welfare. At this stage, therefore, political organizations contend to enhance their clients' welfare by expending effort to make their respective groups more responsive and opposing groups less responsive to government action. This first stage corresponds to more narrowly focused models of near-term rent seeking where interest groups struggle over known resources in a known political economic environment.

The second stage corresponds to longer-term public decisions, to questions of infrastructure development and generally to policies not subject to the same organization strategizing as in the first stage. In this second stage, the government must make a discrete choice of a PERT policy, of altering the surplus possibility frontier. This choice of a PERT is not done in isolation: the choice of the best available PERT must also recognize the rent-seeking activities that occur whichever PERT is chosen. The government's decision to institute a PERT, therefore, is conditioned on the PEST (that is, an optimal rent-seeking surplus trade-off exists for every E) as well as the PEST conditioned on the PERT.[4]

The feasible means of surplus transfer dictates the concavity of the surplus transformation curve. The discovery of a more efficient method of transfer would lead to a shifting out of the transformation curve at every point except at the free-market, zero-transfer combination of group surpluses.[5] Taking as given the sensitivity of group support to welfare changes, the government wishes to choose the optimal combination of consumer and producer surpluses that falls along the available transformation curve. It will do so in the familiar marginalist way: The last dollar transferred will just balance the additional decrease in losers' support, with the additional gain in beneficiaries' support generated by that dollar, less the waste of the transfer.

$$\frac{\partial S_c}{\partial C}\cdot\frac{\partial C}{\partial F}+\frac{\partial S_f}{\partial F}=0. \tag{1}$$

Such a government choice would generally place the resulting combination of consumer and producer surpluses on one side or the other of the free-market point on the curve.

Political Preference Function

The relative weights on the two groups in the *PPF* will be a reflection of the government's allocation of surpluses which will, in turn, be the result of the political support offered by those groups. The *PPF* is a weighted average (here, arithmetic) of the group's surplus measures,

$$PPF = w\cdot C + (1-w)\cdot F,$$

implying that in equilibrium the weights on the two groups that would be consistent with the maximization of the *PPF* are such that

$$-\frac{\partial C}{\partial F}=\frac{(1-w)}{w}. \tag{2}$$

The surplus transformation frontier is a function of the particular PERT and the political support given by the two groups which is, in turn, a function of the costs of organizing activities, e_c and e_f, which we discuss below. Therefore, we may generally write $w = w(E, e_c, e_f)$. This weight is a local representation, dependent on the level of E.

Once the PEST policy has been decided, given each PERT choice, the government then chooses

[4] As in the case of implementing the PEST, we assume that the cost of implementing the PERT is borne by each group in some fixed proportion and not subject to strategic behavior. Thus, we assume that these costs may be incorporated into the degree of the outward shift of the surplus transformation frontier.

[5] Such a change in the transformation frontier would itself be a PERT and more generally should be subject to acceptance or rejection in the government's optimal selection of policies. Allowing that a more generalized view of the strategic government behavior is possible (following the remarks in footnote 3), we shall nevertheless confine ourselves to a choice among PERTs that leads to expansion of the transformation frontier at every point, that is, PERTs tht we refer to as pie expanding. We assume that any more efficient means of deviating from the free-market equilibrium of group surpluses is immediately adopted (as in Becker and Gardner).

the optimal PERT in seeking to maximize support. There is no straightforward rule of thumb for comparing among PERTs their constrained political equilibrium surplus combinations. The government's optimal PERT/PEST mix might lead to an increase in income transfers. For example, suppose that the best PEST policy has been decided for the case of E_0 in figure 1 and the constrained optimal level of transfers to either group is minimal—that is, the political economic equilibrium is (C_M, F_M). If the government chooses the level E_1, the resulting combination of group surpluses may be at point *c* where one group may be harmed, although that group may now receive significant transfers through the PEST. Indeed, more generally, it is possible that the deadweight loss per dollar transferred increases when moving from E_0 to E_1. Therefore, the narrow focus on only the PEST transfers in order to judge the relative power of interest groups may be misleading.

Strategic Behavior of Consumer and Producer Organizations

We assume that the support given to the government by each group is a function of its welfare as measured by its economic surplus and the effort expended by political organizations serving their clients' collective interests. These political organizations are considered endowed with the ability and information necessary to evaluate their clients' best interests in terms of seeking to maximize economic surplus.[6] Thus, these organizations attempt to make their clients' support functions as sensitive as economically justifiable to changes in surplus and to make the opposing group's support function as insensitive. Because of the limited information to decentralized decision makers, changes in welfare may not be connected in their minds with political decisions that otherwise might be influenced by threats or encouragement. Indeed, the problem facing the decentralized decision maker may be the inability to distinguish welfare changes caused by his government and changes caused by persons or events unconcerned with his or her political constituency. It is the purpose of the political organizations serving the decision maker to provide such information and to provide confusion or misinformation to the decision makers not so served.

In particular, consider the case of a producer organization expending effort, e_f, to increase the additional political support producers offer for an increase in the group's welfare. That is, the effort is meant to make producer support more responsive to an increase in F and, thus, to encourage the government to increase F at the expense of C for a given PERT. Similarly, the effort also mitigates any decrease in consumer support due to the change in surplus allocation. In marginalist terms, the producers' organization attempts to increase the marginal rate of producer support with respect to F, $\partial S_f/\partial F$, and reduce the marginal rate of consumer support with respect to C, $\partial S_c/\partial C$.

The consumers' organization expends a similar effort to increase the marginal rate of consumer support and reduce the rate of producer support. We take each group's marginal support as a function of the group's collective welfare and a measure of the relative effectiveness of the efforts expended by the political organizations. Let $n_c = n_c(e_c)$ and $n_f = n_f(e_f)$ measure the effectiveness or influence actually obtained by the organizations' efforts; in effect, effort is an input into the production of influence. Measure the relative influence of the groups by $\rho = n_c/n_f$. The marginal rates of support may be written as

$$(3) \qquad \frac{\partial S_c}{\partial C} = M_c(C, \rho), \text{ and } \frac{\partial S_f}{\partial F} = M_f(F, \rho),$$

where $\partial M_c/\partial \rho > 0$ and $\partial M_f/\partial \rho < 0$. Differential rates of organizational influence for the same level of effort may occur for several reasons. Political organizations may have varying degrees of expertise, professionalism, credibility, access to mass communications, and internal cohesion. Indeed, an "organization" as we have defined it may not be monolithic but a collection of smaller organizations drawn together by belief in a common cause but uncoordinated in their tactics.[7]

[6] A political organization may not strictly be the agent of a group's collective interest but rather have coincidental interests. The knowledgeable, but politically weak, organization may attempt to make its decentralized, but politically powerful, partner more responsive to government actions through the collection, analysis, and dissemination of information. Thus, in this way a political symbiosis is obtained which can be modeled as an organization and its client group.

[7] Although the use of a ratio of organizational efforts can be generalized by separately including e_c and e_f in the above functions, this complication yields little intuitive value for our present purposes. Nevertheless, it is important to note that advertising and promotion messages from the consumer's organization would be just as effective as if the same information was advanced by the producer organization. In this sense the organizations can hide their identities or true purpose. Also implicit is that organizations' activities are not aimed at specific groups. That is, the effort of an organization is not tailored to influencing only the marginal support of a single group.

The unit cost of effort to the consumers' organization is represented by k_c and to the producers' organization by k_f. Differential costs of political activity may arise from several sources, the most important of which is the transactions costs of developing and maintaining politically cohesive groups. For smaller, more homogenous groups, such as farmers in the developed world, the costs of organizing, identifying, informing, and coordinating group membership is relatively low. For larger, diverse groups, such as consumers in the developed world, costs of similar organizational activities are relatively large.

The Level of Wealth Transfer and the PPF Weight Determination

In order for these political organizations to have a role in this model, they must anticipate the effects of their activities on the welfare of their client groups. That is, the organizations understand how their efforts alter government incentives to allocate welfare across groups. In this sense, each organization behaves as a Stackelberg leader with respect to the government's choice of optimal wealth transfer. Intuitively, the organizations are setting the political terrain over which the government seeks to gather the greatest support. With respect to wealth transfers, the two organizations are gaming over the structure of support trade-offs—the iso-support curves of the government-choice problem—leaving the government to find the optimal "consumption" of consumer and producer surpluses along the surplus possibilities frontier, $C = C(F)$.

Each organization wishes to maximize its client group's economic surplus net of the cost of the effort expended. With knowledge of how changes in marginal rates of support affect government support and taking the activity of the opposing organization as given, each organization will expend effort until the marginal gain in its group's surplus is just equal to the unit cost of effort. From the government's decision rule given by expression (1), the definition of the marginal rates of support given by expression (3), and the surplus transformation frontier $C = C(F)$, we can find each organization's reaction function in terms of the PERT, E, and the political effort of the other organization,

$$\text{(4)}\quad \frac{\partial F}{\partial e_f} = \frac{1}{\Delta}\frac{\rho}{e_f}\xi_f\left(\frac{\partial M_c}{\partial \rho}\frac{\partial C}{\partial F} + \frac{\partial M_f}{\partial \rho}\right) = k_f,$$

$$\text{(5)}\quad \frac{\partial C}{\partial F}\frac{\partial F}{\partial e_c} = \frac{\partial C}{\partial F}\frac{-1}{\Delta}\frac{\rho}{e_c}\xi_c\left(\frac{\partial M_c}{\partial \rho}\frac{\partial C}{\partial F} + \frac{\partial M_f}{\partial \rho}\right) = k_c,$$

where ξ_f and ξ_i are the elasticities of effective influence with respect to effort [i.e., $\xi_i = (e_i/n_i)(\partial n_i/\partial e_i)$]. In equilibrium, the optimal level of effort of each organization must be consistent with the effort of its opponent and the government's actions consistent with that political activity.

From the above expressions and the discussion of the implied *PPF*, expression (2), we draw our first result regarding the local *PPF* weights,

$$\text{(6)}\quad \frac{1-w}{w} = -\frac{\partial C}{\partial F} = \frac{e_c k_c}{e_f k_f}\frac{\xi_f}{\xi_c}.$$

That is, the relative weight placed on producers in equilibrium is proportional to the ratio of marginal costs of political activity. For given relative effective efforts in equilibrium (i.e., a fixed equilibrium, ρ), a greater marginal cost of effort by the consumers' organization, *ceteris paribus*, leads to a reduction in the *PPF* weight on consumer welfare.

The levels of effort expended by the two groups, however, will change with changes in the relative marginal costs of organizational activity. We may determine the equilibrium effects of an increase in relative costs by noting that expressions (1) and (6) must hold in equilibrium for every PERT and every ratio of costs, determining both the equilibrium levels of producer surplus [taking $C = C(F|E)$] and the ratio of political organizing efforts. Define the parameters $\eta = e_c/e_f$ and $\theta = k_c/k_f$ and let $\xi_c\ \xi_f$. From expression (1),

$$\text{(7a)}\quad \left(\frac{dF}{de_c}\right) = -\left(\frac{1}{\Delta}\right)\frac{\rho}{e_c}\xi_c\left(\frac{\partial M_f}{\partial \rho} + \frac{\partial M_c}{\partial \rho}\cdot\frac{\partial C}{\partial F}\right) < 0,$$

$$\text{(7b)}\quad \left(\frac{dF}{de_f}\right) = \left(\frac{1}{\Delta}\right)\frac{\rho}{e_f}\xi_f\left(\frac{\partial M_f}{\partial \rho} + \frac{\partial M_c}{\partial \rho}\cdot\frac{\partial C}{\partial F}\right) > 0,$$

where $\Delta = \partial^2 S/\partial F^2 < 0$. From expression (6), (7a), and (7b), we may sign

$$\text{(8a)}\quad \frac{de_c}{d\theta}\frac{1}{e_c} - \frac{de_f}{d\theta}\frac{1}{e_f} = \frac{-\eta}{C_{ff}\dfrac{dF}{de_c}e_c - \dfrac{(1-w)}{w}} < 0,$$

(8b)
$$\frac{dF}{d\theta} = e_c \frac{dF}{de_c}\left(\frac{de_c}{d\theta}\frac{1}{e_c} - \frac{de_f}{d\theta}\frac{1}{e_f}\right) > 0,$$

where $C_{ff} = \partial^2 C/\partial F^2 < 0$. Finally, note that

(9)
$$\frac{d(1-\omega)/\omega}{dF} < 0.$$

Hence, we may state the following intuitively appealing result:

> Defining the (local) weights on group welfare in the *PPF* as those consistent with government wealth transfer policy for a given PERT, an increase in an organization's marginal cost of political activity, relative to the opposing organization's cost, will decrease the weight on its client group's welfare.

In particular, a decrease in the relative cost of political activity of the consumers' organization will increase the effort that organization expends and will decrease the effort that the producers' organization expends. This, in turn, will lead to an increase in the consumer group's welfare (and a decrease in F). As C increases and F decreases, the degree of wealth transfer moves in favor of consumers and, thus, the weight on the consumers in the PPF increases.

The Introduction of a Pie-Expanding PERT

Consider the government's decision to introduce a PERT policy which expands the surplus transformation frontier at every point. That is, the government may move from the selection of E_0 to E_1, implying that, for every F, $C(F|E_1) > C(F|E_0)$. Furthermore, consider the case of a consumer-biased change in PERT policies. We define such a biased shift such that the difference, $C(F|E_1) - C(F|E_0)$, grows as F decreases. In terms of incremental expansions of the surplus transformation curve, a consumer-biased shift implies $\partial^2 C/\partial F \partial E < 0$.

Intuitively, a consumer-biased shift would result in a free-market equilibrium where consumers are better off but producers are worse off. Furthermore, in terms of wealth transfer policies, a given increase in producer welfare through a PEST will come at a greater decrease in consumer welfare under E_1 than under E_0; thus, the marginal loss in consumer support for the marginal transfer from any level of C would be greater. In effect, the producers' organization would find it more difficult to induce the government to transfer additional income from consumers from given levels of surplus allocation and political activity.

Suppose that, in this second stage of public policy making, the government accepts the PERT; that is, let $S[S_c(C_1, \rho_1), S_f(F_1, \rho_1)] > S[S_c(C_0, \rho_0), S_f(F_0, \rho_0)]$. We are interested in the resulting degree of wealth transfers that take place under these new political economic conditions. In terms of the *PPF*, how do the constrained weights on group surplus change with the move to E_1? The answer is that the local weight on producer surplus increases although producer surplus may decrease with the move from E_0 to E_1.

We now prove this result. Note that the *PPF* weights are indicated by the value of η—the relative organizational efforts—in equilibrium as indicated in expression (6). Define $\eta_0 = e_{c0}/e_{f0}$ and $\eta_1 = e_{c1}/e_{f1}$; where $\rho_0 = n_c(e_{c0})/n_f(e_{f0})$ and $\rho_1 = n_c(e_{c1})/n_f(e_{f1})$. It is assumed that $\rho_0 \gtreqless \rho_i$ as $\eta_0 \gtreqless \eta_1$. The weight on producers increases if $\eta_1 > \eta_0$ or if $\rho_1 > \rho_0$; that is, if the equilibrium allocation of surpluses is such that the slope of the surplus transformation curve is greater under the new PERT, $-\partial C(F|E_1)/\partial F > -\partial C(F|E_0)/\partial F$. For example, in figure 1 an initial equilibrium of (C_M, F_M) would imply $\eta_0 = 1$. The weight on producers would increase ($\eta_1 > 1$) with a new equilibrium at point c. To show this, suppose the opposite case, that $\eta_1 \leq \eta_0$ or $\rho_1 \leq \rho_0$, which implies that, since the move from E_0 to E_1 is consumer biased, producer surplus must fall and consumer surplus must rise, $F_1 < F_0$, $C_1 > C_0$. In other words, if $\rho_1 \leq \rho_0$, then the new equilibrium under E_1 would be represented by a point such as b in figure 1. Concavity of the marginal support functions assure that, if $\rho_1 < \rho_0$,

(10)
$$M_c(C_1, \rho_1) < M_c(C_0, \rho_0) \text{ and}$$
$$M_f(F_1, \rho_1) > M_f(F_0, \rho_0);$$

thus, $M_{f1}/M_{c1} > M_{f0}/M_{c0}$. From the government's optimal allocation of surpluses under each PERT, however, $\eta_i\theta(\xi_f/\xi_c) = M_{fi}/M_{ci}$, and we have a contradiction. Hence, we may state the following result:

> Government choice of a consumer-biased PERT leads to an increase in the (local) weight on producers in the *PPF*.

Intuitively, the conditions expressed by (10) imply that consumer sensitivity to surplus changes falls the greater that group's welfare and the lower the relative level of pro-consumer political activity. Similarly, producer sensitivity rises the lower that group's welfare and the higher the relative level of pro-producer activity. In equi-

librium, one would not observe both a decline in producer welfare, an increase in pro-producer effort, and at the same time a decrease in that group's sensitivity to changes in its welfare. The result simply says that, in general, governments will place less weight on any interest group that grows more satisfied and expends less lobbying effort.

This is not to say that both consumer and producer welfare grow but that the degree of wealth transfer (from the noninterventionist point) grows in the producers' favor. In fact, the equilibrium surplus to producers may fall with an introduction in the PERT at the same time the constrained weights on producers may increase in the *PPF*.[8]

Local and Global PPF Weights

The weights on consumers and producers in the conventional *PPF* are local in the sense that they reflect only trade-offs between group welfare measures in the choice of the level of wealth transfer for a given PERT. In a similar manner one may think of the government choosing a PERT conditional on a particular transfer mechanism and level of wealth transfer, that is, given a PEST. In this latter case, also, one would observe weights on each group that reflected only trade-offs in the choice of the PERT. The choice of the PERT is the selection of the surplus possibility frontier $C(F|E)$ along which the government ultimately selects the optimal combination of surpluses. If one does not take into account that the PEST instruments and/or levels may change from one PERT to another, then one may draw erroneous conclusions regarding the relative group weightings.

Figure 2 illustrates the hazards of assessing

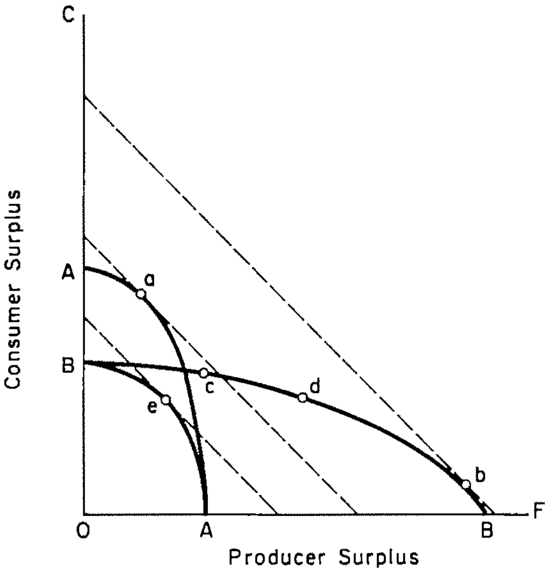

Figure 2. Alternative surplus possibility frontiers for choice of PERT

trade-offs between welfare levels by focusing only on a PERT policy decision. Suppose the government has the choice of moving from a base surplus possibility frontier given by curve *BA* to either of two frontiers given by curves *AA* and *BB*. These two PERTs correspond to a consumer-biased pie-expanding policy and to one that is producer biased. The government chooses curve *AA* and the surplus combination given by point *a*. The point *a* is selected by the particular level of wealth transfer accomplished by the PEST. In this case, for convenience, the level of transfer is zero and a free-market outcome is the result which, in this illustration, is represented by the straight line tangent to curve *AA* at point *a*. Now, if one were to compare total welfare possibilities under the PERT yielding curve *AA* with that yielding curve *BB*, given the existing transfer scheme and level, one would conclude that the weight on consumer relative to producer surplus must be high. The total surplus given the existing PEST for curve *BB* is greater than that for curve *AA*, implying that the government must be willing to forego more than a unit of producer surplus for a unit of consumer surplus. In reality, however, the level of wealth transferred by the PEST under the PERT yielding curve *AA* would not be the same level as under the PERT yielding curve *BB*. Indeed, the optimal surplus combination conditional on being on curve *BB* will be to the left of point *b*, implying less weight on consumers relative to producers. The optimal combination under the pro-

[8] A sufficient condition for an incremental increase in E to lead to a decline in producer surplus is found from the expressions defining the political economic equilibrium (1) and (6). After some comparative statics manipulations,

$$dF/dE = -(AC_{f\epsilon} - \theta B)/(C_{ff}A - \theta\Delta),$$

where $A < 0$ is the derivative of expression (1) with respect to ρ, B is the derivative of (1) with respect to E, and $\Delta < 0$ is the second-order condition of the government's optimization problem. Now, the denominator of the above expression is positive, so a sufficient condition for the entire expression to be of negative sign as if $B < 0$; that is, if

$$B = \partial M_c/\partial C . \partial C/\partial E . \partial C/\partial F + C_{f\epsilon} . M_c .$$

Intuitively, producer welfare will decrease in equilibrium if the percentage decline in consumer sensitivity to a welfare change is less than the increase in the slope of the surplus possibility frontier (i.e., the slope becomes more negative).

ducer-biased PERT may be, in fact, at a point such as point *c*, implying that the surplus combination is consistent with more equal weighting between groups if not a relatively greater weight for producers.

Local weights reflected by a PERT selection would change as constraints on PESTs change, just as in the previous section where the local weights changed with the introduction of a PERT. Pie-expanding PERTs are usually associated with infrastructure development, technological R&D, and other policies usually thought to promote economic progress. The choice set of PESTs, on the other hand, is usually considered a given. Nevertheless, constraints on the choice of transfer schemes do exist and change over time. External events, such as changes in the cost of financing, may alter the potential choices of PESTs and, thus, also alter the final equilibrium choice of both PEST and PERT. Other countries and international agencies may impose restrictions on the wealth transfer policies of some governments for their own purposes. Finally, technological developments, and other advances usually disassociated from rent-seeking and wealth transfers, will alter the shape of the surplus possibilities frontier itself. For example, better mechanisms for tax collection may imply less distortion relative to taxation via the manipulation of commodity prices.

Take, for example, the case of an outside agency, such as the World Bank, imposing certain constraints on a government's choice of wealth transfer policies. The agency considers its own objectives consistent with an expansion of total social welfare, as measured by the equal-weighted sum of consumer and producer surpluses, in the country in question. Using only observed local weights on the choice of the PEST, for a given PERT, the agency may conclude that all that is needed to expand welfare is to balance the weights on groups represented in the *PPF*. It seeks to effect this equal-weighting outcome by constraining the government to using the market to allocate social welfare. By constraining the PEST, however, the only instrument left to the government to maximize its support is its choice of PERT. The result may very well be a decrease in total social welfare as the government alters the surplus possibility frontier.

This possibility is illustrated in figure 2. Suppose the point *e* represents an initial political economic equilibrium on the surplus possibilities frontier given by curve *BA*. Point *e* happens to be a noninterventionist outcome. A future political economic equilibrium, conditional on two potential PERTs discussed above, is given by the surplus combination at point *d*. The free-market equilibria under the two PERTs are given by points *a* and *b*. The combination of group surpluses given by point *d* lies to the northeast of point *e* and is consistent with the outcome of a cooperative game with the conflict point *e* being the outcome if either consumers or producers veto a move from the original situation.

Suppose some outside agency, anticipating the apparent relative strength of consumers and hoping to maximize future total social welfare, enters the game between consumer and producer organizations and the government and constrains the government to enforcing free-market allocations. Suppose the outcome represented by point *b* is unacceptable to consumers and the government finds, of the two free-market points, that the outcome given by point *a* maximizes its support. Although the surplus combination given by point *a* is a free-market one, it yields nevertheless a smaller total sum of equally weighted consumer and producer welfare measures than that associated with point *d*.

In fact, as illustrated, there is a loss in the welfare of producers relative to the initial equilibrium point on curve *BA* and, thus, point *a* is inconsistent with a cooperative game. If producers and consumers have a veto over any move from the initial equilibrium that causes a decrease in their welfare and the only choices are constrained to be at points *a* and *b*, then the outcome will be no PERT at all. The outcome of an outside agency's constraint on the operation of a PEST would be a surplus combination given by point *e*, implying not only a decrease in the total sum of surpluses but a decrease in the welfare of both groups.

Implications and Concluding Remarks

The primary implication of the model is that the introduction of an expansion of total social welfare biased toward one group (e.g., a consumer-biased PERT) leads to a change in the degree of wealth transfer in favor of the other group. That is, a biased PERT such as a technical advance with inelastic demand yields an increase in the local PPF weight on the group not favored by the PERT. Moreover, although the local weight on a group may increase with the introduction of a pie-expanding PERT, the group's actual welfare may decline. The degree of wealth transfer relative to a noninterventionist state will increase, but absolute welfare of the PEST ben-

eficiary will decline if the new noninterventionist allocation of surpluses does sufficient harm to that group.

The *PPF* is a reduced-form expression of the more complicated (and richer) structure of a political system. Therefore, when speaking about reform (and almost always one is referring to ending wealth-seeking transfers), one is implicitly, if not explicitly, speaking about changing the weights on groups in the *PPF*. Grudging reforms, forced on a political system by an outside government or international body, will fail if these underlying weights remain unchanged. Such reforms will be temporary reactions to external demands and, once those demands abate, the political system will likely return to its previous policy equilibrium. Only if outside pressures force the restructuring of the weights of institutions would such reforms be permanent.

Indeed, unless the weights in the *PPF* change, unsustainable alterations in agricultural policies should not be termed reforms at all. To move from a current mixture of policies to sustainable reforms entails the movement from one policy equilibrium to another. The emphasis of this perspective is on a government's problem of selecting the mixture of public goods and transfers that maximizes its political support. Simply put, reforming food and farm policies implies changing the forces conditioning government behavior.

The movement from one equilibrium to another, with a new discrete selection of a PERT and PEST mixture, is equivalent to eliminating a missing market. As with the Coase theorem, if all parties negotiate efficiently, then the existence of incomplete political economic markets is not an obstacle to efficient policy reforms. However, because of transactions costs and incomplete information, the Coase theorem does not provide an attractive solution. In this instance we are left with no alternative but to turn to collective action or government behavior to effectively lower the transactions costs and provide more adequate information so that a market for reform naturally emerges. For this argument to make sense, we must appeal to the economies of size, the willingness of governments to impose effective penalties and rewards, and new negotiation techniques.

The demand for reform is an increasing function of the degree of social waste generated by wealth transfer programs but the supply of reform is not. Much like the demand for goods imagined, but yet beyond the present state of technology to produce profitably, the demand for reform will remain unfulfilled without a change in a country's political technology. The reform of agricultural policies must come through changes in the means of compensating groups who would otherwise be losers or through institutional changes in the relative costs of political activity by groups paying the compensation (typically consumers). If we do not see a supply of reform, then we must not despair for the economic rationality of governments. We must, instead, invent the intellectual and political machinery that will allow reform to be profitably supplied.

From the perspective developed here, reforms that lessen the distortionary and inefficient aspects of agricultural policy may be induced from two important sources—the development of less wasteful means of compensation and the lowering of costs associated with making those paying the compensation more sensitive to government decisions. Developing better compensation schemes may be thought of as finding improved means to negotiate the allocation of society's welfare. Valuable transactions can take place between consumers and producers, involving the savings of many wasted resources, and yet these transactions remain unnegotiated. This is, in part, because there are no satisfactory means of satisfying both groups because of the inadequate stock of ideas. Rather than altering the political power relationships between groups, reform may be accomplished by demonstrating the feasibility of alternative, more efficient programs of wealth transfer. In the framework of the analytical model, the introduction of a less wasteful transfer scheme would be an expansion of the surplus possibility frontier at every combination of consumer and producer surplus levels (except at the free market point). Such an alteration in the surplus transformation curve would imply that the PEST more closely approximates a lump-sum transfer. In a world of perfect knowledge, where every imaginable type of policy is possible, nondistorting lump-sum transfers would be the government's optimal means of allocating society's welfare. In the real world, however, a lump-sum transfer most often is not a practical means but rather a standard by which we can measure how advanced is the state of the art in wealth transfers.

A second means of obtaining sustained reforms is a change in the relative costs of organizing those who would benefit by those reforms. By increasing the responsiveness of a group—in particular, consumers and taxpayers in the developed world—to changes in its wel-

fare, the government would take advantage of present transfer mechanisms and would move the allocation of surpluses to less wasteful combinations. Reducing the costs of organizing the beneficiaries of reform may be done in several ways—from direct subsidization to the reform of the institutions in which political activity takes place. The direct subsidization of efforts to increase the sensitivity of consumer/taxpayer groups in the developed world may, at first glance, seem to hold little promise. Nevertheless, some countries do have institutional arrangements to keep watch over consumer interests, and the experience of Australia, for example, could serve as a model for other nations. One should note, however, that the expense of decreasing the cost of pro-consumer activity and increasing the cost of pro-producer activity must be borne, at least in part if not in full, by those potential winners outside a political system targeted for reform.

The point is to move to a new political equilibrium, and this implies changing the structure on which outcomes hang; after all, for the case of constant political technology, if changing the relative costs of political activity were a simple matter of decisions made within the political system, then presumably it would already have been done. External groups (even entire nations), who would gain coincidentally with the strengthened political power of internal groups, must therefore carry part of the responsibility of beginning the reform process; and they must be prepared to share in the direct expense of increasing pro-reform activities.

There are, in addition, less direct ways of lowering the cost of organizing pro-consumer activities such as the provision of information regarding the welfare effects of government policies. Such transparency analysis has developed a great many proponents in the last several years. Although greater information to potential beneficiaries of reform may be necessary to motivate opposition to the present state of wealth transfer schemes, there are significant reasons to believe that improved knowledge will not be sufficient. First, to place all the emphasis on making transparent the effects of a government's agricultural policies implies a severe lack of intelligence by those who bear the cost of wealth transfers. Yet, food and farm policies have been in place for decades, consumers especially have enjoyed ever-cheapening food prices, and the developed world goes on in apparent good order despite the years of social waste. Second, improved knowledge is subject to the same politicization and manipulation as other information and misinformation supplied to interest groups.

Adoption Ceilings and Modern Coarse Cereal Cultivars in India

Hans G. P. Jansen, Thomas S. Walker, and Randolph Barker

The concept of, and evidence for, regional adoption ceilings is assessed for modern coarse cereal cultivars in India. Adoption is defined as the proportion of total area of a given coarse cereal planted to modern cultivars. Agroclimatic and soil differences are more important than disparities in infrastructure in explaining the variation across regions in estimated adoption ceilings. Qualitatively different modern cultivars from those now released are necessary to change regional adoption behavior. The results support an agricultural research strategy that gives higher priority to more regionally oriented breeding and testing programs in preference to the past emphasis on wide adaptation.

Key words: adoption ceilings, coarse cereals, modern cultivars.

Modern cereal cultivars were released throughout India in the 1960s.[1] Across the major cereals of wheat, rice, sorghum, pearl millet, and maize, the modern cultivars (MCs) represented a substantial change from local varietal types. MCs were photoperiod-insensitive, fertilizer-responsive, and short statured. Grown with good management on fertile soil with access to reliable rainfall, they gave markedly heavier grain yields than local varieties.

By the mid-1980s, the pattern of diffusion of MCs varied sharply among cereals and across space. The wheat MCs had largely completed their diffusion process (Dalrymple 1986b). Rice MCs had also been adopted on most of the area planted to paddy (Dalrymple 1986a). Coarse cereal MCs had penetrated into many major producing regions, but their uptake by farmers has been less uniform than for wheat and rice MCs (table 1).

In India, coarse cereals are mainly produced in the harsh production environment of rainfed agriculture which is often beset by considerable location specificity in the incidence of physical and biotic stress. Rural infrastructure in the major coarse cereal-growing regions is also often poor relative to the better endowed, more heavily irrigated areas (Wanmali).

A notable characteristic about the adoption performance of coarse cereal MCs in India is the persistence of "ceiling" levels of adoption during the 1980s. For many producing regions, adoption has oscillated around a plateau significantly less than 100%. This research seeks to (*a*) assess the relative importance of climatic, edaphic, and infrastructural factors in constraining regional adoption, and (*b*) to draw implications for agricultural investment and research strategy to increase the hypothesized ceiling levels of MC adoption.

The research represents a departure from the previous literature (Griliches 1957, Martinez, Wattleworth) in two important ways. First, the emphasis is not on explaining interregional variation in the speed of diffusion but on understanding spatial differences in endogenously estimated ceiling rates of adoption (Griliches 1980). This emphasis addresses enduring regional imbalances in MC adoption and reflects the view that welfare levels are usually determined by who ultimately adopts rather than by who first adopts (Gerhart). Second, the focus is on whether aggregate diffusion analysis of secondary data can generate insight on the desirability of investing research resources in specific-trait improvement.

Adoption Ceilings: Concept and Context

The diffusion path of aggregate adoption of a new technology often resembles a sigmoid curve, largely reflecting the dynamics of the spread of information (Feder, Just, and Zilberman). The long-run upper limit or ceiling on aggregate adoption is determined by the economic characteristics of the new technology and by the state of the economy (Griliches 1980).

Although long-run upper limits are associated with permanency, these levels can shift upwards over time in response to "second generation" technical change. For example, in 1957 Griliches estimated aggregate diffusion ceilings on corn hybrids of less than 100% for many states and crop reporting districts in the United States. Shortly thereafter, hybrids had entirely replaced open-pollinated varieties in the same regions (Dixon).

The need for and the impact of second generation technical change in shifting up initial adoption ceilings is illustrated in figure 1 for two cereal-producing regions. The first is the idealized case; the second is what often happens. In homogenous region A, the first-released groups of MCs are economically and uniformly superior to the local varieties; consequently, the long-run level of adoption of 100% is quickly attained. In contrast in heterogenous region B, the first-generation MCs are more profitable than local varieties in only some selected locales, probably those of higher production potential. As a result, the adoption ceiling falls far short of 100%. Suppose at time t^* second-generation MCs are released to farmers. If the second-generation MCs are successful in addressing the location-specific problems of earlier MCs, full

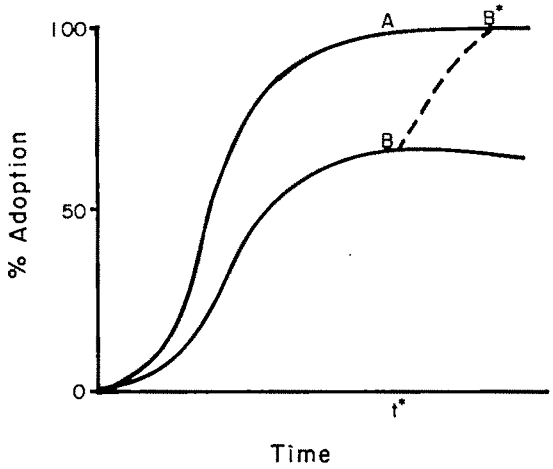

Figure 1. Adoption ceilings and second generation technical change in two regions

adoption may still occur but on a secondary diffusion path such as the dotted line in figure 1.

Although the concept of an adoption ceiling is potentially useful, it can be empirically elusive. Because agricultural technologies are ultimately location specific and because administrative reporting units are usually comprised of multiple soil and rainfall environments, ceiling levels of adoption can vary substantially. More important, data on area planted to specific cultivars are often not available. Usually, one has access only to the area planted to MCs as a whole. Therefore, one cannot distinguish between the adoption profiles of the first and second generation MCs in figure 1.

In other words, estimating an aggregate adoption curve on OBB^* may give results that are neither fish nor fowl. As Griliches (1980) points

out, the slow upper tail may be associated with the lack of well-adapted MCs, thereby confounding summary information on the speed of acceptance of the innovation. To overcome this problem, Griliches recommends that aggregate adoption analysts use a model with an endogenous and shifting ceiling parameter. Alternatively, one can choose a time horizon that largely restricts the analysis to the first wave of MCs, as occurs in this paper.

With the exception of some maize composites, the first wave of modern coarse cereal cultivars was largely synonymous with hybrids. Exotic lines and foreign breeding efforts played a crucial role in their development, and selection procedures in breeding were heavily biased towards yield potential and wide adaptability. Improved open-pollinated sorghum and pearl millet varieties were introduced commercially on a wider scale only in the early to mid-1980s.

By the mid-1980s in India, second and third generation modern coarse cereal cultivars had been introduced only recently or were not that qualitatively distinct from their first generation counterparts. Incentives in public-sector plant breeding still centered on national yield performance in multilocational trials. The emphasis on wide adoption did not explicitly address the more specific problems of ecological niches. Hence, except for the second generation pearl millet hybrids and to a lesser extent later maize hybrids and composites, the period ending in 1983–84 corresponds mainly to the diffusion of the first batch of MCs.

Later generation technical change is not the only plausible explanation for upward shifts in adoption ceilings in figure 1. Expanding and deepening rural infrastructure could also lead to increasing equilibrium adoption levels. But changes in rural infrastructure likely would have a greater effect on the earlier than on the later properties of the diffusion process. Improving rural infrastructure can result in higher profitability of the more input-intensive MCs, but it cannot fully compensate or directly substitute for susceptibility to physical and biotic stress that constrain profitability of MCs.

Estimation

The research method is a modified version of Griliches' (1957) two-stage approach that has been widely used to examine adoption behavior (e.g., Martinez, Globerman, Romeo, Rapoport, Wattleworth, Jarvis).

First Stage

The first stage consists of fitting a logistic curve to the historical diffusion data, thus summarizing, for each cross-sectional entity, the adoption process in two parameters: the diffusion speed and the adoption ceiling.[2] The first-stage logistic equation is

$$(1) \qquad F_i(t) = y_i/(1 + \exp(-a_i - b_i t)),$$

where $F_i(t)$ is the cumulative percentage of area sown with MCs for production region i and time t, y is the ceiling coefficient or long-run equilibrium value, b is the diffusion speed coefficient, and a is a constant of integration that positions the curve on the time scale. Treating the ceiling level of adoption as endogenous results in a nonlinear estimation problem which can be solved only through numerical optimization. Marquardt's method was used to generate the nonlinear logistic estimate of the ceiling coefficient y (Judge et al.).

Second Stage

The second stage examines the determinants of the variation in the first-stage estimates by hypothesizing that the adoption ceilings are functions of specific sets of variables. Because the estimated adoption ceilings lie between 0 and 1 (or between 0 and 100%), the dependent variable is truncated, and a linear probability model (LPM) estimated with ordinary least squares (OLS) is inappropriate (Judge et al.). A popular alternative to a LPM is the logistic specification (2).

$$(2) \qquad y_i = (1 + \exp(-a - bX_i - e_i))^{-1}.$$

Equation (2) is often transformed into the linear logit model (3) which can be estimated by OLS:

$$(3) \qquad \ln (y_i/(1 - y_i)) = a + bX_i + e_i.$$

Two methodological improvements on (2) or (3) are offered for the second-stage estimation. The first improvement derives from the notion that the slope of the cumulative logistic probability function is greatest at the midpoint. Therefore, changes in explanatory variables will have their greatest impact on the dependent

[2] Weibull and Gompertz functions were also fitted to the time-series adoption data to allow for asymmetry in aggregate adoption behavior (Dixon). Based on goodness-of-fit criteria, neither the Weibull nor the Gompertz was a significant improvement over the logistic (Jansen).

variable at the midpoint of the distribution. Similarly, the low slopes near the endpoints of the distribution imply that relatively large changes in the independent variables are necessary to bring about a small change in the dependent variable. Because the tail values of the dependent variables are associated with large errors, in a proportional sense, the logit model in (2) with its multiplicative error structure is not ideal. To redress this implicit weighting imbalance, the logit model in (4) with an additive error structure was used.

$$(4) \qquad y_i = (1 + \exp(-a - bX_i))^{-1} + e_i.$$

The second improvement is an application of generalized least squares. It was first applied in aggregate diffusion analysis by Wattleworth. The information embedded in the different standard errors of the adoption ceilings estimated in the first stage can be used to derive more accurate second-stage parameter estimates. Consequently, each error term e_i is assumed normally distributed with variance σ_i^2, where $\mathrm{Var}(e_i) = E(e_i^2) = \sigma_i^2$ is not constant across production regions. Each observation on all variables in the second stage was divided by the standard error of the estimated adoption ceiling, and weighted least squares was used to estimate (4).

In addition, each observation in the second stage was also weighted by the average area under the crop in each producing region. Consequently, as a result of the two weighting procedures, a producing region attained more importance the smaller is the estimated standard error of its adoption ceiling and the larger is its area under the coarse cereal.

Data

The analysis was based on secondary district data from a ten-state, time-series data base assembled by the International Crops Research Institute for the Semi-Arid Tropics (ICRISAT) and the World Bank largely from the state season and crop reports and statistical abstracts. The time-series spanned 1966–67 to 1983–84.[3]

For each coarse cereal, the production regions correspond to major producing districts which are equivalent to large counties in the United States. A district was included in the sample if it accounted for at least 0.5% of the average total production of the crop during the 1981–82, 1982–83, and 1983–84 agricultural years. Applying this rule gave sample sizes of sixty-six districts for sorghum, sixty for pearl millet, and fifty-eight for maize.

In the early 1980s, the study districts for sorghum and pearl millet accounted for virtually the entire all-India production. The study districts for maize covered only 70% largely because the important maize growing state of Bihar was excluded due to lack of data.

[3] The ten states were Andhra Pradesh, Madhya Pradesh, Karnataka, Tamil Nadu, Maharashtra, Gujarat, Rajasthan, Punjab, Haryana, and Uttar Pradesh.

First-Stage Estimates of Adoption Ceilings

The hypothesis of logistic adoption ceilings received considerable empirical support for both sorghum and pearl millet but not for maize. For sorghum and pearl millet, the estimated ceiling was statistically significant at the .05 level for, respectively, forty-seven (out of 66) and thirty-five (out of 60) districts. Out of those, thirty-nine sorghum districts and nineteen pearl millet districts exhibited a ceiling significantly different from 1.00 (table 2). For maize, the first stage results are characterized by a relatively large number of districts reporting negligible adoption. In general, the logistic did not fit the data that well for many of the maize districts. In districts where adoption was negligible or where the logistic did not converge or did not give a statistically significant estimate of the adoption ceiling, the ceiling estimate was generated by

Table 2. Evidence (in Number of Producing Districts) for Adoption Ceilings of Modern Coarse Cereal Cultivars in India from 1966–67 to 1983–84

	Coarse Cereal		
Adoption Status	Sorghum	Pearl Millet	Maize
Full adoption[a]	8	16	5
Partial adoption and no ceiling[b]	16	20	23
Partial adoption and ceiling[c]	39	19	8
Negligible adoption[d]	3	5	22

[a] Estimated ceiling with a logistic specification greater than 0.90 and statistically significant at the .05 level.
[b] Estimated ceiling with a logistic specification not statistically significant at the .05 level.
[c] Estimated ceiling with a logistic specification less than 0.90 and statistically significant at the .05 level.
[d] The proportion of MC area never exceeded 0.10 during any year in the period of analysis.

averaging the last five years of data in the time series.[4]

Pearl millet districts with a nonsignificant adoption ceiling largely correspond to areas where the first-released pearl millet hybrids became susceptible to downy mildew, resulting in significant economic losses in the early 1970s. In response to those losses, many farmers reverted to local types. In the mid- and late-1970s, hybrid adoption again picked up as farmers accepted the second-generation hybrids which, at that time, were much less susceptible to downy mildew. Therefore, several pearl millet districts had a diffusion curve that better resembled a roller coaster than the conventional S-shape.

In the case of maize, of the thirty-six districts where some diffusion of MCs had occurred, only thirteen were associated with a statistically significant adoption ceiling at the .05 level. The relatively recent release and partial adoption of "second generation" shorter duration MCs in some districts of North India in the early 1980s is a plausible explanation for the poor fit of the logistic to the time-series data from 1966–67 to 1983–84.

A comparative statement of the adoption experience between the modern coarse cereal cultivars and the wheat and rice MCs is made in table 3. For wheat and rice, the ten-state data base is the same as was used for the coarse cereals, and the procedures described earlier were employed to estimate the ceiling levels of adoption.

The contrast between coarse cereal MCs and wheat and rice MCs is marked in table 3. The distribution of the major wheat- and rice-producing districts in the ten-state sample is concentrated in the higher frequencies of more than 50% MC adoption. The coarse cereal districts display a much wider range of diffusion experience.

Coarse cereal MC ceilings approaching full adoption have been confined to specific regions of peninsular India. These eminently successful cases of diffusion of MCs correspond to central Maharashtra where sorghum hybrids are grown in an environment of high production potential, to Gujarat where pearl millet hybrids are widely cultivated, and to regions in South India where maize is nontraditionally produced. Explaining the interregional variation in adoption ceilings is the objective of the next section.

Table 3. Distribution (in Number of Producing Districts) of Estimated Ceiling Levels of Adoption by Cereal

Frequency Range in %	Cereal: Sorghum	Pearl Millet	Maize	Wheat	Rice
<10	11	7	22	0	0
10–25	12	2	9	1	1
26–50	20	13	12	4	7

76–90	2	3	1	19	18
>90	8	19	7	34	21
Total	66	60	58	67	67

Second-Stage Model Specification

The explanatory variables, corresponding to the X vector in equations (2), (3), and (4), can be classified into two groups: (*a*) agroclimatic and (*b*) infrastructural variables.

Agroclimatic Variables

The agroclimatic variables reflect the quality of the production environment and the potential sources and incidence of yield reducers on each crop. They were identified from literature reviews and discussions with crop improvement scientists (Jansen).[5]

The agroclimatic variables can be subdivided as follows: (*a*) soil by mean annual rainfall dummy variables, (*b*) growing season monthly rainfall and its variability, for months where prior expectations were strong, and (*c*) other considerations related to the physical and biotic production environment. In general, the soil by rainfall interactions represent the physical quality of the production environment; the monthly rainfall variables are associated with specific types of physical and/or biotic stress.

Expectations regarding the influence of specific yield reducers are based on perceptions on the quality of the production environment (better endowed regions should be more conducive to MC adoption) or on expected differences in tolerance to stress and disease or in growing duration between local varieties and MCs which results in the ability to avoid physical or biotic stress.

[4] For those districts, the standard errors used in the second-stage estimation were also calculated from the last five years of the data series.

[5] A table containing a description of the agroclimatic variables, their sample means and ranges, their expected signs, and associated yield reducers by coarse cereal is available from the senior author upon request.

Average pre-MC yield in the early 1960s is a regressor in the subset of other considerations for each coarse cereal. This variable controls for aspects of the production environment that are not captured by the soil-rainfall interactions or by the monthly rainfall levels or variabilities. *Ceteris paribus,* one expects that higher pre-MC yields are positively associated with MC adoption (Griliches 1957).

Other agroclimatic variables include (*a*) the percentage of rainy season area in the sorghum equation (sorghum MCs have been successfully developed for rainy season cultivation but not for post-rainy season sorghum cultivation) and (*b*) a low rainfall-irrigation interaction because of the high expected productivity of maize in a dry production environment with assured irrigation.

Infrastructural Variables

The infrastructural variables, described in table 4, reflect use of irrigation and access to fertilizer, markets, and roads.[6] In contrast to the agroclimatic variables, they were the same for each coarse cereal.

In the spirit of Boserup; and Pingali, Bigot, and Binswanger, a demographic variable reflecting population pressure on land was also included as a regressor for each coarse cereal. *Ceteris paribus,* a higher ratio of persons to land should be accompanied by increased demand for yield-increasing technical change.

Six models were specified for each of the three cereals; each specification differed in functional form, combination of independent variables, and sample size (Jansen). The nonlinear logit with the additive error structure in equation (4) gave a consistently better statistical fit than either a linear probability or a conventional logit model for all three crops.

[6] Other infrastructural variables (e.g., literacy rate and percentage of villages electrified) were tried in some initial runs of the second-stage estimation. They were highly collinear with the other regressors and did not contribute significantly to the explanatory power of the model. District data on credit or extension infrastructure were not available at the time of the analysis.

Second-Stage Results

Before discussing the second-stage estimated coefficients for each coarse cereal, the overall contribution of the agroclimatic variables and infrastructural variables in explaining the variation in adoption ceilings among major producing districts is considered.

Relative Importance of Agroclimatic and Infrastructural Variables

To test the relative importance of agroclimatic and infrastructural variables, the R^2s are compared for the following three models in table 5: (*a*) an infrastructural model with the independent variables in table 4, (*b*) an agroclimatic model with agroclimatic independent variables, and (*c*) a combined or full model containing both sets of variables as regressors.

The infrastructural variables explain a large share of the interregional variation in MC adoption particularly for pearl millet and maize, but the agroclimatic variables have higher explanatory power. The additional explanatory power of the infrastructural variables in the combined model is not statistically significant at the .05 level with an F-test for both sorghum and pearl millet. Inclusion of the agroclimatic variables to the infrastructural model does lead to significantly enhanced explanatory power for each of the coarse cereals.

Investment in infrastructure has been biased toward the agroclimatically superior regions. This

Table 4. Means of the Infrastructural Variables by Coarse Cereal

Variable	Unit of Measurement	Coarse Cereal: Sorghum	Pearl Millet	Maize
Irrigation	Proportion of cropped area	0.03	0.07	0.28
Fertilizer outlet density	Distribution points/10 km^2	0.35	0.41	0.52
Road density	km of road/10 km^2	3.24	2.68	2.70
Market density	Number of regulated markets/10 km^2	0.02	0.02	0.04
Population	People/ha	2.26	1.82	2.07

Table 5. Proportion of Variation in Estimated Adoption Ceilings Explained by Different Models by Coarse Cereal

	Coarse Cereal		
Model	Sorghum	Pearl Millet	Maize
	($\bar{R}^2$)		
Infrastructural	0.43	0.67	0.78
Agroclimatic	0.80	0.93	0.90
Combined	0.84	0.94	0.95

translates into multicollinearity between the agroclimatic and the infrastructural variables. Such multicollinearity explains why infrastructural variables on their own can explain a substantial part of the variation in adoption ceilings, while at the same time their marginal contribution in the combined model is small.[7]

Sorghum

Rainy season area as a percentage of total sorghum area has the strongest effect on adoption of any of the statistically significant regressors in the sorghum model (tables 6 and 7). Varietal change has been negligible in the postrainy season when sorghum is grown under the relatively assured but low productivity environment of receding soil moisture.

The estimated coefficients of the dummy variables for soil by growing season all tell the same story: too much rain limits the adoption of sorghum MCs. Moving from the reference point of medium black soil and medium rainfall to a higher rainfall regime on black soil is accompanied by a significant fall in the adoption level. Contrary to a priori expectations on drought as a constraint to adoption, switching to a lighter rainfall regime on either medium black, deep black, or red soils results in a significant shift upwards in the estimated ceiling level of adoption. Sorghum in general and MCs in particular are sensitive to water stagnation and to untimely rains favoring pest and disease infestation.

Early growing season rainfall in June also is a significant constraint to the adoption of sorghum MCs. The significance and size of the corresponding coefficient indicate the importance of stand establishment in influencing the adoption of MCs.

[7] Another potential problem consists of a simultaneous equation bias caused by the possibility that infrastructure investments were spurred by the availability of modern cultivars in the favorable areas.

Road density (km of road/10 km^2)			0.61

Note: Elasticity values for continuous variables in logistic-based models equal $bx(1 - y)$, where b is the estimated regression coefficient, x the regressor value, and y the estimated ceiling value. Elasticities were evaluated at arithmetic means of the variables. For the soil-rainfall dummy variables the reported figures are simple marginal coefficients which equal $by(1 - y)$.
[a] Dry districts only.

Regions with more variable September rainfall are also less likely to adopt sorghum MCs than other producing zones. Because sorghum MCs are usually harvested before the monsoon recedes in October and rainfall just before harvesting favors the development of grain mold and earhead pest infestations, sorghum MCs should be more affected by rainfall variability in September than the later-maturing, photoperiod-sensitive local varieties.

The infrastructural variable with the strongest effect on sorghum MC adoption is the density of fertilizer distribution points. Under good rainfall conditions, sorghum MCs can be highly responsive to fertilizer. Irrigation is also statistically significant although its effect on adoption is relatively small.

The negative and significant coefficient of the person-to-land ratio in table 6 is also contrary to a priori expectations. The importance of sorghum as a fodder could explain this finding. The demand for milk, particularly in urban areas, is high in India, and sorghum stover is widely fed to dairy cattle. Because local varieties produce more fodder and less grain per plant, they might be preferred in areas where the urban demand for milk fuels rising stover to grain price ratios (Walker).

Pearl Millet

Explanations for the interregional variation in MC adoption in pearl millet centered on the levels and variability in monthly rainfall. Six of the eight monthly rainfall-related regressors are sta-

tistically significant in table 6. Variability in June, July, and August rainfall, associated with early, mid-, and end-of-season drought, have a negative impact on the ceiling level of adoption. More abundant early season rain in June should result in improved stand establishment and, as expected, June rainfall was signed positive. Heavier rain later in the season should foster panicle diseases and, as expected, was signed negatively.

The significant results for the variabilities in annual rainfall and in September rainfall are inconsistent with a priori expectations. Those results imply that *ceteris paribus,* the adoption of pearl millet MCs is greater in more variable annual and September rainfall conditions. Perhaps these results attest to the robust character of pearl millet MCs which suffer from fewer yield reducers than either maize or sorghum MCs. Shorter duration pearl millet MCs may also better escape variable drought stress in September than longer duration locals.

Three of the eight soil by growing season rainfall regions have adoption ceilings significantly different from the benchmark sandy soil, medium rainfall region. In the dry sandy soil, low rainfall region comprised mainly of Rajasthan, pearl millet MCs have made limited headway. Districts with heavier black soil and low rainfall represent a high potential production environment for pearl millet hybrids. Waterlogging limits the profitability of pearl millet hybrids in districts with alluvial soils and high rainfall.

Unlike sorghum and maize, pre-HYV millet yields do contribute significantly to explaining the interregional variation in MC adoption. Net of the included climatic, soil, and infrastructural variables, districts with heavier pearl millet yields before the MCs were released also had higher levels of adoption.

Consistent with the sorghum result, population density significantly and inversely affects adoption. The urban demand for milk may apply equally well for pearl millet as for sorghum.

Maize

The results for maize were more sensitive to model specification. Infrastructural variables, particularly fertilizer, loomed larger in explaining interregional variation in adoption than for sorghum and pearl millet. Unlike the sorghum and pearl millet hybrids, the maize MCs are mostly of longer duration than local varieties, and they may not fit as well in farmers' cropping systems. In general, the yield differences of the MCs over the local varieties are less for maize than for sorghum or millet. Maize is also less drought tolerant, more responsive to inputs, and less susceptible to panicle diseases than the other two coarse cereals. Thus, the size and significance of the fertilizer density variable and the low rainfall-irrigation binary variable is consistent with a priori expectations.[8] Because more maize is marketed than sorghum and millet, a finding of the significant bearing of road density on adoption is also not surprising.

Similar to the results for millet, too much or too little water can erode productivity and incentives for MC adoption. Within production regions, mainly in North India, where alluvial soil is common, both the high and low rainfall districts are inferior in adoption performance to the more moderate rainfall regions. Excess rainfall can also be a problem in the sandy soil regions but does not appear to be a constraint to adoption in the nontraditional, predominantly black-soil, maize-producing belt in South India.

A positive and significant estimated coefficient on July rainfall and a negative and significant coefficient on the variability of annual rainfall indicate the presence of drought as a yield reducer. More support from drought as a yield reducer comes from the linear logit specification (not reported) where the coefficient of the variability in June rainfall was signed negatively and significant.

The negative influence of August rain on MC adoption is attributed to waterlogging and stalk rot, which is a problem in areas of higher rainfall during the early August preflowering period. In some years, shorter duration local varieties can escape the adverse consequences of excess rainfall in August.

Implications and Conclusions

This study finds evidence for (*a*) ceiling levels of adoption, (*b*) the importance of agroclimatic variables relative to infrastructural considerations in conditioning those ceilings, and (*c*) the use of diffusion analysis of secondary data to

[8] In order to separate out the effect of irrigation in "dry" maize districts (annual rainfall < 750 mm) and "wet" maize districts (annual rainfall > 750 mm), a new variable was created consisting of the product of a dummy variable (equaling one for dry districts and zero otherwise) and a variable measuring the percentage of irrigated maize area. The effect of irrigation on the adoption ceiling is then measured by the sum of the estimated coefficients of the newly created variable and the irrigation variable for dry districts and by the coefficient of the irrigation variable for the wet districts.

shed some light on priorities for agricultural research in coarse cereals to shift the adoption ceilings.

For agroclimatic variables, excess moisture significantly influences adoption of coarse cereal MCs in some producing regions. Sorghum in particular is highly susceptible to rainfall-induced disease and pest infestations. While early season drought can curtail MC adoption, the possible influence of mid- to end-season drought on adoption ceilings was not supported empirically. Thus, except for the sandy soil, low rainfall pearl millet growing regions and the post-rainy sorghum growing belt, the findings suggest that early season moisture stress warrants higher priority in drought research than mid- to late-season stress.

For infrastructure, the inverse relationship between population pressure and the ceiling levels of sorghum and pearl millet MC adoption suggests that more weight should be given to fodder as an end use in MC development.

The findings also indicate that expanding and deepening input and output market infrastructure alone are unlikely to substantially increase the present adoption ceilings. Qualitatively different MCs from those now released appear necessary to change regional adoption behavior. Fertilizer availability, especially for sorghum and maize, was the most important infrastructural variable in explaining interregional variation in MC adoption. The significance of the dummy variables for soil by growing season rainfall associated with excess moisture also suggest that investment in drainage could stimulate adoption of MCs in some producing districts.

The results highlight the importance of regionally specific production conditions in crop improvement research in India. The past emphasis on wide adaptation in breeding research has stimulated aggregate productivity growth and aided in identifying the regions of higher production potential. With growing private sector research on coarse cereal hybrids (Pray et al.), the public sector could reallocate its resources to more location specific and difficult problems of the lagging adoption regions. In addition, as suggested by the results for maize, the total cropping system rather than individual crops should be emphasized.

Household Inventories and Marketed Surplus in Semisubsistence Agriculture

Mitch Renkow

A model of semisubsistence agriculture explicitly accounting for the ability of farm households to hold inventories of staple foods is developed. Comparative statics analysis highlights the potential importance of wealth effects attributable to price-induced changes in the value of household inventories. Empirical results for three groups of households in an Indian village confirm that failure to account for household inventories leads to an overstatement of the responsiveness of both consumption demand and marketed surplus.

Key words: agriculture household model, inventories, marketed surplus.

A notable feature of nearly all developing countries is that most agricultural households produce a significant portion of the staple foods that they consume. This is the case for a wide cross section of geographical locations, levels of technological advancement, and land tenure arrangements. How these semisubsistence households allocate output of staple foods between home consumption and market sales is an issue that has received considerable attention from economists because of its important implications for aggregate market supply, food disappearance patterns, and the attendant nutritional consequences for rural and urban dwellers.

A major focus of past research has been measuring the response of marketed supply (or marketed surplus) to changes in prices and other exogenous variables. Most analyses begin by positing an identity that sets marketed surplus equal to the difference between output and consumption (Behrman, Haessel). Differentiating this identity then yields an expression for the price elasticity of marketed surplus as a function of the price and income elasticities of consumption and the price elasticity of total output. Recently, Strauss (1984, 1986) has made an important contribution to this literature by explicitly recognizing the wealth effects on consumption resulting from the impact of price changes on farm profits. His theoretical work demonstrates that under certain circumstances these wealth effects may be large enough to induce positive own-price demand response and negative marketed surplus response.

The point of departure for this paper lies in the omission of household storage of staple foods from existing research on semisubsistence households. Implicitly, all work to date has assumed that households costlessly store exactly the amount allocated to home consumption over the period between harvests. Arguably, this is a relatively harmless simplification, especially if the marginal cost of storage is low. A more serious conceptual problem, however, is that existing models take consumption, output, and sales as occurring simultaneously. A change in the price of a commodity that is produced by the household thus affects marketed surplus through its impact on both contemporaneous consumption and production. Within a given cropping cycle, this is not normally the case; rather, the output from which marketed surplus is drawn is predetermined and exists as currently held inventories and/or recent harvests. Stocks on hand and expected future output are likely to influence short-run marketing decisions, but only through wealth effects on consumption. Even in the long run, when output can adjust to price movements, these wealth effects may still significantly affect marketed supply response.

Two factors may motivate semisubsistence

Mitch Renkow is a Rockefeller Foundation research fellow at the International Maize and Wheat Improvement Center, El Batan, Mexico.

The author is grateful to Jerry Carlson, Mike Wohlgenant, Wally Thurman, Tom Johnson, Tom Walker, Derek Byerlee, John Strauss, and Harold Alderman for insightful comments on earlier versions of this paper.

households to hold inventories of staple foods. First, households might want to minimize their reliance on local markets for the satisfaction of basic food needs, holding stocks of food as a contingency against unanticipated supply disruptions. Second, inventories of home-produced staples might result from profit-seeking behavior in response to seasonal price movements for a particular storable commodity. Subject to storage costs and on-farm storage capacity, such arbitrage opportunities could influence the timing of market sales.[1]

In the next section, a simple model of the economic behavior of semisubsistence farm households is developed. The model follows in the tradition of the household-firm literature (Jorgensen and Lau, Barnum and Squire), but it is distinguished from previous work by its recognition of the ability of households to store important consumption items (specifically, staple foods). The model's solution highlights the importance of expected future prices as arguments of both inventory and commodity demand functions, and yields a simple inventory demand equation which provides an empirically tractable way of distinguishing between different motives for holding stocks. Expressions for short- and long-run response of demand for and marketed surplus of storable commodities are then derived. These differ considerably from comparable expressions found in the literature. In particular, it is shown that as long as household inventories are nonzero, the earlier methods will have overstated the own-price elasticities of both demand and marketed surplus.

The empirical analysis is directed at estimating these elasticities and comparing them with those computed using more traditional methods. Econometric results are presented for three groups of households in a poor West Indian village in which stocks of grain comprise a significant share of household wealth. The results provide evidence that inventories of staple foods can indeed have important effects on the own-price response of both demand and marketed surplus, primarily through wealth effects on consumption. Finally, a comparative analysis confirms that by failing to account for the role of inventories, earlier methods systematically overstated the own-price elasticities of both demand and marketed surplus for stored commodities.

[1] A referee points out that an additional motive for holding inventories is a household's desire to diversify its portfolio of savings assets. Such a savings motive is related to the first motive discussed above in that both stem from a desire to minimize risk.

An Agricultural Household Model with Storage

Consider a representative semisubsistence household that produces a single storable food commodity (X_1) that is either consumed or traded for one other (composite) commodity (X_2). Utility is derived solely through the consumption of the two goods and leisure (X_L),[2] with the one-period household utility function given by

$$(1) \qquad U_t = U(X_{1t}, X_{2t}, X_{Lt}),$$

where $U(\cdot)$ is twice-differentiable, continuous, quasi-concave, and intertemporally strongly separable. The household is assumed to maximize the expected (discounted) value of a stream of current and future utilities up to the end of the current cropping cycle. Each cropping cycle is composed of $T + 1$ periods $(0, \ldots, T)$, extending from harvest to harvest, and cycles overlap in the sense that period T of one coincides with period 0 of the next.

At the beginning of each cropping cycle the quantity Q_o is harvested. In each period, the household sells or buys the quantity M_t at price P_{1t} (positive for sales, negative for purchases), consumes an amount X_{1t} of the produced commodity, and purchases an amount X_{2t} of the alternate commodity at price P_{2t}. The portion of marketable surplus not sold or consumed in a given period must be stored. Disappearance of the produced commodity in period t is governed by the stock identity[3]

$$(2) \qquad I_t - I_{t+1} + Q_t = X_{1t} + M_t,$$

where I_t and I_{t+1} are carryin and carryout inventory levels, respectively, and Q_t is output of the produced commodity in period t. Output is modeled as certain, with production assumed to depend only on one variable input (labor) and one fixed factor (land):[4]

$$(3) \qquad Q_T = Q(L_o, \ldots, L_{T-1}; A_o),$$

where L_t denotes total labor used by the household in period t (both family and hired) and A_o

[2] The model can be expanded easily to include vectors of storable and nonstorable commodities, cash crop production, and production of nonstorable foods. However, the "bare-bones" model presented here is sufficient to illustrate the salient points.

[3] Storage losses are ignored here because they do not substantively affect the behavioral implications of the first-order conditions. Assuming proportional losses has an effect identical to lowering the household's subjective rate of time preference (Wohlgenant, p. 740).

[4] See Roe and Graham-Tomasi for a treatment which introduces production risk into an agricultural household model.

is the household's fixed quantity of land. By definition, $Q_t = 0$ for $t = 1, \ldots, T - 1$.

Assume that the one-period cost of carrying inventories from period t to period $t + 1$ is given by

$$(4) \quad C(I_{t+1}, X_{1t}) = a_o + {}^1\!/_2 f^{-1} \cdot (I_{t+1} - g_o - gX_{1t})^2,$$

where a_o, f, g_o, and g are parameters assumed to be positive. This specification, discussed in Holt et al. and Belsley and more recently employed by Wohlgenant, posits inventory costs as composed of two offsetting components. The first is the physical cost of holding stocks, which is increasing in I_{t+1}. The second is a convenience yield, expressed as a linear function of consumption. In the production-oriented inventory literature this latter component typically refers to the opportunity cost of stock-outs and back-ordering. Here the emphasis is on consumption, but the logic is the same: convenience yield is the value to the household of being able to meet demand for the storable commodity from its own stocks.[5] Thus, convenience yield from household inventories is similar to the benefits attributed to liquidity in the savings literature.

In the context of semisubsistence agriculture, the cost of stocking out likely rises more steeply than the physical cost of holding inventories. This certainly would be the case if a market for the stored commodity were absent, as then stocking out would mean doing without. Alternatively, the existence of covariate production risk over a large geographical area—a feature characteristic of rainfed agriculture in many locations—would cause the marginal cost of stocking out to be high, even in the presence of complete markets. In this event, an individual household's poor harvest would be correlated with diminished aggregate supply (and attendant higher prices).

The preceding discussion is illustrated in figure 1. Inventory holdings are plotted on the x-axis and costs on the y-axis. For positive inventory holdings, storage costs rise in proportion to the quantity held. To the left of the vertical line that indicates zero inventories, the cost of not

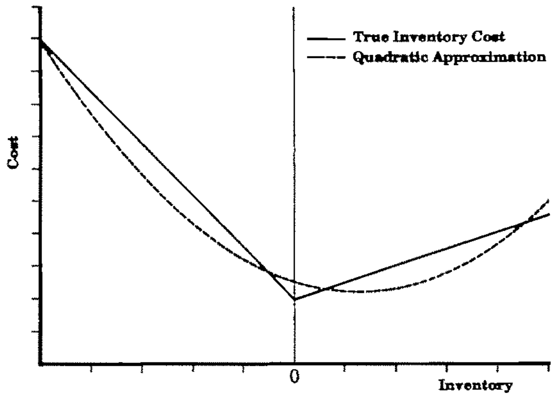

Figure 1. Quadratic approximation of inventory cost

having stocks on hand to meet demand rises more steeply. The quadratic specification of equation (4), shown as a dotted line, approximates the true inventory cost function.[6]

Sources of cash income for the household include sales of agricultural output, off-farm labor earnings (at a wage P_{Lt}), and exogenous non-wage income (Y_t). Households can also borrow any amount B_t at a one-period interest rate r.[7] Household expenditures consist of commodity purchases, storage costs, production costs, and loan repayments. Thus, in each period the household faces a budget constraint given by

$$(5) \quad P_{1t}M_t + P_{Lt}(F_t - L_t) + Y_t + B_t = P_{2t}X_{2t} + C(\cdot\,,\cdot) + (1 + r)B_{t-1},$$

where F_t is family labor. If $F_t - L_t > 0$, then the household is a net supplier of labor to the market (and vice versa).

It is assumed that markets exist for all commodities and labor, that the household is a price taker in these markets, and that hired and family labor are perfect substitutes, thus insuring that the model is recursive (Barnum and Squire). To complete the model, a time constraint states that in each period the total time available to the

[5] Implicit in the inventory cost function specified in equation (4) is the notion of negative inventories. This is equivalent to back-ordering and stock-out costs as treated in conventional inventory models. In the present context, it may be rationalized by noting that semisubsistence households often have access to in-kind credit markets whereby grain will be borrowed in lean periods and repaid at harvest time. Thus, household consumption may exceed market purchases even when no stocks are carried over from a previous period without violating the stock identity of equation (2).

[6] Another interpretation is that the quadratic approximation simplifies fixed costs of entry into the market—i.e., a jump when the slope of the true inventory cost schedule shifts from positive to negative. If true, this would invalidate the recursiveness of the model, by endogenizing output price.

[7] The assumption of perfect credit markets, while nearly universal in this class of models, is often dubious. While all households in the village considered in this study do have access to some form of credit, there is evidence of segmentation between formal and informal credit markets and equilibrium rationing (Binswanger et al).

household (T^*) is devoted to either leisure (X_{Lt}) or labor:

(6) $$T^* = X_{Lt} + F_t.$$

Equations (1)–(6) define an optimization problem to be solved in each period by the household. To obtain a solution to this problem, first solve (2) for M_t and (6) for F_t. Next, substitute these and (3) into the budget constraint and form the Lagrangian

(7) $$\underset{z}{\text{Max}}\, E_t \sum_{s=t}^{T} b^{s-t}\{U(X_{1s}, X_{2s}, X_{Ls}) + \lambda_s[P_{Ls}(T^* - X_{Ls} - L_s) + P_{1s}(Q_s + I_s - I_{s+1} - X_{1s}) + B_s + Y_s - P_{2s}X_{2s} - C(I_{s+1}, X_{1s}) - (1 + r)B_{s-1}]\},$$
$$Z = (X_{1t}, X_{2t}, X_{Lt}, I_{t+1}, B_t, L_t).$$

Here $b = (1 + r)^{-1}$ is the discount rate (assumed constant) and E_t denotes a mathematical expectation conditional on information Ω_t available at time t. Ω_t is assumed to include all current and past values of the control variables in Z and prices.

Differentiating (7) with respect to the control variables yields the following first-order conditions for any period t:[8]

(8) $$U_{1t} - \lambda_t(P_{1t} + C_x) = 0$$

(9) $$U_{2t} - \lambda_t P_{2t} = 0$$

(10) $$U_{Lt} + \lambda_t P_{Lt} = 0$$

(11) $$bE_t(\lambda_{t+1}P_{1t+1}) - \lambda_t(P_{1t} + C_I) = 0$$

(12) $$E_t(\lambda_t - \lambda_{t+1}) = 0$$

(13) $$b^{T-t}E_t P_{1T}(\partial Q_T/\partial L_t) - P_{Lt} = 0$$

plus the budget constraint. Here, C_I and C_X denote the partial of the inventory cost function with respect to I_{t+1} and X_{1t}, respectively, and λ_t is the marginal utility of period t income.[9]

Given the inventory cost function [equation (4)], equations (11) and (12) imply that optimal inventory holdings will be a linear function of the difference between the current and (discounted) expected value of the next period's price for the stored commodity and the household's demand for the commodity in the current period. Substituting (4) and (12) into (11) and rearranging:

(14) $$I_{t+1} = g_o + f \cdot \Delta P_t + g \cdot X_{1t},$$

where $\Delta P_t = bE_tP_{1t+1} - P_{1t}$. A natural interpretation of the f and g parameters is that they indicate the strength of arbitrage and food security motives for holding inventories discussed earlier.

Equations (8)–(10) yield the standard result that at the optimum the marginal rate of substitution between any pair of goods (including leisure) will equal the ratio of the prices of those goods.[10] Equation (13) provides another standard result, namely, that the optimal allocation of labor into the production process is such that the (expected) value of its marginal product equals the wage rate. This result also highlights the recursiveness of the model in that none of the demand-side control variables appear in (13).

Comparative Statics

Short-Run Response

The model developed above treats the timing of the household's economic activity over the cropping cycle more carefully than previous work. In particular, the assumption that production, consumption and sales occur simultaneously has been abandoned. Instead, the present analysis recognizes that the output from which marketed surplus is drawn by the household is predetermined, existing as currently held inventories and new production. This has implications for marketed surplus response.

Differentiating (2) with respect to P_{1t} (and noting that within the cropping cycle $dQ_t/dP_{1t} = dI_t/dP_{1t} = 0$)

(15) $$\frac{dM_{1t}}{dP_{1t}} = -\frac{dX_{1t}}{dP_{1t}} - \frac{dI_{t+1}}{dP_{1t}}.$$

[8] It is assumed that the random disturbances of the forcing variables in (7) are normal with zero means. This insures that first-order certainty equivalence holds (Malinvaud), allowing the optimization problem to be solved as if no uncertainty existed.

[9] The result that $E_t\lambda_{t+1} = \lambda_t$—i.e., that the marginal utilities of current and expected income are equal—is derived somewhat differently by Browning, Deaton, and Irish in the context of a life-cycle model of labor supply. Here, it hinges on the assumption that the utility rate of time preference equals the rate of interest on borrowed funds.

[10] A referee points out that the assumption of intertemporally separable utility implies that, conditional on current period expenditure, prices in other periods affect current demands only via changes in total expenditure over the entire planning horizon. Insofar as periods are defined in terms of seasons, this could be problematic if seasonality in prices or consumption is important. In the area under study, however, no seasonality in prices was observed (see footnote 16), and t-tests revealed no significant differences in mean consumption between seasons for any group of households considered (Renkow, p. 76).

From equation (14),

$$(16)\quad \frac{dI_{t+1}}{dP_{1t}} = \frac{\partial I_{t+1}}{\partial E_t P_{1t+1}} \cdot \frac{dE_t P_{1t+1}}{dP_{1t}} + \frac{\partial I_{t+1}}{\partial P_{1t}} + \frac{\partial I_{t+1}}{\partial X_{1t}} \cdot \frac{\partial X_{1t}}{\partial P_{1t}} = -f\left(1 - b \cdot \frac{dE_t P_{1t+1}}{dP_{1t}}\right) + g \cdot \frac{dX_{1t}}{dP_{1t}}.$$

Thus, the response of marketed surplus to a contemporaneous price change is given by

$$(17)\quad \frac{dM_t}{dP_{1t}} = -(1+g) \cdot \frac{dX_{1t}}{dP_{1t}} + f\left(1 - b \cdot \frac{dE_t P_{1t+1}}{dP_{1t}}\right).$$

Because the effect on expected future price of a change in the current price will in general be positive and no greater than unity, the sign of dM_t/dP_{1t} depends on the price responsiveness of consumption.

The first-order conditions imply that the Marshallian demand for the produced commodity may be written as

$$X_{1t} = X(P_{1t}, P_{2t}, \hat{P}_{1t+1}, W_t),$$

where

$$W_t = Y_t + \left[P_{1t}S_t + b^{T-t}E_t\left(P_{1T}Q_T - \sum_s P_{Ls}L_s\right)\right] + P_{Lt}T^* = Y_t + \Pi_t + P_{Lt}T^*.$$[11]

Here, W_t is an expression for the household's period t wealth that includes exogenous income, expected net revenue from production over the planning horizon (π_t), the value of stock on hand ($P_{1t} \cdot S_t$, where $S_t = I_t + Q_t$), and the value of household time.[12] The effect of a change in P_{1t} on current consumption may then be written as

$$(18)\quad \frac{dX_{1t}}{dP_{1t}} = \left.\frac{\partial X_{1t}}{\partial P_{1t}}\right|_{d\Pi = 0} + \frac{\partial X_{1t}}{\partial \Pi_t} \cdot \frac{d\Pi_t}{dP_{1t}} = \left.\frac{\partial X_{1t}}{\partial P_{1t}}\right|_{dU = 0} - X_{1t} \cdot \frac{\partial X_{1t}}{\partial W_t} + \left(S_t + \hat{Q}_T \cdot \frac{d\hat{P}_{1T}}{dP_{1t}} + \hat{P}_{1T} \cdot \frac{\partial \hat{Q}_{1T}}{\partial \hat{P}_{1T}} \cdot \frac{\partial \hat{P}_{1T}}{\partial P_{1t}}\right) \cdot \frac{\partial X_{1t}}{\partial W_t}.$$

This analysis bears a strong resemblance to that of Strauss (1986) in its explicit recognition of wealth effects induced by a price change. In addition to the usual substitution and income effects of a conventional Slutsky equation (the first two terms of the second equality), consumption also depends on an extra wealth effect (or profit effect in Strauss' parlance) that is a function of stocks on hand, expected future output, and the mechanism by which the household forms price expectation.[13] It is therefore possible that the overall response to a price increase might be positive if this wealth effect is sufficiently large.

Long-Run Response

The comparative statics in the previous section yielded expressions for uncompensated demand and marketed surplus response in the short run when output is fixed. Previous work has tended to emphasize long-run (or steady-state) marketed surplus response.[14] In the context of the model developed above, consideration of long-run effects shifts the focus from analyzing the impact of exogenous shocks (e.g., price changes) within the cropping cycle to analyzing impacts across cycles. In particular, steady-state output will adjust to current price changes and thus long-run marketed surplus response will be more elastic.[15]

[11] For notational simplicity, "^" will hereafter be used to denote the appropriately discounted conditional expectation formed in period t.

[12] In actuality, the discounted expected value of all future net revenue ought to be included here. A reasonable argument for truncating this infinite stream at the end of one planning horizon is that discounting reduces the present value of net revenue from subsequent cropping cycles to an insignificant magnitude.

[13] Note that to the extent that expected input prices (especially wages) adjust to changes in the current output price, the profit effect in (18) is incomplete. Because a positive relationship between P_t and, say, the expected wage rate is likely to exist, the profit effect would be smaller than depicted in (18) for net purchasers of labor (e.g., large farms) and larger than depicted in (18) for net sellers of labor (in many instances, small-farm households).

[14] The analysis in this section owes substantially to comments made by John Strauss on an earlier draft of this paper.

[15] In addition to direct price response of output, one might postulate indirect effects via induced investment. Such indirect effects are ignored here.

Derivation of long-run marketed surplus response stems from the observation that in the steady-state inventory changes go to zero (i.e., $dI/dt = 0$). A steady-state version of the identity in equation (2) is thus given by

$$(2') \qquad M^* = Q^* - X^*,$$

where asterisks denote steady-state values and the subscript denoting the commodity has been dropped. This identity is formally identical to that traditionally used in derivations of marketed surplus elasticities and implies that long-run marketed surplus response is of the form

$$(17') \qquad \frac{dM^*}{dP_{1t}} = \frac{dQ^*}{dP_{1t}} - \frac{dX^*}{dP_{1t}}.$$

Equation 17′ differs from the expression for short-run marketed surplus response derived above in two important ways. First, it directly accounts for output response to price. Because output is fixed in the short run, (expected) output response has only an indirect effect on marketed surplus response via wealth effects in consumption, as in equation (18). When output is free to vary, output response enters the equation directly as well.

Second, because steady-state inventory is constant, the parameters associated with the price response of inventories disappear. As in the short run, however, long-run response of consumption is expected to depend in part on the wealth effect of price changes due to changes in the value of household inventories. This additional wealth effect distinguishes the analysis developed in this paper from earlier approaches. As long as household inventories are nonzero, this stock effect implies that both consumption demand and marketed surplus will be less elastic than previous analyses have indicated.

The Data

For the empirical analysis, inventory and consumption demands were econometrically estimated using panel data from a West Indian village collected between 1976 and 1983 as a part of the "Village-Level Studies" project of the International Crops Research Institute for the Semi-Arid Tropics (Singh, Binswanger, and Jodha). Shirapur, the village considered, is a poor and extremely drought-prone village located in the semiarid tropics of India. It is dependent on agriculture, with crop production and agricultural labor providing the bulk of household income. Most farm households in the village satisfy a large part of their demand for the predominant dietary staple (sorghum) through their own production. Sorghum is the dominant crop, occupying over 50% of total cropped area on average. Given the harshness of the village's agronomic environment, relatively few cash-cropping alternatives are available.

Monthly data on agricultural production, consumption, and market transactions were organized on a quarterly basis. These data, in conjunction with annually collected inventory data, provided a complete record of the sources and uses of the various commodities consumed. Quarterly inventory schedules of the most important staples stored by households were then derived by subtracting consumption and sales (including in-kind payments) from production and purchases (including in-kind receipts).

Except for nonfood items, quarterly price data were derived by taking the arithmetic means of the ratio of value and quantity for all transactions involving a particular commodity. Where more than one commodity was aggregated, individual prices were weighted by their mean expenditure shares over the entire sample. All prices were then deflated by village-specific consumer price indices reported in Walker et al. For nonfood items, a statewide price index reported by Walker et al. was used.

Table 1 presents summary statistics on average quarterly consumption, inventory holdings, and marketed surpluses of stored grains in Shirapur. Inventories tend to be large relative to consumption in the village, with mean quarterly inventories exceeding mean quarterly consumption for all farm-size classes.

Econometric Considerations

Measuring the own-price elasticities of demand and marketed surplus for stored commodities required estimates of the parameters of output supply response, inventory demand, and consumption demand. The econometric strategy consisted of separately estimating inventory demand equations [of the form suggested by equation (14) above] and systems of commodity demand equations for each of three farm-size classes within the village. The estimated demand-side parameters were then combined with existing estimates of the parameters of output supply in order to compute own-price elasticities of de-

Table 1. Quarterly Consumption, Inventories, and Marketed Surplus of Stored Commodities by Farm Size

	Consumption		Inventory		Marketed Surplus	
Farm Size[a]	Mean[b]	C.V.[b]	Mean[b]	C.V.[b]	Mean[b]	C.V.[b]
Small	210.0	29.0	247.2	51.9	62.3	248.2
Medium	297.8	23.0	413.9	38.6	133.3	82.0
Large	386.7	28.3	631.5	36.8	84.3	227.3

[a] These use the classification system employed by ICRISAT and defined as follows: small farms: 0.21–2.50 hectares; medium farms: 2.51–5.25 hectares; large farms: >5.25 hectares.
[b] These are quarterly household means (in kilograms) and coefficients of variation across individual household means expressed in percentage terms.

mand and marketed surplus for stored commodities.

Eight years of quarterly inventory data were available for thirteen households in Shirapur. Large quantities of sorghum and wheat were stored by all of these households during at least a portion of each crop year. Preliminary analysis revealed that the prices of wheat and sorghum were highly correlated. For this reason, these were combined into a "grains" aggregate. Pretest estimation indicated that the inventory data satisfactorily supported grouping the households into small, medium, and large farm-size classes, but that the data did not support pooling across farm-size classes. The household data were thus pooled for each farm-size class, and fixed effects models were estimated by two-stage least squares, using the price of sorghum and the nonfood price index as instruments for X_{1t}.

Univariate ARMA forecasts were used to generate one-period-ahead expected prices. The price of grain in Shirapur was best represented by an AR1 model.[16] As a check on the consistency of the estimator using ARMA price forecasts, Wu-Hausman tests were conducted to compare this with an alternative estimator which was known to be consistent. The alternative was an instrumental variable (IV) estimator in which the realized future price was used in the construction of ΔP_t and the ARMA forecast price was used as an instrument. Where the consistency of the estimates using the ARMA estimator was rejected, the results from the use of the IV estimator will be reported.

[16] The price of stored grain did not follow the saw-toothed seasonal pattern one might normally expect for annually harvested crops. Rather, the model which best represented the data—$P_t = 0.183 + 0.844\, P_{t-1} + \varepsilon_t$—was empirically indistinguishable from a random walk. This may result from the success of government price stabilization policies, coupled with the relatively free flow of grain across regions.

Consumption Demand

Commodity demand systems were estimated by farm-size class for each village using a Rotterdam model. An important reason for choosing the Rotterdam model over other functional forms was that it eliminated the need to explicitly model household-specific characteristics (as these are effectively differenced out of the data), thereby greatly simplifying the econometric procedures. Commodities included as dependent variables in the analysis were stored grains, nonstorable home-grown foods, and commodities procured exclusively from the market. Leisure was assumed to be weakly separable from the other arguments of the utility function, thereby eliminating the necessity of estimating labor supply as part of the system. The theoretical model developed above indicated that the appropriate independent variables in the system included all contemporaneous prices, household wealth (including the value of stocks on hand and the expected value of future output), and the expected prices of stored commodities one period in the future.

The wealth variable used on the right-hand side of the estimating equations ($\Delta\log Y^*$) was that suggested by Deaton and Muellbauer:

$$Y^* = \Delta\log Y - \sum_k \omega_k \Delta\log P_k,$$

where Y is total expenditure and the ω_k's are expenditure shares. The quantity Y^* represents the proportional change in real total expenditure—an index of real income. Given the way in which the data were constructed, Y included the value of stocks on hand. Thus, Y^* incorporated all contemporaneous real income flows. An intercept term was included to account for expected net revenues from future production. Finally, the

theoretical model indicated that commodity demands depend also on the (one-step-ahead) expected price of stored commodities. Since the price of grain was found to follow an AR1 process, however, it was not necessary to include lagged price terms in the reduced-form equations.

The individual commodity demand equations were estimated as a system of seemingly unrelated regressions. Significant serial correlation was evident in the individual demand equations, and was corrected using a Cochrane-Orcutt procedure. Given the construction of the real income variable, adding-up was automatically imposed on the system. Because all prices and the expenditure variable were deflated by a common price index, homogeneity was implicitly imposed. Finally, because of the inclusion of inventories in the model, the Hessian matrix of second derivatives is not symmetric. Hence, symmetry was neither imposed nor tested in the estimation.

Eight of the twenty-seven price coefficients were significant at the 10% level or better, and nearly all income coefficients attained the 1% significance level. Most constants were insignificant, and those that were significant were quite small. A complete listing of the parameter estimates is available from the author upon request.

Income and compensated price elasticities implied by the regression results are found in table 2. In most cases, own-price elasticities of the stored commodities are smaller in magnitude than those of the other commodity groups. In several instances, cross-price elasticities indicate some complementarity among commodities.

Income elasticities are all positive, which is expected at this level of aggregation. The income elasticities of the stored commodities are strikingly smaller than those for other commodity groups in all instances. This relationship between the income elasticities of grains and other commodities in Shirapur was also found by Sharma. In contrast, Behrman and Deolalikar found the opposite pattern. However, their empirical estimates were for a sample drawn from three villages (one of which was Shirapur) located in distinctly different agroclimatic zones of semiarid tropical India. Additionally, they pooled the data from all farm-size classes (including landless households).

Uncompensated own-price elasticities of demand for stored grains were calculated using the formula derived above. Crop years were split into two periods—the two quarters immediately preceding harvest (the "lean season") and the two quarters immediately following harvest (the "harvest" season)—and elasticities were evaluated at the quarterly means for each season. Observed mean annual output was used as a proxy for mean expected output. The derivative of expected price with respect to current price was based on the AR1 model of grain prices (see footnote 16). Estimates of the required supply response parameters were taken from those reported by Bapna, Binswanager, and Quizon.

A quarterly discount rate of .95 was used throughout. In Shirapur, interest rates in the informal sector are high, in many instances approaching 50% (on an annual basis). At the same time, some institutional credit is available at much lower interest rates (although there are sometimes significant transactions costs involved in securing such loans). Finally, short-term interest-free loans among friends and relations are often observed. The discount factor used, which corresponds to an annual interest rate of 23%, was chosen as a median value.

Uncompensated elasticities are presented in table 3. In all instances, profit effects proved large enough to induce positive own-price elasticities in the demand for storable grains in both the lean and harvest seasons. That is, the positive effects of a price change on perceived household wealth, through the enhancement of the value of currently held stocks and expected future net revenue, dominate normal income and substitution effects on consumption. Such positive own-price demand elasticities have long been recognized as a theoretical possibility among semisubsistence households and have been increasingly found in empirical studies which account for profit effects.[17] In the present case, they are attributable to the inclusion of both stocks and the expected value of output into the analysis.

In order to distinguish the relative importance of these two components of the profit effect, the demand elasticities were recalculated, this time omitting stocks of stored commodities from the computations. The results of this exercise (found in table 4) indicate the existence of distinct seasonal differences in the relative magnitude of stock effects and production effects. While there are no dramatic differences in the computed elasticities across seasons, stock effects are particularly strong in the harvest season (when in-

[17] For example, four of the seven empirical studies of semisubsistence households included in Singh, Squire, and Strauss report positive own-price demand elasticities.

Table 2. Income and Compensated Price Elasticities of Demand

Medium	1.104	1.28	1.162	1.34
Large	0.476	0.98	0.590	1.10

Note: Lean season corresponds to the two quarters preceding harvest. Harvest season includes the quarter in which harvest occurs and the following quarter. Profit effects calculated as the difference between the computed demand elasticity and that computed using a conventional Slutsky equation.

ventories are large) and production effects are relatively more important in the lean season. For small farms, ignoring the stock effects reverses the sign of the demand elasticity in both seasons.

The first column in table 4 lists the share of stocks of the stored commodities in household wealth (computed by dividing the value of stocks on hand by the sum of the value of stocks and the value of total consumption). In addition to being large relative to consumption, inventories of grain account for a sizeable proportion of household wealth for all farm-size classes, a fact which explains the empirical importance of stock effects on demand response.

Table 4. Comparison of Demand Elasticities for Stored Grain with and without Stock Effects

Farm Size	Wealth Share of Stocks[a]	Lean Season With Stock Effect	Lean Season No Stock Effect	Harvest Season With Stock Effect	Harvest Season No Stock Effect
Small	.38	0.090	−0.054	0.159	−0.511
Medium	.46	1.104	0.938	1.162	0.488
Large	.52	0.476	0.306	0.590	0.016

[a] Wealth share computed as the value of stocks divided by the sum of the value of stocks and the value of total consumption.

Inventory Demand

Inventory demand equations based on equation (14) were estimated for each farm-size class. In addition to the structural parameters of the theoretical model, sets of household, quarterly, and yearly dummies were included as independent variables in order to account for cross-sectional and intertemporal differences. Because negative inventories (in the form of forward sales, tied credit, and the like) were not observable, a limited dependent variable situation existed. To account for this, a Tobit procedure was used.

The estimated structural parameters of inventory demand are presented in table 5.[18] Only in the case of large farms is there evidence of significant arbitrage motives for holding inventories. This is consistent with the notion that it is only the best-endowed farm households who have the ability to engage in inventory management as a profit-maximizing strategy. Estimates for the food security parameter (g) are highly significant for both the large and medium farm-size classes. For small farms, neither of the parameters representing arbitrage and food security motives were significantly different from zero.

Other results of the inventory demand analysis may be summarized as follows. A large proportion of the household and quarterly dummies were significant, indicating marked seasonal and interhousehold effects. The yearly dummies were in general not significant. Wu-Hausman tests rejected the consistency of the price differential estimator constructured using the ARMA forecasts for the large farm-size class, but not for medium or small farms.

The nonsignificance of the food security parameter for small farm households is somewhat surprising, as it had been thought a priori that food security motives would be greater for households with smaller land holdings. A possible explanation for this is that members of these households were more likely to participate in government-sponsored food-for-work programs. These were plentiful in the village during the period of the analysis and, for the households involved, tended to reduce the necessity of holding stocks for food security purposes.[19]

Table 5. Tobit Estimates of Inventory Demand Parameters

Parameter[a]	Small Farms[b]	Medium Farms[b]	Large Farms[c]
g_o	−754.3***	−1298.0***	−915.1***
	(222.2)	(292.4)	(307.5)
f	−2564.8	−419.5	1395.1***
	(1885.7)	(2132.7)	(456.8)
g	0.99	1.79***	1.48***
	(0.78)	(0.64)	(0.47)

[a] f is the coefficient on the expected price differential (ΔP_t); g is the coefficient on current consumption; and g_o is an intercept. Asymptotic standard errors are in parentheses and significance levels of .10, .05, and .01 are denoted by single, double, and triple asterisks, respectively.
[b] Estimates using ARMA forecast to construct ΔP_t.
[c] IV estimates using the realized price to construct ΔP_t and the ARMA forecast as an instrument.

Short-Run Marketed Surplus Response

The short-run, own-price response of marketed surplus [equation (17)] may be restated in elasticity terms as

$$(19)\quad \mu_i = -(1+g)\cdot\epsilon_{ii}\cdot\frac{X_i}{M_i} + f\cdot\left(1 - b\cdot\frac{dE_tP_{it+1}}{dP_{it}}\right)\cdot\frac{P_i}{M_i}.$$

Here μ_i is the own-price elasticity of marketed surplus of good i, ϵ_{ii} is the uncompensated own-price demand elasticity, and g and f are the parameters of inventory demand associated with food security and arbitrage motives, respectively.

As with demand elasticities, marketed surplus elasticities were evaluated at the seasonal means for the lean and harvest seasons. In the cases where the f and g parameters were not significant, these were set to zero. For ease of interpretation, the absolute value of mean marketed surpluses was used. Thus for households that were net sellers, a positive (negative) marketed surplus indicates that a price increase will lead to greater (less) sales. Similarly, for households that were net purchasers, a positive (negative) elasticity indicates that a price increase will lead to less (more) market purchases.

[18] A .95 discount factor was used in constructing ΔP. To determine the sensitivity of the econometric estimates to the chosen discount factor, several regressions were run with values of b ranging from .90 to 1. The only parameter values affected were g_o and f. The significance level of these parameters remained the same throughout, however, and the implied elasticity of inventory demand with respect to (discounted) expected price was close for all values of b. It was therefore concluded that the chosen discount factor, while somewhat arbitrary, did not significantly modify the implications of the results presented.

[19] The author is indebted to Tom Walker for this insight.

Table 6. Marketed Surplus Elasticities by Season

Farm Size	Lean Season[a] Average Marketed Surplus	μ_t	Harvest Season Average Marketed Surplus	μ_t
Small	−93	−0.20	198	−0.17
Medium	−67	−13.01	287	−3.42
Large	−76	−1.88	225	−1.04

[a] Lean season corresponds to the two quarters preceding harvest. Harvest season includes the quarter in which harvest occurs and the following quarter.

The computed marketed surplus elasticities are presented in table 6. These vary considerably, both seasonally and across farm-size class, and in some cases are extremely large. However, the large values for some of the groups considered are primarily an artifact of the computational method. That is, in cases where the average marketed surplus is small, the computed elasticity tends to be greatly inflated.

Short-run marketed surplus elasticities are negative in both seasons for all farm-size classes. The indication here is that the stock and production effects on consumption that give rise to positive own-price demand elasticities outweigh the positive effect of the diminished intertemporal arbitrage opportunities implied by a narrowing of the gap between current and expected prices. Thus, in the short-run households appear to respond to price rises by increasing consumption at the expense of market sales.

Long-Run Elasticities

Table 7 presents two sets of long-run demand and marketed surplus elasticities, one set computed using the methods developed above and one set computed by the methods described in Strauss (1986). To facilitate comparison, all elasticities were calculated using annual averages for production and consumption and the Bapna, Binswanger, and Quizon supply response parameters. Steady-state inventory holdings were taken to be quarterly means over the entire year, i.e., average stocks held by a household in any given period. Finally, in computing the production effects on demand, dE_tP_{1t}/dP_{1t} was set equal to 1 on the grounds that steady-state prices would be expected to follow a random walk.

Table 7. Long-Run Own-Price Demand and Marketed Surplus Elasticities for Stored Grain

Farm Size	Strauss' Method ϵ_{ii}[a]	μ_i[a]	New Method ϵ_{ii}	μ_i
Small	−0.977	7.59	−0.778	6.80
Medium	0.043	2.54	0.236	2.02
Large	−0.344	6.40	−0.180	5.56

[a] ϵ_{ii} is uncompensated demand elasticity; μ_i is marketed surplus elasticity.

Not surprisingly, long-run own-price elasticities computed using the methods developed here are more elastic than their short-run counterparts. Importantly, all long-run marketed surplus elasticities are positive, indicating the importance of output response in determining long-run marketed supply. Additionally, long-run demand elasticities are negative for two of the three groups of households. Only for households of the medium farm-size class are wealth effects large enough to dominate normal income and substitution effects.

While all elasticities computed using Strauss' method are of the same sign as those computed using the new method, the magnitudes differ. Strauss' method also yields positive own-price demand response for medium farms, an indication of the strength of production effects for households of this farm-size class. In all cases, however, demand response computed using Strauss's method is considerably more elastic than that computed using the new method, indicating that stock effects are also empirically important.

Marketed surplus elasticities calculated using Strauss's method are 11% to 25% larger than those computed using the new method. That the estimates using Strauss's method are uniformly larger than those computed using the new method is true for much the same reason that the demand elasticities differed uniformly. That is, the earlier method systematically understates wealth effects on consumption by failing to recognize the role of stocks and therefore tends to overstate the elasticity of demand (and hence marketed surplus).

Concluding Comments

A model of semisubsistence agriculture explicitly accounting for the ability of farm households to hold inventories of staple foods has been developed in this paper. The theoretical and em-

pirical analyses sought to determine the nature of demand and marketed surplus response both within the cropping cycle (when output is fixed) and in the long run (when it can vary).

Long-run marketed surplus response was found to be positive and quite elastic for all farm-size classes considered. Using the same data and parameter estimates, the method employed in earlier work to compute marketed surplus elasticities was found to overstate marketed surplus elasticities by 11% to 25%. This difference occurs because the earlier method failed to incorporate the wealth effect on consumption of changes in the value of household stocks resulting from price changes.

Short-run marketed surplus elasticities were negative in all cases. In conjunction with the finding of positive short-run demand elasticities, this result indicates that within the cropping cycle households respond to price rises by increasing consumption at the expense of market sales. Determining whether this result is due to the methodological refinements developed here rather than to peculiarities of the data used will require additional research. It would be of particular interest to conduct such research in areas where stocks account for a large share of total household wealth because the findings here suggest that negative marketed surplus response is most likely to occur in these cases.

The important methodological conclusion is that the value of currently held stocks should be included in analyses of commodity demand and marketed surplus response in the context of semisubsistence agriculture. This is true whether or not inventories are responsive to price changes because stock effects on consumption depend on the absolute level of inventory holdings. These stock effects were shown to have potentially large impacts on the own-price response of consumption demand (and thus marketed surplus) for stored commodities.

Pass-Through of Exchange Rates and Tariffs in Brazil–U.S. Tobacco Trade

Gregory K. Pompelli and Daniel H. Pick

This paper examines the extent to which exchange rate and tariff changes are passed through in U.S. import prices of unmanufactured tobacco from Brazil. The model used considers the possibility of market imperfections in international trade and the potential effects of strategic trade policies. The results indicate that agricultural prices may not be as flexible as commonly thought. Furthermore, exchange rate and tariff changes are not fully passed through to U.S. tobacco import prices, which indicates that firms selling Brazilian tobacco may use trade strategies to maintain or even increase their trade shares in the U.S. tobacco market.

Key words: Brazil, international trade, pass-through effects, strategic trade policy, tobacco.

Historically, U.S. tobacco producers have maintained significant product quality differences which have helped insulate them from international competition. However, these quality differences have diminished as the quality of foreign tobacco has improved (GAO). Certainly, the growing share of imported tobacco in the U.S. domestic market is partial evidence that quality no longer acts as a sufficient barrier. As the following analysis of Brazilian tobacco imports highlights, strategic trade policy actions have become important factors that will potentially exert even greater influence on U.S. tobacco producers in the future.

Imports of Brazilian unmanufactured tobacco by cigarette makers in the United States have become an important part of the market. Between 1975 and 1985, the Brazilian share of the U.S. domestic unmanufactured tobacco market increased from 3% to 6%. Although this may not appear to represent a substantial share of the market, it reflects significant changes in the U.S. market for unmanufactured tobacco. At present, imports of Brazilian tobacco represent almost 20% of the tobacco imported into the United States.

In addition to, but typically divorced from, concerns voiced by domestic tobacco producers, these changes have heightened interest in the influence of government intervention in trade and the use of strategic trade policies. While much of the attention has centered on trade barriers, there has also been an increased interest in the use of strategic trade policies and the relationship between exchange rate and tariff changes and prices of imported goods (Baron, Jabara and Schwartz, Richardson). Since the mid-1970s, the scope of interest has grown to include the effects of trade policies in situations where nations and/or firms possess market power in international markets or where markets are not perfectly competitive (Eaton and Grossman, Feenstra, Venables).

This paper examines the extent to which exchange rate and tariff changes are passed through in U.S. import prices of unmanufactured tobacco from Brazil. A number of studies, including Isard, Richardson, Dunn, Jabara and Schwartz, and more recently Feenstra, have found that the "law of one price" has failed to hold for a fairly wide range of traded goods. That is, exchange rate changes are less than fully passed through in import prices. Thus, treatment of agricultural commodities as price-flex goods is

Greg K. Pompelli is an assistant professor of agricultural economics, University of Tennessee; Daniel H. Pick is an economist with the U.S. Department of Agriculture, Economic Research Service, Agriculture and Trade Analysis Division.

questioned, especially in markets where trade barriers and/or strategic trade policies are implemented.

Literature

Various studies have addressed imperfect competition and the use of strategic trade policy. At the same time, a separate literature pertaining to transmission effects of exchange rates to domestic import prices has also been developed. Dunn analyzed the pass-through effect of exchange rates on import prices in the Canadian markets under the hypothesis of imperfect competition. Under this hypothesis firms that wish to maintain stable prices in foreign markets must exhibit market power with a system of variable price discrimination. Dunn's results for Canadian imports support this hypothesis. Support for Dunn's hypothesis of discriminatory pricing behavior was also found by Giovannini, who studied Japanese and U.S. markets.

A different approach to exchange rate pass through was introduced by Goldstein, who studied the so called "ratchet" hypothesis. This concept states that exchange rate changes have inflationary bias since world prices are inflexible downward. His results show some support for the hypothesis of discriminatory pricing behavior in certain nations.

Other studies that have examined the effect of exchange rates on import prices include Kreinin, Dornbusch, and Woo. While Kreinin concentrated on pass-through effects, the Dornbusch analysis emphasized the importance of market structure on the transmission of exchange rate changes to prices. Woo found that import prices fail to fall by the full amount of the depreciation of the foreign currency. His findings are consistent with the price discrimination model where foreign firms are able to discriminate by charging higher prices in countries with high costs and lower prices in countries with lower costs.

Jabara and Schwartz investigated the asymmetric effects of exchange rate changes on domestic prices of agricultural commodities in Japan. Their results indicate that commodity prices in Japan exhibit "stickiness," which supports the "ratchet" hypothesis proposed by Goldstein.

The issue of tariff and exchange rate pass through in domestic prices has also been explored by Feenstra, who applied his model to the case of small truck and motorcycle imports from Japan. His results suggest a symmetric pass through of exchange rates and tariffs in domestic prices. Feenstra's results are based on products that are subject to ad valorem tariffs. As a result, he was able to test whether tariff and exchange rate pass-through effects were symmetric.

Note, however, that Feenstra's symmetric pass-through hypothesis pertains to the similarity of the pass-through effects for tariffs and exchange rates. The Jabara and Schwartz, and Goldstein "ratchet" symmetry hypotheses are concerned with similarity of pass-through effects when exchange rates are falling and rising. This paper does not examine the "ratchet" symmetry case because, on an annual basis, the cruzeiro/dollar exchange rate only moved in one direction during the period used. Instead, symmetry between tariff and exchange rate pass-through effects may be examined by comparing the coefficients in the estimation results.

Methodology

Following Feenstra, the model used in this analysis assumes that a foreign or multinational firm (in this study a firm operating in Brazil) faces an import demand function $X(Pm, Pd, Ps, Y)$, where X denotes quantity; Pm and Pd denote the import and domestic good prices in the domestic currency of the importing nation; Ps is the price of substitutes denominated in the domestic currency of the importing nation; and Y denotes domestic expenditure or absorption of the importing nation. In this study, tobacco firms in Brazil face a U.S. demand function for their tobacco which is a function of the price of Brazilian tobacco (Pm), the price of United States tobacco (Pd), the price of substitute tobacco (Ps), and income or domestic expenditure (Y). A tobacco firm in Brazil (foreign firm) faces a cost function $C(X, W)$, where W denotes a vector of aggregate foreign input prices. Thus the profit-maximization problem facing a firm in an imperfectly competitive industry can be derived by maximizing profit with respect to the choice variable, Pm, as follows:

$$(1) \quad \text{Max } [q(Pm - t)X(Pm, Pd, Ps, Y) - C(X, W)],$$

where q is the cruzeiro/dollar exchange rate and t is a specific or unit tariff. While other studies suggest that currency invoicing decisions are important (Baron, McKinnon), it is assumed under the above specification that the foreign firm receives payments in the domestic currency

($US).[1] Bilson, and Hooper and Kohlhagen provide a more detailed discussion of this assumption.

Given that the cost function is homogenous of degree one, equation (1) can be written as follows:

$$(2) \quad \text{Max } [q(Pm - t)X(Pm, Pd, Ps, Y) - f(X)W)],$$

or equivalently,

$$(2a) \quad q\text{Max } [(Pm - t)X(Pm, Pd, Ps, Y) - f(X)W/q].$$

The first-order condition for equation (2a) can be written as

$$(3) \quad f'(X)(W/q) + t = Pm[1 - 1/\eta] \equiv R(Pm, Pd, Ps, Y),$$

where $\eta = (-\partial X/\partial Pm)(Pm/X)$, and $R(Pm, Pd, Ps, Y)$ represents marginal revenue.

The first-order condition of this specification implies that marginal revenue is equal to marginal cost plus the unit tariff. Assuming that $[f''X_{pm}(W/q) - R_{pm} \neq 0$, then equation (3) can be inverted into a pricing equation. Solving the first-order condition for the producer price $P\tilde{m} = (Pm - t)$, equation (4) may be used to represent the general functional form for the pricing equation:

$$(4) \quad P\tilde{m} = g[W/q, Pd, Ps, Y, t].$$

Equation (4) is homogenous of degree one and using a loglinear specification, it can be written as follows:

$$(5) \quad \ln P\tilde{m} = \alpha + \beta_1 \ln(W/q) + \beta_2 \ln(Pd) + \beta_3 \ln(Y) + \beta_4 \ln(t) + \beta_5 \ln(Ps) + \ln(e_t).$$

This model assumes that all exchange rate adjustments occur in the current period because annual data are used in the analysis.

As shown in Feenstra, β_1 is expected to be positive and may be greater than one, though the standard case would be that factor cost/exchange rate changes are positive but less than fully passed through. The domestic price coefficient, β_2, is expected to be positive but not greater than one. Again, the standard case would be that domestic price changes are positive but less than fully passed through. However, the pass-through effect could be negative in the case where exporters' marginal costs decline as imports rise. The income coefficient, β_3, theoretically may be positive or negative, as Deardorff and Stern note. The tariff pass-through coefficient, β_4, is expected to be positive and follow the exchange rate pass-through effect; yet, it is not restricted to equal the exchange rate effect. Finally, the substitute price coefficient, β_5, is expected to be positive.

For estimation, the error term (e_t) is assumed to be lognormally distributed with an expected value of zero. Normally, the import tobacco price equation could be tested for homogeneity of degree one by testing if $\beta_1 + \beta_2 + \beta_3 + \beta_4 + \beta_5 = 1$. However, the validity of the test was questioned due to multicollinearity problems that are discussed in the following section.

Data

All the data used in this study are annual data covering the period 1964 to 1983. The annual U.S. import prices of tobacco from Brazil (Pm), and Italy (Ps) were calculated using the quantity and value figures from annual issues of the U.S. Bureau of the Census *U.S. Imports for Consumption and General Imports Report FT246*. The U.S. import price for Italian tobacco represents the substitute price (Ps).[2] All prices are calculated exclusive of the specific tariff rate. The Brazilian exchange rate (cruzeiros per U.S. dollar) (q) and producer price index (W) data were obtained in issues of the *International Financial Statistics Yearbook* (IMF). The domestic price (Pd) data for tobacco were obtained from the United States Department of Agriculture issues of the annual *Tobacco Situation and Outlook Reports*. Retail expenditure (Y) data for tobacco products were obtained in *Business Statistics: 1986* (USDC 1987).

The United States tobacco tariff rates (t) were collected from the U.S. International Trade

[1] This assumption is particularly appropriate for the case of tobacco because international prices are denominated in U.S. dollars, and trade occurs in U.S. dollars as well. The pass-through effects of exchange rate changes in such cases where prices and receipts are denominated in the same currency can be viewed as an outcome of a trade strategy. For example, if the U.S. dollar appreciates in value relative to the Brazilian cruzeiro, then firms operating in Brazil will experience a windfall gain in their revenues (once converted into cruzeiros). These firms might then decide to try to gain market share in international markets by lowering the U.S. dollar price of the tobacco they export, while leaving their revenues denominated in cruzieros unchanged.

[2] The U.S. import price of Italian tobacco is used as the representative substitute price because its quality was relatively close to Brazilian tobacco and it maintained a consistent presence in the U.S. market.

Commission. Tariff rates for Brazilian tobacco imports were adjusted to account for the import classification changes that occurred in the early 1980s. Prior to 1980 roughly 75% to 100% Brazilian imports were classified as scrap tobacco. After 1980, Brazilian tobacco was classified as manufactured/unmanufactured tobacco. Finally, in 1983, Brazilian tobacco was reclassified as stemmed leaf. The stemmed leaf tariff, beginning in 1979 at 45¢ per pound, was reduced by 3¢ per pound per year with a tariff rate goal of 23¢ per pound. Currently, most of Brazil's tobacco is imported into the United States at stemmed rate. The combination of the reclassifications and the declining tariff schedule for stemmed tobacco has caused the effective tariff on Brazilian import to fluctuate during the period of the analysis.

In general, most of the independent variables in the data did not exhibit high simple correlations. However, multicollinearity problems in estimation were a primary concern because of the correlation coefficient of 0.98 for the domestic price (*Pd*) and the domestic absorption (*Y*) variable; therefore, neither variable was dropped from estimation. As a result, the only property claimed for the resulting estimates is that they are at best unbiased. Multicollinearity problems may have been mitigated somewhat by imposing the restriction that equation (5) is homogenous of degree one (Judge et al., chap. 22). However, no efficiency gains are claimed for the resulting estimates.

Table 1. Tobacco Import Price Equation Results

Variable	Parameter Estimates
Intercept	−1.360
	(−1.13)[a]
Pass-through (W/q)	0.145
	(0.30)
Domestic (Pd) price	−0.985
	(−1.14)
Domestic (Y) absorption	1.082*[b]
	(1.88)
Tariff (t)	0.549*
	(2.19)
Italian (Ps) price	0.208*
	(1.95)
Durbin-Watson statistic	1.27
Observations	20
R^2	0.79
Adjusted R^2	0.74

[a] Numbers in parentheses are t-values.
[b] Significant at the .95 level.

Results

Table 1 contains the estimates for the restricted tobacco import price equation. The Durbin-Watson statistic at 1.27 falls into the inconclusive range of first-order autoregression. However, residual plots did not indicate any problems that justified correction for a potential autoregressive error term. In addition, the limited number of observations and the presence of multicollinearity further reduced any potential gains from correction. As indicated by the R^2 value of .79, the overall fit of the restricted tobacco import price equation is good.

The exchange rate pass-through coefficient at 0.145 is insignificant. It appears that Brazilian prices of unmanufactured tobacco imported into the United States, at best, only partially reflect changes in exchange rates or factor prices. This may indicate that Brazilian firms have used exchange rate changes to maintain, or even increase, their share of the U.S. tobacco market. Given that most of the United States imports from Brazil are sold by U.S. subsidiaries or multinational tobacco corporations, this may also reflect an attempt on their part to substitute cheaper Brazilian tobacco for more expensive U.S. tobacco. The growth of Brazilian import share in the U.S. tobacco market from less than 10% in 1977 to roughly 20% in 1986 supports this result. However, time trends were unable to capture quality changes in earlier estimations and were dropped from the analysis.

The statistically significant tariff pass-through effect of 0.549 indicates that the U.S. tariffs on unmanufactured tobacco are only partially passed through to import prices. As Feenstra, and Brander and Spencer note, a tariff pass-through effect that is less than one indicates that the importing country achieves terms of trade gains. Thus, there is some evidence in favor of import protection for U.S. tobacco growers through the use of tariffs.

The influence of the domestic producer price on the import price of Brazilian tobacco is not statistically significant. At −0.985, it indicates that U.S. domestic prices have little or no impact on the import price of Brazilian tobacco. This may be the result of the U.S. tobacco program, which maintained domestic tobacco prices above world prices during that period.

The domestic tobacco absorption coefficient at 1.082 is statistically significant at the .95 level and indicates that changes in consumption of to-

bacco in the domestic market are fully reflected in Brazilian import prices. The positive value yields some information about the general relationship between domestic absorption and tobacco import prices. As one reviewer noted, this may represent a "demand shifter to represent the effects of the business cycle. . . ." However, as Deardorff and Stern observe considerable debate surrounds the relationship between import prices and domestic expenditures.

The substitute tobacco import price coefficient (Ps), represented by the Italian import tobacco price, at 0.208 is statistically significant. Thus, Brazilian import tobacco prices are somewhat sensitive to price changes of substitutes. The lack of greater cross-price influences may be attributable to the degree of substitutability between the tobaccos from each of these regions.

While there are no other exchange rate and tariff pass-through estimates available for tobacco that can be used to compare with these results, the Jabara and Schwartz estimates for several other agricultural commodities provide some reference. They estimated the exchange rate pass-through effects to equal −.45 for beef, .31 for corn, and .25 for soybeans. However, comparisons are limited because Jabara and Schwartz estimated a quarterly model for the period from 1974 to 1984, and they focused on trade with Japan. Nonetheless, their findings and the results from this study indicate that agricultural prices may not be as flexible as commonly assumed.

Conclusion

This paper develops a model for assessing the pass-through effects of exchange rates and per unit tariffs in the case when the market is not purely competitive. The results provide interesting insights into the transmission of exchange rate and tariff changes to tobacco import prices. Most notably, exchange rate changes do not appear to be passed through in import prices, which would tend to indicate an attempt to increase the Brazilian share in the U.S. tobacco market. The .549 tariff pass through, however, indicates that part of the tariff is being borne by Brazilian firms.

In addition, the exchange rate pass through result corresponds with the findings in other pass-through studies that the treatment of agricultural goods as price flexible, needs to be reconsidered. This is especially true where firms or industries operate in imperfect international agricultural markets or where strategic trade policies aimed at trade promotion are used.

A Revised Test of the Law of One Price Using Rational Price Expectations

Barry K. Goodwin, Thomas J. Grennes, and Michael K. Wohlgenant

The law of one price (LOP) is an important ingredient in theories of international trade. Typical analyses of the LOP assume that parity should hold contemporaneously. This assumption overlooks temporal elements of trade. Recognizing this fact, we expect parity to hold for expected prices. Two empirical procedures are utilized to consider the LOP in international markets for U.S. agricultural commodities. The first utilizes econometric procedures to test an expectations augmented version of the LOP. A second approach uses nonparametric procedures to provide an alternative consideration of expectations. In each case, results provide support for a rational expectations view of the LOP.

Key words: generalized method of moments, international trade, law of one price, rational expectations.

The law of one price (LOP) is an essential ingredient in theories of international trade and exchange rate determination. As Officer (1986) notes, without this principle the traditional "pure" theory of international trade would not exist. In short, the LOP maintains that foreign and domestic prices of a commodity will be equal when both are expressed in the same currency and net of transportation costs. This equality will be established and maintained by the profit-seeking actions of international commodity traders and arbitragers.

Empirical literature on the LOP is extensive. The strand of literature dealing with aggregate price indexes is usually called absolute purchasing power parity. The large literature on disaggregate products is summarized by Officer (1989), and most of the results are unfavorable to the LOP. "Of 40 tests, 28 reject the LOP, eight have mixed findings, and only four unambiguously cannot reject the LOP" (Officer 1989, p. 3).

The law of one price in international agricultural markets has received limited attention. Jabara and Schwartz find that the behavior of agricultural prices between the United States and Japan is not as flexible as is commonly perceived. Smith found weak support for the LOP using annual data for wheat, corn, and rice. Ardeni indicates that the LOP fails as a long-run relationship in several important agricultural markets, and that deviations from the LOP are permanent.

An important shortcoming of these studies is the assumption that parity should hold contemporaneously.[1] This assumption overlooks the fact that international commodity arbitrage and trade occur over time as well as across spatially separated markets. Thus, parity should not be expected for contemporaneous spot prices unless arbitragers have perfect foresight or unless prices are constant. Rather, international commodity arbitragers likely act upon the expected sale prices for when their goods are delivered. Thus, we would instead expect parity to hold for expected prices.

The authors are, respectively, an assistant professor in the Department of Agricultural Economics, Kansas State University, and professors in the Department of Economics and Business, North Carolina State University.

This is Contribution No. 90-200-J of the Kansas Agricultural Experiment Station.

The authors gratefully acknowledge the helpful comments of John Dutton, A. Ronald Gallant, Paul Johnson, and three anonymous *Journal* reviewers.

[1] An important exception is Magee, who recognized that ignoring delivery lags could result in spurious deviations from purchasing power parity.

The objective of this paper is to incorporate expectations into an empirical investigation of the law of one price. The application is to international markets for relatively homogenous U.S. agricultural commodities. The empirical investigation proceeds along two distinct lines. The first makes use of the generalized method of moments (GMM) procedures set forth by Hansen, and Hansen and Singleton (1982, 1983).[2] A second approach employs nonparametric tests of parity conditions (Frenkel and Levich). These results are utilized to provide an alternative consideration of the role of delivery lags in international price linkages which may overcome potential limitations associated with regression-type tests of the LOP.

The paper is organized as follows. The next section develops a model of the law of one price in international commodity markets. The model then is applied econometrically to international markets for several important U.S. agricultural commodities, and the nonparametric approach is utilized as well. The final section reviews the results and offers some concluding remarks.

A Model of the Law of One Price

The law of one price is tested using prices of primary commodities for three basic reasons. First, a good's price may reflect the presence and quality of certain utility bearing attributes (Rosen). In this case, goods with different attributes are expected to have different values and thus different prices. A primary commodity is most likely to possess identical attributes regardless of origin or destination. Second, aggregated data experience the problems associated with indexes and aggregation measurement errors. Tests which use aggregate data may fail in part because of aggregation and index construction errors. Finally, it is likely that exchange rates will be endogenous to the system used for testing when highly aggregated price data are used. The existence of such endogeneity explicitly biases the results of standard regression tests. Using primary commodity prices substantially reduces the likelihood of this problem.

Most LOP tests utilize a model similar to Richardson's:

$$P_{it} = \alpha_0 P_{it}^{*\alpha 1} \pi_{12t}^{\alpha 2} T_{it}^{\alpha 3} R_{it}^{\alpha 4}, \tag{1}$$

where P_{it} is country one's price of commodity i in time t, P_{it}^* is country two's price of commodity i in time t, π_{12t} is the rate of exchange for currency two in terms of currency one, T_{it} is transfer and transactions costs of trade in commodity i between countries one and two, R_{it} is the residual reasons for price differences between countries one and two, and α_0, α_1, α_2, α_3, and α_4 are parameters. Strict adherence to the law of one price requires that the domestic price of a good, once adjusted for exchange rates, transfer costs, and any differences in quality, will be equal to the foreign price of the good. If a disparity between these prices is detected by international commodity arbitragers, they will buy the good in the lower-priced market and sell it in the higher-priced market until prices are equalized. Thus, for a basic homogenous commodity, adherence to the LOP requires that

$$\alpha_0 = \alpha_1 = \alpha_2 = \alpha_3 = 1, \text{ and } \alpha_4 = 0. \tag{2}$$

Thus, equation (1) becomes a statement of the law of one price.

Several weaknesses are inherent in the standard approach to testing the law of one price. First, independent information about transportation costs is rarely available. Thus, transport costs usually are assumed constant or proportional to commodity prices over the period of study. Under these specifications, T_{it} could be removed as a variable in the equation and transport costs could be represented in an intercept term. Such an approach is implicitly assumed by Jabara and Schwartz and by Ardeni. However, these assumptions are questionable in light of the potential volatility of transport and other transactions costs. Binkley and Harrer show that transport costs can be highly variable and may be influenced by several factors including ship sizes and trade volumes. Goodwin, Grennes, and Wohlgenant show that deviations from parity may be correlated with transport and interest costs.

The empirical analyses conducted in this study utilize actual freight rates for wheat to represent transactions costs associated with trade in seventeen oilseed and grain markets. Moreover, because homogenous primary commodities are the focus of this analysis, there are no residual reasons for price differences. Thus, R_{it} is omitted and treated as an unobservable random disturbance.

Another shortcoming of the standard approach to testing price parity is that regression tests of the form given by equation (1) require that one of the commodity prices is exogenous.

[2] This method has been applied by Antle to a measurement of risk.

This may be incorrect for an individual commodity. While exchange rates often are exogenous to a particular commodity price, prices in two trading countries may be simultaneously determined regardless of the relative sizes of the countries (Protopapadakis and Stoll). Information may be shared across markets and agents may operate in multiple markets. Such simultaneity biases the resulting parameter estimates and confounds statistical inference. Accordingly, the approach followed in this study is designed to overcome this weakness by utilizing instrumental variables.

A major shortcoming of the standard LOP tests is the use of contemporaneous domestic and foreign prices in the empirical analysis. This analysis will instead utilize a simple expectations model. Each market is assumed to specialize in either importing or exporting the commodity in question, consistent with the concept of comparative advantage. In particular, the home country is an exporter and the foreign country is an importer. The consideration of expectations is limited to one side of the exchange so that exporters respond to their expectations of prices at the time of delivery in the foreign market. In turn, this response influences the price of the commodity in the domestic market. The result is parity between current domestic prices and expected future foreign prices. Comparisons in which both markets are net importers or net exporters are also possible. However, these comparisons are less relevant for U.S. agricultural commodities.

It is instructive to consider a simple intertemporal model which yields the LOP conditions as a result of arbitrage and trade profit maximization.[3] The arbitrager's problem is to maximize expected profits from trade over time, given a stream of exogenous commodity prices. Consider a representative agent engaged in arbitrage and trade for a single commodity in two spatially separated markets with no storage opportunities. The agent maximizes expected profits by choosing quantities of a commodity to sell in the domestic market in time t and to export to the foreign market for sale upon delivery in time $t + j$. The delivery lag of j periods reflects the physical transfer of commodities in the trade process. The agent faces transportation and nontransportation costs associated with trade and arbitrage activities. The latter costs include set-up costs, acquisition expenses, and the costs of inputs into the arbitrage and trade process. This cost component is assumed to vary directly with the total amount of the commodity placed into arbitrage and trade activities (in both the domestic and foreign markets).

Under these conditions, the agent's problem is to maximize expected profits, given by $E_t V(q_t, q_t^*)$, where

$$(3) \quad V(q_t, q_t^*) = \sum_{t=0}^{\infty} \{\delta^t [p_t q_t + \delta^j \pi_{t+j} p_{t+j}^* q_t^* - C(Q_t) - \tau_t q_t^*]\},$$

q_t is the quantity of the commodity sold in the domestic market in time t, q_t^* is the quantity of the commodity exported to the foreign market in time t, p_t is the commodity price in the domestic market in time t, p_{t+j}^* is the commodity price in the foreign market in time $t + j$, π_{t+j} is the rate of currency exchange in time $t + j$, $C(\ )$ is the commodity arbitrage cost function, Q_t is the total quantity of commodity engaged in trade and arbitrage activities in time $t (Q_t = q_t + q_t^*)$, τ_t is the per-unit transactions charges in time t, and δ is a discount factor $(0 < \delta \leq 1)$.

Note that $E_t(x) = E(x | \Omega_t)$, where E is the mathematical expectations operator conditional on the information set available at time t, Ω_t. We assume that $\Omega_t \supset \{p_t, p_t^*, x_t, \Omega_{t-1}\}$ for all t, where x_t is a vector of random variables exogenous to the agent.

The first-order conditions for profit maximization for all $k \geq 0$ are given by

$$(4) \quad E_{t+k}\{\delta^k [p_{t+k} + C'(Q_{t+k})]\} = 0,$$

$$(5) \quad E_{t+k}\{\delta^k [\delta^j \pi_{t+j+k} p_{t+j+k}^* - C'(Q_{t+k}) - \tau_{t+k}]\} = 0.$$

If these conditions adequately represent aggregate profit-maximizing behavior, they can be arranged at $k = 0$ to yield:

$$(6) \quad E_t\{p_t - \delta^j \pi_{t+j} p_{t+j}^* + \tau_t\} = 0,$$

which is equivalent to

$$(7) \quad p_t - \beta_0 E_t\{\pi_{t+j} p_{t+j}^*\} + \tau_t = 0,$$

[3] The behavioral model which follows is an abstract representation of actual grain trading practices. In reality, international grain trade is highly organized and shipments may flow through several agents before reaching end-users. A large percentage (85%–90%) of U.S. grain exports are handled by five companies: Cargill, Continental, Bunge and Born, Louis Dreyfus, and Andre Garnac (Davies). These companies conduct marketing and arbitrage activities as they arrange the exchange of grain and oilseed commodities between domestic producers and foreign end-users. Such activities are often carried out under contract. However, despite our simplified representation of the trade and arbitrage process, the fundamental result that trade profit maximization ensures the equalization of expected marginal returns remains valid.

where $\beta_0 = \delta^j$. Equation (7) is a formal statement of the law of one price.

Rational expectations specifies that the future price equals the agent's subjective price expectation plus a random error term. In turn, this implies that the actual future price will be correlated with the contemporaneous disturbance term. Thus, least squares estimators will be biased and inconsistent. The generalized method of moments (GMM) estimator is used to purge this price variable of its correlation with the disturbance term and to obtain consistent and asymptotically efficient estimates of the parameters of the expectations-augmented model of the LOP. The GMM estimator exploits the property that rational expectations are conditional expectations of sample moments. It minimizes a sample error objective function by applying instrumental variables estimation techniques directly to orthogonality conditions which are implied by the first-order conditions (4) and (5). The resulting parameter estimates provide a rational expectations interpretation of the law of one price which can be compared to the standard formulations of the LOP which utilize *ex post* contemporaneous prices.[4]

An Application to U.S. Agricultural Commodity Prices

This section applies the standard and expectations-augmented models of the law of one price to internationally traded agricultural commodities. If standard tests of the LOP misrepresent the intertemporal elements of commodity trade and arbitrage, tests explicitly recognizing the role of expectations should find stronger empirical support for the concept of international price parity. The empirical applications are to international markets for U.S. origin wheats (see table 1 for the six classes of U.S. wheat), oilseed products, corn, and grain sorghum. These markets are of special interest because of their prominent role in U.S. agricultural trade. In 1987, the grain and oilseed markets accounted for over 59% of the total value of U.S. agricultural exports (U.S. Department of Agriculture 1988).

The data represent monthly market observations for internationally traded primary commodities.[5] Statistical price data for internationally traded commodities are available from various sources. The oilseed product prices were collected from the Foreign Agriculture Service's *Oilseeds and Products*. These prices were quoted monthly at various U.S. interior and export market locations and at Rotterdam. Wheat prices were collected for several varieties of wheat from the International Wheat Council's *World Wheat Statistics*. These prices were quoted monthly at various U.S. export markets and at Japanese and Rotterdam import markets. The corn and grain sorghum prices were taken from the Foreign Agriculture Service's *Grain Market Outlook*. These prices were quoted monthly at various U.S. markets and at Rotterdam. The Rotterdam market is a major port of entry and transshipment point for U.S. agricultural products moving into the European market.

Border prices are more appropriate for the LOP than internal prices because they better represent arbitrage opportunities. Internal prices may differ because of tariffs, domestic transport costs, processing costs, and sales taxes, without providing any opportunity for profitable arbitrage. For example, Officer (1989, p. 17) found that the largest deviations from the LOP among ten categories of food, beverages, and tobacco occurred for alcoholic beverages and tobacco. He attributed the large deviations to special indirect taxes and monopoly distribution (Officer 1989, p. 17). The use of border prices avoids this problem.

Characteristics of the data are summarized in table 1. However, two important issues should be addressed at this point. First, several of the price series had a small number of missing observations. Because of the importance of the time series structure of the data, deletion of observations was considered too strong a step. Thus, portions of the data that were complete or nearly complete were isolated, and univariate time-series models were used to forecast the missing observations. In no case were more than two consecutive missing observations or more than five missing data points overall estimated in this fashion. The number of missing observations for each series is included in table 1. Of course, such a procedure may introduce biases and inconsistencies in the estimation and subsequent statistical inferences.

A second issue is that international trade in

[4] A more detailed discussion of the econometric procedures and alternative applications of the LOP models are contained in Goodwin. A detailed discussion of the GMM procedures applied to the expectations augmented model of the LOP is available from the authors upon request.

[5] The homogenous product categories are based on grade and variety attributes whenever possible, and are narrower than most found in the literature.

Table 1. Description of Price Variables

Commodity	Description	n	n-miss	period
U.S. soybeans	U.S. farm-level average	72	0	1/80–12/85

U.S. agricultural products is customarily invoiced in dollars in both domestic and foreign markets (Hathaway, p. 14). Thus, prices of U.S. agricultural products in foreign markets are often quoted in dollars, as occurs in this analysis. Because trade is conducted solely in dollars, the implied rate of currency exchange is everywhere identically equal to one. The elimination of a direct consideration of exchange rates focuses attention upon the real issue of arbitrage and price behavior. Attempts at separating price and exchange rate effects in empirical tests of the law of one price have been criticized as being too restrictive and without justification by Crouhy-Veyrac, Crouhy, and Melitz.

The empirical implementation of the expectations augmented version of the law of one price requires a fixed delivery lag length. Because of the wide range of commodities and markets under consideration, actual delivery lags could be quite variable across commodities. A consideration of actual trade flows tends to limit the reasonable range of delivery lags to be between one and four months. A straightforward means for choosing the optimal lag length involves the sample error objective functions for the alternative lag lengths $j = 0, \ldots, 4$. For the GMM estimator, the sample error objective function is given by

$$(8) \quad S(\gamma, V) = \left[\sum_{t=1}^{n} (e_t(\gamma) \otimes z_t)\right]' \cdot V^{-1}\left[\sum_{t=1}^{n} (e_t(\gamma) \otimes z_t)\right],$$

where

$$(9) \quad e_t(\gamma) = p_t - \beta_0 p_{t+j}^{*\beta_1} \pi_{t+j}^{\beta_2} + \tau_t,$$

$$(10) \quad V = \mathrm{Cov}\left\{\left[\sum_{t=1}^{n} (e_t(\gamma) \otimes z_t)\right], \left[\sum_{t=1}^{n} (e_t(\gamma) \otimes z_t)\right]'\right\},$$

$\gamma = \{\beta_0, \beta_1, \beta_2\}$ is the parameter set to be estimated, z_t is a vector of instruments, and $\otimes$ denotes the Kronecker product. Gallant (pp. 464–65) shows that the estimated GMM sample objective function $S(\cdot)$ offers a convenient model specification test. With the test of overidentifying restrictions, one rejects the hypothesis that the model is correctly specified when $S(\cdot)$ exceeds the upper $\alpha \times 100\%$ critical point of the chi-square distribution with $k - p$ degrees of freedom (where k is the number of instruments and p is the number of parameters being estimated). In this light, the "most correct" delivery lag specification minimizes the estimated value of $S(\cdot)$ and thus maximizes the significance level of the specification. The test of overidentifying restrictions also provides a convenient goodness-of-fit measure for comparing the lag lengths. Empirical support for an expectations-augmented view of the LOP will be generated in those cases where specifications with delivery lags ($j > 0$) are superior to that with no delivery lag ($j = 0$).[6]

Finally, actual transactions charges might be highly correlated across all basic agricultural commodities. In this light, a proxy measure of transactions charges will be constructed from a linear function of observable average monthly freight rates for wheat trade between the relevant markets, collected from the International Wheat Council's *World Wheat Statistics*.[7] Specifically, transactions costs are represented by

$$f(T_t) = \phi_0 + \phi_1 TW_t, \tag{11}$$

where TW_t is the quoted freight rate for wheat trade between the markets under consideration. This approach to representing transactions costs may have several weakness. First, freight rates for wheat may not provide an acceptable proxy for transactions costs for other commodities, especially the oilseed products, most notably, the oils. Second, freight rates do not include transportation costs between hinterland and export markets, risk premia and insurance, demurrage, handling fees, and information costs.

Under the assumptions outlined above, the basic econometric tests of the law of one price are specified by the following equations:

$$P_{it} = \alpha_0 + (P^*_{it})^{\alpha 1} - \alpha_2 TW_t, \tag{12}$$

$$P_{it} = \beta_0 + E_t\{(P^*_{it+j})^{\beta 1}\} - \beta_2 TW_t, \tag{13}$$

where $E_t\{P^*_{it+j}\}$ is the mathematical expectation of the value of P^*_i in time $t + j$, conditional on information available in time t, and TW_t is the proxy measure of per-unit transaction charges. The law of one price is rejected for the respective models when the parameters α_1 and β_1 are significantly different from one.

Formal tests of the law of one price for the standard and expectations-augmented versions of the basic model were conducted using the standard F and chi-square representations of the Wald test, respectively. The Wald test is discussed in detail in Judge et al. (pp. 182–87). The distinction between the standard F and chi-square representations of the Wald test occurs because denominator degrees of freedom are undefined in the GMM procedures.

The standard version of the law of one price, as represented by equation (12), was estimated using the conditional nonlinear least squares (NLS) procedures to correct for first-order autoregression. This procedure (Judge et al., pp. 287–89) is asymptotically equivalent to maximum likelihood if the residual errors are normally distributed. Such an explicit correction for autoregressive correlation is often employed in applications of the standard model (e.g., Protopapadakis and Stoll; Crouhy-Veyrac, Crouhy, and Melitz).

Parameter estimates and hypothesis testing results for the standard version of the law of one price are presented in table 2. In nearly every case the autoregressive parameter, ρ, is highly significant. Similarly, the price coefficients are highly significant in every case. Overall, the data are not inconsistent with the LOP theory. The price coefficient, α_1, lies within the interval [.90, 1.10] for thirteen of the seventeen markets.

The formal test of H_0: $\alpha_1 = 1$ is rejected at the 1% level of significance in eight of the seventeen cases. The test is supported for soybean meal, cottonseed meal, soybean oil, cottonseed oil, sunflowerseed oil, peanut oil, Wheat 4, Wheat 5, and corn. However, the remaining markets have price coefficients which are statistically different from one but are not so far from one as to be in strong conflict with price parity. The greatest deviation from parity conditions under the standard representation occurs for grain sorghum, which has a price coefficient

[6] The final choice of delivery lag is representative of the normal flow of commodities. It does not imply that individual transactions may not be quicker or take longer under special circumstances. Neither is the occasional resale of commodities at some point during shipment necessarily precluded by our specification.

[7] Specifically, the wheat market applications utilize the freight rates relevant to each comparison (U.S. Gulf, Pacific, or Atlantic export markets and Rotterdam or Japan import markets), while the oilseed market applications utilize freight rates for trade between the U.S. Gulf ports and Rotterdam.

of .8446. Adherence to the LOP for the standard model is especially limited in the wheat markets, with only two of the six markets supporting parity. Soybeans fail to support the standard version of the LOP.

McCloskey's distinctions between the statistical and economic significance of empirical results are especially relevant here.[8] In several cases, small standard errors result in statistical rejection of the LOP in cases where the price coefficients are close to one. However, in an economic sense, care should be used in interpreting these results as significant evidence against the LOP. In light of the evidence summarized by Officer (1989), the results provide some degree of support for price parity in international commodity markets because the price coefficients are generally closer to one than those usually obtained from the standard model.

The test of overidentifying restrictions utilized estimated sample error objective functions from the GMM estimates to select the most appropriate lag length from five specifications ($j = 0, \ldots, 4$ months) for each market. The test statistics and associated chi-square significance levels are given in table 3. The instrumental variables employed in the estimation were

$$z_{it} = \{1, p_{it-k}, p^*_{it-k}, r_{it-k}, TW_{it-k}, \pi_{it-k+1}\}, \quad \text{for } k = 1, 2; \tag{14}$$

[8] McCloskey notes: "In the usual test of purchasing power parity, a sample size of a million yielding a very tight estimate that $\beta = .999$, 'significantly' different from 1.0, could be produced under the usual procedures as evidence that the theory had 'failed'. Common sense, presumably, would rescue the investigator from asserting that . . . we should abandon purchasing power parity" (McCloskey, p. 202).

[a] An asterisk indicates the minimal value across the alternative lag orders.
[b] Chi-square probabilities for each value of $S(\cdot)$ are given in parentheses.

where r_{it} is the interest rate on U.S. federal funds, collected from the U.S. Department of Commerce's *Business Conditions Digest* series, and π_{it} is an exchange rate relevant to trade in the market under consideration, collected from the International Monetary Fund's *International Financial Statistics* series.

Except for the corn market, the test of overidentifying restrictions concludes in favor of a specification which incorporates delivery lags. In several cases, the test statistic $S(\cdot)$ declines significantly when going from no delivery lag to lagged price relationships. The minimal value of the test of overidentifying restrictions statistics across the five lag alternatives indicates the probability-maximizing specification and thus indicates the optimal lag order choice. Thirteen of the seventeen markets have optimal lag orders of a single month. Results suggest an optimal lag order of two months for cottonseed meal and sunflowerseed meal and three months for the Wheat 3 market.[9] In every case, the hypothesis that the optimal lag order yields a correct specification at the 1% level of significance is not rejected. In all, such results strongly favor an expectations augmented view of the LOP.

Parameter estimates and hypothesis testing results for the expectations augmented version of

[9] Wheat 3 is a northern spring wheat moving out of the Gulf ports. Although prices are taken at the Gulf, the longer lag length may reflect the greater logistical arrangements associated with exporting grain which originates in northern interior regions through the Gulf to Japan.

the law of one price are presented in table 4. Estimation was accomplished using the GMM procedures and was made conditional on the preceding choice of optimal lag lengths.[10] The price coefficients are highly significant in every case and are numerically closer to the theoretically implied value of one than are the price coefficients for the standard model in twelve of seventeen cases. In four of the five remaining cases, the differences between the estimated price coefficients for the standard and expectations-augmented versions of the LOP are less than .015.

The results of formal hypothesis testing for the expectations augmented version of the LOP support parity in fourteen of the seventeen cases.[11] The LOP is rejected for cottonseed oil, sunflowerseed meal, and Wheat 5. The LOP is supported in every case considering trade between the United States and Japan. The results support parity between prices in U.S. and Rotterdam markets in ten of thirteen cases. With the possible exception of sunflowerseed meal, which has a price coefficient of .9003, none of the commodities are in strong violation of the LOP. A price coefficient with a value of .90 does provide tempered support for the LOP.

[10] The results for the corn market are conditional on a lag order of zero. Thus, for the corn market, the revised model specification is identical to the standard specification of a contemporaneous price relationship. The application differs only with respect to the econometric technique used for estimation.

[11] In eleven of the seventeen cases, the parameters of the expectations-augmented version of the LOP have slightly larger standard errors than those of the standard version. However, under our argument for an alternative expectations-augmented model, the standard model parameter estimates and standard errors are subject to specification biases. In no case does this result allow the LOP to be supported by the reformulated version and rejected by the standard version when the price coefficient for the reformulated version is actually numerically farther from one.

A Nonparametric Test of the Law of One Price

A possible weakness of regression-type tests of the LOP involves inferential biases in situations where prices vary in a nonsynchronous manner within the band created by transactions costs. Under such circumstances, the LOP may be erroneously rejected. However, under such conditions, trade is not profitable and thus should not occur. In this light, concerns of such biases are tempered when a continuous flow of commodities is observed between the markets in question (as occurs for all of the markets in this analysis). Alternatively, adherence to the LOP might be incorrectly supported by regression-type tests when price changes in spatially separated markets move in a synchronous manner outside of the transactions cost band.[12]

An alternative approach to testing international parity relationships has been developed by Frenkel and Levich. This approach employs nonparametric tests that involve estimating the transactions costs band and counting the observations outside of the band. Such observations imply *ex post* profit opportunities. However, such tests are conditional upon the correct measurement of transactions costs.

Frenkel and Levich's nonparametric tests were applied to the six wheat commodities in this analysis. Direct observations of actual freight rates were only available for these commodities. Frenkel and Levich consider the role of transaction timing by examining noncontemporaneous parity relationships.[13] In a similar manner, the nonparametric procedures were applied to the noncontemporaneous price linkages implied by the previously identified delivery lags as well as to contemporaneous price comparisons.

The results of the nonparametric tests are presented in table 5. In five of the six cases, fewer observations violate the conditions for parity when delivery lags are explicitly recognized. *Ex post* arbitrage profits are given by the difference between price differentials and transactions costs. In three of the six cases, the incorporation of delivery lags results in smaller mean implied profits. However, in every case, the t-ratios for the mean-implied profits are smaller when delivery lags are recognized, implying less significant profit levels. The magnitude of the differences between the alternative tests is often quite small. However, the results are similar in magnitude to those obtained by Frenkel and Levich and provide similar support for an expectations augmented view of price parity.

Though the nonparametric tests provide additional evidence in favor of an expectations-augmented view of the LOP, this approach also has its limitations. In particular, the nonparametric tests depend upon the correct measurement of transactions costs. Such measurement may be relatively straightforward in the financial markets considered by Frenkel and Levich. However, Bahmani-Oskooee and Das, and Clinton have criticized Frenkel and Levich's measurement approach. Physical commodity trade is much more complex than financial arbitrage and presents greater difficulties in measuring transactions costs, as illustrated earlier in the article. Thus, the nonparametric results should be interpreted with considerable care.

Concluding Comments

The empirical literature has produced only weak support for the law of one price. However, typical representations have compared contemporaneous prices in geographically separate markets. These tests fail to incorporate time lags, which are potentially important in spatial arbitrage. When time lags are considered, expected future prices must be included in the analysis. In addition, standard approaches to testing parity conditions have neglected to consider transportation costs in specific terms.

This paper pursues two distinct approaches to testing the LOP. The first approach uses the generalized method of moments econometric procedures to estimate rationally formed expected future prices. Actual freight rates for wheat trade are utilized to provide a proxy measure of transactions costs. To focus on the role of expected prices, a comparison was made between dollar prices in the United States and other countries for seventeen homogenous agricultural products. A second approach employs a nonparametric analysis of price parity using the actual freight rates for trade between several important wheat markets.

Under each approach, empirical results using a simple expectations-augmented model pro-

[12] This criticism is analogous to the well-recognized problem of spurious correlation. Such a criticism is equally applicable to any regression test of economic equilibrium conditions. Because this situation would imply persistent profit opportunities, it is precluded by highly efficient markets.

[13] Frenkel and Levich apply a simple trading rule according to which investors calculate a profit signal at period t and execute their transactions at period $t + 1$ (using weekly security price quotes). Their approach is analogous to the use of delivery lags in this study.

Table 5. Nonparametric Tests of the LOP for Wheat, Contemporaneous and with Delivery Lags

Market	n	No. Observations Outside Band	Percentage of Observations Outside Band	Average Profits
Contemporaneous Tests				
Wheat 1	69	56	81.16	.0287
(U.S./Japan)				(6.5474)[a]
Wheat 2	76	33	43.42	−.0012
(U.S./Japan)				(−.3871)
Wheat 3	76	41	53.95	.0045
(U.S./Japan)				(.6654)
Wheat 4	76	33	43.42	−.0034
(U.S./Japan)				(−1.1887)
Wheat 5	125	71	56.80	.0029
(U.S./Rott.)				(1.1077)
Wheat 6	76	71	93.42	.0505
(U.S./Rott.)				(14.1807)
With Delivery Lags				
Wheat 1	68	50	73.53	.0332
(U.S./Japan)				(4.6583)
Wheat 2	75	37	49.33	.0010
(U.S./Japan)				(.1741)
Wheat 3	73	32	43.84	.0061
(U.S./Japan)				(.5047)
Wheat 4	75	32	42.67	−.0025
(U.S./Japan)				(−.4440)
Wheat 5	124	66	53.23	.0027
(U.S./Rott.)				(.6465)
Wheat 6	75	59	78.67	.0456
(U.S./Rott.)				(6.6074)

[a] Numbers in parentheses are t-ratios for the means.

duce greater support for the LOP than the same model using contemporaneous prices. Specification testing with the test of overidentifying restrictions and the subsequent applications of the expectations augmented version of the LOP support contentions that price parity is more likely when price expectations are given explicit attention. The LOP appears quite strong in international markets for U.S. agricultural products. Hence, the outcomes of previous tests may have been influenced by inadequate spatial price linkages and by a neglect of the transactions costs associated with international commodity exchange.

Exchange Rate Risk and U.S. Agricultural Trade Flows

Daniel H. Pick

This paper analyzes the effect of exchange rate risk on U.S. agricultural trade flows. A model which incorporates exchange rate risk is applied to ten countries. While exchange rate risk was not significant in the seven developed markets, results indicate that the exchange rate variable adversely affected U.S. agricultural exports to the three developing countries used in the analysis. These findings underscore the importance of exchange rate risk in developing countries trading behavior. Issues such as establishment of well-developed financial and commodity markets in developing countries must be addressed in future research.

Key words: agricultural exports, developing countries, exchange rate risk.

The effects of exchange rates on agricultural trade was raised by Schuh (1974, 1976) and was followed by numerous efforts to quantify the effects of the nominal exchange rate on trade (Chambers and Just 1979, 1981; Konandreas, Bushnell, and Green; and others) or the effects of the real exchange rate on trade (Longmire and Morey; Batten and Belongia; Henneberry, Henneberry, and Tweeten). A neglected issue in those studies is the impact of exchange rate risk on agricultural trade flows (Williamson, Kenen and Rodrik, Anderson and Garcia).

In this paper, a model which incorporates exchange rate risk is applied to ten countries to evaluate the impact of exchange rate risk on agricultural bilateral trade flows. The first section will present the development of the conceptual model. This is followed by the data and estimation results. Finally, conclusions and implications are drawn.

Exchange Rate Risk and Model Specification

Studies of the effects of exchange rate risk on trade by Clark, Hooper and Kohlhagen, Gotur, Cushman (1983, 1988), De Grauwe, Maskus, and others postulate that exchange rate risk reduces trade. However, earlier results (Hooper and Kohlhagen) lend little support to this hypothesis; although Cushman (1988), by using measures of real exchange rate risk, found significant adverse effects of exchange rate risk on U.S. trade flows.

The model (adopted from Hooper and Kohlhagen) assumes that the demand for imports is a derived demand, where imports are used in the domestic production of the final goods. This assumption is particularly true in agricultural trade since most goods are intermediate in nature. Further, the importer faces a domestic demand for its output, Q, which is a function of domestic income Y, price of other goods (substitutes and complements), PD, and own price, P:

$$Q = aP + bPD + cY. \tag{1}$$

The risk-averse importer is assumed to maximize expected utility with respect to profits. (Utility is assumed to be an increasing functon of profits and a decreasing function of the standard deviation of profits.) While the importer receives orders for its output in the first period, it only pays for the imports and receives payments for its output in the second period. Thus, prices are determined in the first period and the expected utility problem is

$$\max_{Q} EU(\pi), \tag{2}$$

where E is expectations, U is utility and π is profits.

Daniel H. Pick is an agricultural economist with the Agricultural and Trade Analysis Division, Economic Research Service, U.S. Department of Agriculture.

The comments by Margot Anderson, Mary Burfisher, Colin Carter, Mathew Shane, Tom Vollrath, and two anonymous reviewers are greatly appreciated by the author.

Assuming a constant input-output ratio, the input can be presented as

$$q = \lambda Q, \tag{3}$$

where q is total input and λ is the fixed input-output coefficient. Thus, the importer's profits are

$$\pi = QP(Q) - UC \cdot Q - HP^*\lambda Q, \tag{4}$$

where UC is the unit cost of production, H is the foreign exchange variable, and P^* is the import price in the foreign currency.

The model distinguishes between imports denominated in the importer's and the exporter's currency. It further distinguishes between imports denominated in the exporter's currency and hedged versus unhedged in the forward exchange market. The foreign exchange cost variable can be presented as

$$H = \beta(\mu F + (1 - \mu)R_1) + (1 - \beta)F, \tag{5}$$

where β is the share of imports denominated in the exporter's currency, $(1 - \beta)$ is the share of imports denominated in the importer's currency, μ is the proportion of foreign currency costs hedged in the forward market, F is the forward cost of the exporter's currency in terms of the importer's currency, and R_1 is the spot exchange rate realized in the second period.

Denoting the price of imports in the exporter's currency as P^*, and q as the quantity of inputs imported, then the costs of importing the share denominated in the importing country's currency is $(1 - \beta)FP^*q$. The cost of the proportion denominated in the exporter's currency and hedged in the forward exchange rate market is $\beta\mu FP^*q$. The cost of the proportion of imports denominated in the exporter's currency and not hedged in the forward exchange market is then $\beta(1 - \mu)R_1P^*q$. Given the definition of H, if all imports are denominated in the importer's currency ($\beta = 0$) or all imports which are denominated in foreign currency are hedged ($\mu = 1$), then the costs of imports would be known with certainty. However, the most likely case is that $\beta > 0$ and $\mu < 1$, and uncertainty is introduced since R_1 is unknown in the first period.

While the magnitudes of β and μ are unknown, most of U.S. agricultural exports are denominated in U.S. dollars, and not all foreign exchange involved in the transaction is hedged in the forward exchange market. For example, McCalla and Schmitz note that world grain trade, which accounts for over one-third of U.S. agricultural exports, is primarily denominated in U.S. dollars. Thus $\mu < 1$, and importers are facing exchange rate risk in their import transactions with the United States.

Assuming that $\beta > 0$, $\mu < 1$, and the introduction of uncertainty by the exchange rate variable R_1, the variance of profits is

$$V(\pi) = [P^*\lambda Q\beta(1 - \mu)]^2\sigma^2_{R1}, \tag{6}$$

where σ^2_{R1} is the variance of R_1.

Exporter's behavior can be modeled in a similar fashion:

$$\text{Max } EU^*(\pi^*), \tag{7}$$

where the asterisk denotes exporter's variables. Exporter's profits can be presented as

$$\pi^* = q^*P^*H^* - q^*UC^*. \tag{8}$$

Hooper and Kohlhagen use the above specifications of the exporter's and importer's expected utility maximization problem to derive the nonlinear reduced-form equilibrium equation for the quantity exported. However, they used a linear approximation in their final estimation procedure because of statistical difficulties.

Cushman (1983) extended the Hooper and Kohlhagen model by defining profits in real terms; and this approach was then further utilized by Cushman (1988) and Kenen and Rodrik, who used the following reduced-form equation:

$$Q^* = \alpha + \eta Y + \rho UC_{im} + \phi UC_{ex} + \xi R + \kappa M + \upsilon S, \tag{9}$$

where Q^* is the real export value (as a measure of quantity), Y is the importer's real income (GNP), UC_{im} is the importer's real unit production cost, UC_{ex} is the exporter's real unit production cost, R is the foreign currency per U.S. dollar exchange rate, M is a four-quarter moving-average of recent percentage change in R, which is a proxy for the expectations of the uncertain growth rate of the real exchange rate defined in Cushman 1983, and S is a risk measure representing the uncertain growth rate of the real exchange rate.[1]

Equation (9) provides the basis for the empirical application. The expected sign for the income variable is positive, indicating that as real income in the importing country rises so will the quantity exported. UC_{im} and UC_{ex} are expected

[1] Cushman (1983) formulated the uncertain component of the exchange rate as $R_1 = R_0\theta$, where R_0 is the known current real exchange rate and θ is the uncertain growth rate of R.

to have negative coefficients although a positive coefficient is possible for the UC_{tm} variable (Cushman 1988). A negative coefficient is expected for the foreign exchange variable because appreciation of the U.S. dollar (increase in R) will lead to decrease in exports. M and S (assuming risk-averse agents) are expected to be negative.

Data

Quarterly data from 1978–87 were used in the empirical analysis. Ten countries were included in this study: Japan, South Korea, Canada, Australia, West Germany, France, Netherlands, United Kingdom, Brazil, and Mexico. Collectively, these countries accounted for over 51% of U.S. agricultural exports in 1988. Agricultural (value) export data from the United States to these countries were obtained from the Department of Commerce.

Quarterly gross national product (GNP) data as well as the consumer price index (CPI), wholesale price index (WPI), and exchange rates (foreign currency per U.S. dollar) data were obtained from *International Financial Statistics* published by the International Monetary Fund. Since continuing quarterly data of GNP for Netherlands and South Korea were not available, gross domestic product (GDP) was used as the income variable for these countries. CPI's were used as price deflators to obtain estimates of real GNP and real exchange rates.[2]

Unit costs of production were obtained by using indices of prices paid by farmers. The index of prices paid by U.S. farmers for production items, interest, taxes, and wage rate was obtained from *Agricultural Prices* published by USDA Agricultural Statistics Board. For the EEC countries of West Germany, Netherlands, France, and United Kingdom, the purchase price indices of the means of agricultural production for each of the countries were obtained from *EC Agricultural Price Indices* published by Eurostat. For Canada, total farm input price indices were obtained from *Farm Input Price Index* published by Statistics Canada. Price indices of all commodities purchased by farmers were used for Japan. These indices were found in *Monthly Statistics of Agriculture Forestry and Fishery* published by the Japanese Ministry of Agriculture, Forestry and Fishery. In the case of South Korea, price indices of all farm supplies, goods, wages and charges were obtained from the *Monthly Review* published by the National Agricultural Cooperative Federation. Average price indices paid by farmers in the states of Victoria and New South Wales was used for Australia. These data were obtained from *Indexes of Prices Received and Paid by Farmers* published by the Australian Bureau of Agricultural and Resource Economics.

Estimation and Results

The first step in the empirical analysis was to construct the exchange rate risk proxy (S). Following Cushman (1988), two measures of exchange rate risk were used. Each measure assumes that traders use variability of the exchange rate in deviation form as a risk proxy. The first, (S_1), is a moving four quarters standard deviation of the relative change in the real exchange rate. The second, (S_2), is similar to S_1 except that it is based on monthly observations, and therefore, is calculated as a moving twelve months standard deviation of relative changes in the real exchange rate; S_1 assumes that quarterly variations affect trade, while S_2 assumes that monthly variations affect trade.

Equation (9) was estimated using a double log specification (except the risk variable which takes negative values) for each importing region. Data limitations required changes in the specification of some equations. The equation for Brazil was estimated without the income variable because no quarterly GNP (or GDP) exist for this country. The wholesale price index (WPI) was substituted as a proxy for unit cost of production in Brazil and Mexico because data were unavailable for this latter variable.

Each equation was first estimated using ordinary least squares (OLS). Non-risk variables which generated a t-value of close to zero were omitted from the equation. Equations which exhibited autocorrelation were corrected using the iterative Yule-Walker procedure offered in SAS. Cushman's (1988) approach was adopted by estimating (9), first with S_1 as the risk measure. The initial lag was set at one, although different lags provided better results for some variables. Once the lag length was determined for each of

[2] David Stallings (USDA ERS) provided the exchange rate data in both nominal and real terms.

the variables, equation (9) was estimated again with S_2 as the risk variable.[3]

Because short-run (quarterly) data were used in the analysis, the lag length for the risk variable is not known, and different lags were tested. Coefficients of the equations which yielded the "best" results with S_1 as the risk variable are reported in table 1, while those with S_2 as the risk measure are reported in table 2. Overall, the equations performed relatively well, considering the usual problems of using aggregate data.

The results with S_1 as the risk proxy in table 1 reveal some interesting outcomes. In seven out of the ten equations, the bilateral real exchange rate variable (R) was negative and significantly different than zero at the 90% level. In two of the remaining equations (West Germany and Australia), the exchange rate coefficient was also negative but significant at only the 85% level. These results suggest that as the real value of the U.S. dollar appreciates (R increases), agricultural imports by these countries decrease. Thus, the importance of the real exchange rate in determining agricultural trade flows is confirmed.

[3] The determination of the appropriate lag length when using quarterly data poses a problem because the lag structure which affects the dependent variable is unknown. Cushman's (1988) approach was utilized by estimating each equation with different lag specification and arriving at the "best" (as Cushman states) equation. While this approach is ad hoc, it provides a way of observing alternative lag specifications.

Batten and Belongia; and Henneberry, Henneberry, and Tweeten found that the real exchange rate significantly affected U.S. agricultural exports. However, both studies used a single real trade weighted exchange rate in their analysis. Our findings demonstrate that bilateral real exchange rates are also important in determining agricultural trade flows.

The income variable (Y) is positive for all countries and significantly different than zero for the United Kingdom, Australia, Japan, and South Korea. Because the equations were estimated in double log form, the coefficients can be interpreted as elasticities. They indicate that high income elasticities generally exist, except for Canada and Mexico. In two countries, France and Netherlands, the income coefficients are 1.03 and 1.05, respectively, indicating an almost unitary income elasticity.

The unit cost of production variable in the importing region (UC_{im}) is positive in seven out of the ten countries. It implies that as production costs in the importing countries increase, imports will increase as well. In Japan and Brazil this variable was both significant and negative. The negative sign indicates that as the unit cost of production in the importing region rises, the price of the domestically produced product also rises. The rise in the domestic price will lower demand for the product and, thus, the import demand for intermediate goods declines. The unit cost of production variable in the exporting

country (United States) was included in eight countries. The coefficient was negative in five countries, indicating that as the unit cost of production in the United States increases less will be demanded in the importing country.

The moving average of the change in the real exchange rate variable was included in only four equations, generating the expected negative sign in three of the cases. The coefficients are significant for Canada and Japan and positive and significant (90%) for Mexico.

The risk variable (S_1), as expected, is negative in all ten countries and significantly different than zero in South Korea, Brazil, and Mexico. A negative sign for the risk coefficient indicates that as risk increases trade decreases. One can make a general observation regarding the risk coefficients.

In the three developing countries analyzed in this study (South Korea, Brazil, and Mexico), the risk coefficient was negative and significantly different than zero. Either developing countries do not hedge against exchange rate risk or their financial markets are not well developed. This conclusion is supported by Quirk et al., who studied the forward exchange markets in developing and developed markets. Furthermore, Coes and Diaz-Alejandro found that exchange rate risk adversely affected trade in Brazil and Colombia, both of which are developing countries.

Developed countries, on the other hand, use different hedging strategies (futures and forward markets) to eliminate exchange rate risk. The negative but insignificant risk coefficients in the developed countries also suggest the use of well-developed financial markets to hedge against exchange rate risk.

These results are consistent with the findings of Collins, Meyers, and Bredhal. They found that exchange rate effects on domestic prices were more pronounced under nominal exchange price insulation policies than under free trade. Therefore, it is not surprising that exchange rate risk plays an important role in developing countries where imports are highly restricted and centralized.

Table 2 summarizes the results of the equations when S_2 was used as the risk proxy. The risk variable becomes insignificant in South Korea and Brazil and remained significant in Mexico. In Australia, the risk coefficient is close to being significant at the 90% level. Otherwise, the results were not substantially different than those reported in table 1. Although the distinction between the results for the developed countries and developing countries is not as strong as those with S_1 as the risk measure, these results do not discount those obtained using the S_1 measure. The risk coefficients, for both S_1 and S_2, which were significantly different than zero were obtained only for developing countries.

Comparison of the results to other studies is difficult because of the different nature of this study. However, some general observations can be made. Anderson and Garcia found that ex-

change rate risk has a significant adverse effect on exports to three developed countries: France, Japan, and Spain. Their results were obtained from a disaggregated analysis. Perhaps exchange rate risk plays a more prominent role in trade of particular agricultural commodities compared with aggregate agricultural trade.

Cushman (1988) and Kenen and Rodrik found more significant adverse effects of exchange rate risk on exports to developed markets than the results of this study. One would expect exchange rate risk to be less significant in food products than industrialized products; agricultural products are considered necessities and, therefore, less sensitive to exchange rate variability.

Our results are somewhat contradictory to those obtained by Maskus (p. 23), who stated that "agricultural trade was the most susceptible to exchange rate uncertainty." His results, however, produced a significant negative risk coefficient only for U.S. agricultural exports to Germany. On the other hand, nonsignificant risk coefficients were obtained for Japan, United Kingdom, and Canada.

Concluding Comments

This paper analyzes the effects of exchange rate risk on U.S. agricultural exports to ten different countries. A model which incorporates exchange rate risk was formulated and estimated. Two measures of exchange rate risk were constructed. While the results suggest that the real exchange rate is significant in determining U.S. agricultural exports, they do not indicate that exchange rate risk is always important. The results with regard to the exchange rate risk variable (S_1 and S_2) were not significant in the seven developed markets. However, the risk variable S_1 was negative and significant in the three developing markets of Brazil, Mexico, and South Korea, indicating that exchange rate risk adversely affected U.S. agricultural exports to these countries.

These findings underscore the importance of exchange rate risk in developing countries' trading behavior. Issues such as establishment of well-developed financial and commodity markets in developing countries must be considered at both aggregate and specific commodity levels (Anderson and Garcia), so that the nature of exchange rate risk can be better understood.

Grain Price Expectations of Illinois Farmers and Grain Merchandisers

James S. Eales, Brian K. Engel, Robert J. Hauser, and Sarahelen R. Thompson

The study's purpose is to measure the extent to which futures and option prices reflect the subjective price distribution of a subset of market participants, farmers, and grain merchandisers in Illinois. Findings suggest that in most instances the futures price is an appropriate proxy for expected price. However, volatilities implied by option premia usually overestimate the subjective variances of producers and merchandisers. These differences between individual and market expectations of variance are consistent with findings of overconfidence in the psychology literature and should be considered by analysts when making observations about hedging decisions and risk aversion.

Key words: implied volatilities, judgment, options and futures markets, price expectations, subjective distributions.

Little empirical attention has been given to the relationship between the prices, or implied price distributions, quoted on organized futures and options markets and the subjective expectations of individuals. Yet, this issue is central to the validity of many studies that use the futures price as a proxy for expected price (e.g., Gardner, Helmberger and Akinyosoye, Just and Rausser). This issue is also important because the relationship between expectations and futures and options prices is fundamental to most hedging decisions. The purpose of this study is to measure the extent to which futures and option prices reflect the subjective price distribution of a subset of market participants, farmers and grain merchandisers in Illinois.

One of the reasons individual expectations may not agree with futures and option prices is that the expectations of individuals may not accurately reflect the underlying distribution of prices; that is, individual probability assessments may not be well calibrated with the distribution of actual outcomes. As a result of "anchoring," people systematically misestimate the probabilities of uncertain events (Tversky and Kahneman, Kahneman and Tversky).[1] In addition, evidence suggests that people often are "overconfident"; that is, their probability distributions are too narrow.[2]

Market and individual expectations may also differ because market expectations reflect an assessment made by a group. Sniezek and Henry found that group judgments are significantly more accurate than mean or median individual judgments, and that group judgments are not accurately described by averages of the assessments of individual group members. However, they also found that groups are no less (over)confident in their assessments than individuals.

Given these findings, it is plausible that individual probability assessments would display overconfidence. Moreover, the probability assessments of futures markets, representing a group judgment, would be more accurate than individual assessments but may not display less overconfidence than individual assessments. Therefore, a lack of agreement between the fu-

[1] Anchoring refers to the process of forming estimates of uncertain events or quantities by adjusting from an initial value. The initial value may be obtained in a number of ways, e.g., in the formulation of the question or some historical value. Generally, adjustments from the anchor are insufficient and the resulting estimate is poorly calibrated.

[2] Overconfidence has been found to be related to the difficulty of the prospect being assessed and to the time horizon between the assessment and the occurrence of the event. For a review of literature related to overconfidence and other calibration issues, see Lichtenstein, Fischhoff, and Phillips.

tures price distribution and the distributions of individuals may reflect routine errors in the judgment of individuals and may indicate that the market has a different model for generating price distributions.

Our analysis will compare the subjective price distributions of individuals aggregated in groups to the distributions embodied in the futures and option prices quoted during the same time period. The comparisons will be for both a nearby and a more distant time horizon. The next section of this article describes the method used to elicit and represent the subjective distributions of survey respondents. The methods for generating and comparing statistics that summarize these distributions and the distributions embodied in futures and option prices are then described, followed by the results and concluding comments.

Method for Determining Price Expectations

During the summer and fall of 1987, farmers and grain merchandisers in Illinois were surveyed to obtain their subjective distributions of future corn and soybean prices for dates in the 1987–88 crop year. A total of 237 corn and soybean producers in six groups from 68 of the 102 counties in Illinois were surveyed. Fourteen merchandisers from four counties in east central Illinois were also surveyed. Table 1 lists survey groups, number of respondents, elicitation periods, forecast dates, and the length of each forecast in days. To obtain expectations from a large number of respondents during a brief period, large gatherings of farmers were used as the survey arena. The farmers who participated in the survey were not selected at random but instead volunteered to participate in response to requests for participation. The grain merchandisers were those who responded to randomly generated requests made at visits to elevators in east central Illinois.

Using a technique suggested by Bessler and Moore, survey respondents were asked to provide a distribution of cash corn and soybean prices as well as a distribution of their local basis for each grain, for both a nearby and more distant forecast horizon. Thus, each respondent provided a total of eight subjective distributions. The method used to elicit distributions provides a direct, although restricted, estimation of an individual's subjective probability distribution. Cash and basis price lines were partitioned into eighteen discrete intervals for the summer elicitation periods and sixteen intervals for the fall elicitation periods. Producers and merchandisers were asked to provide price distributions by assigning any number of a total of ten weights to price intervals to indicate how strongly they believed the realized price would fall within an interval. Their confidence in the likelihood was indicated by the number of weights assigned to an interval; i.e., if all ten weights were assigned to an interval, the respondent was indicating 100% confidence that the realized price would fall in that interval. Pilot tests of the survey conducted during the spring of 1987 indicated that respondents were able to complete the survey with greater ease when given an example; thus, an example regarding football scores was given

Table 1. Composition of Survey Groups, Number of Respondents, Elicitation Periods, Forecast Dates, and Forecast Length in Days

Group	Description of Groups	Number of Respondents	Period of Elicitation	Forecast Dates	Forecast Length (Days)
1	Illinois Farm Bureau Meeting; producers selected in exhibit hall.	44	8 Dec. 1987	1 Jan. 1988	23
				1 March 1988	82

				1 March 1988	228
7	Whiteside County, options extension meeting; producers selected prior to meeting.	14	25 June 1987	1 Nov. 1987	128
				1 March 1988	248

on the cover of each survey along with instructions. The pilot tests also indicated that producers did not have difficulty keeping track of the ten weights. No monetary rewards were used to motivate accurate assessments.[3]

To compare the expectations of survey respondents to futures and option prices, cash and basis distributions of survey respondents are combined to obtain a subjective futures price distribution. Respondents were asked to provide subjective probability distributions for cash prices and the local basis rather than directly eliciting their futures distribution. This approach prevented respondents from responding with current futures quotes and minimized the likelihood that respondents would use the current futures quote as an anchor.

A subjective distribution of the logarithm of the futures price was constructed by crop, forecast horizon, and respondent by combining each respondent's cash and basis distributions for a particular crop. The subjective mean for each group was then calculated as follows:[4]

$$\sum_i \sum_j \sum_k p_{ik} p_{jk} \ln(C_{ik} - B_{jk}),$$

where C_{ik} is the cash price represented by interval i for respondent k; B_{jk} is the basis (cash–futures price) represented by interval j for respondent k; p_{ik} is the subjective probability associated with cash interval i for respondent k; and p_{jk} is the subjective probability associated with basis interval j for respondent k.

The cash and basis level used for a particular interval is the interval's midpoint. The summations, i and j, are over the sixteen or eighteen intervals, as appropriate. The summation over respondents, k, in each group differs across groups. All calculations are based on the natural logarithm of $C_{ik} - B_{jk}$ to conform with the assumption of lognormality in the futures price distribution. Each possible value obtained in the summation was assigned a subjective probability based on the sum of $p_{ik}p_{jk}$ for each value (e.g., ignoring logs, if $p_{ik}p_{jk}$ for \$2.00 + \$.20 is .04 and $p_{ik}p_{jk}$ for \$2.10 + \$.10 is .25, then the subjective probability for \$2.20 is .29). This method of combination assumes independence between p_{ik} and p_{jk}, that is, that cash and basis distributions are independent. This assumption was supported by weak correlations between expected mean values of cash prices and expected mean basis values.

Methods for Comparing Price Expectations to Futures and Option Prices

As described above, individual subjective distributions of futures prices were aggregated by summing the probabilities associated with each possible futures price value over individuals surveyed during the same time period. These summed probabilities and respective (log) price values were then used to calculate the moments of the aggregate distributions of expected futures prices. Because the mean and variance completely determine the lognormal distribution, only these moments of the distributions of expected prices are considered.

The subjective variances are represented for each aggregate distribution in two ways. First, because it is easier to think in terms of levels as opposed to the logs, the variance of the ratio P_{t+1}/P_t is reported. Under the assumption that log of this ratio is normally distributed with mean μ and variance σ^2, the variance of the ratio P_{t+1}/P_t is calculated as

$$\text{var}(P_{t+1}/P_t) = \exp(2\mu + \sigma^2)[\exp(\sigma^2) - 1]$$

(Mood, Graybill, and Boes).[5] Here, μ and σ^2 are the mean and variance of each group's subjective distribution of the logarithm of futures prices.

Variances of subjective price distributions are also considered as annualized expected volatilities, or "annualized percentage standard deviations." These values are consistent with the measure of price variability used and reported by industry and academia for option pricing. The variance of daily log price differences yields a variance rate per day and represents the variance expected for tomorrow's price distribution. The time diffusion process underlying the estimate implies that the variance is proportional to time. The variances obtained from survey respondents are for distributions x days away. To annualize their variance, var[ln(P_{t+1}/P_t)] for each aggregated distribution is multiplied by $365/x$. For example, if the variance for a 60-day forecast is .01, then the annualized variance is (365/60).01

[3] A copy of the survey is available from the authors upon request.

[4] The subjective variance for each group was calculated analogously.

[5] This variance is not appropriate for calculation of confidence intervals, which would be asymmetric in this case.

= .061. The square root of this is .246, and the annualized volatility is expressed as 24.6.

Futures prices are assumed to follow a lognormal diffusion process. Numerous random-walk tests on log-price returns of agricultural futures do not provide clear support for or against lognormality (Kamara). Direct tests have often found leptokurtoticity, but these may result from a changing variance over time (e.g., Anderson and Danthine, Cootner, Neftci). Further, the assumption of lognormality is consistent with the Black option pricing model, which is used here to estimate the market's variance forecast.

Under the assumption of lognormality of futures prices, the mean of the distribution expected for the forecast date is the current log futures price. The market's variance forecast is based on implied volatilities of corn and soybean option premiums quoted for the forecast dates for each commodity. Implied volatilities (IVs) were calculated under Black's model for calls with strike prices nearest to but out of the money (the first strike above the relevant futures price). Calls slightly out of the money were used because (*a*) calls are usually traded more than puts, and (*b*) studies indicate that options deep in or out of the money are "mispriced" (wrong implied volatility) more often than those near the money. (See Hauser and Neff for a brief review of some of these studies.)

In addition to the IV based on options traded on the ending date of each elicitation period, an average IV is reported. This is a five-day average based on the IV of the ending date of the elicitation period and the IV from the four preceding trading days. An average IV presumably reduces the effect of possible outliers in the option premia while maintaining an information period comparable to that of the survey respondents.[6]

Differences between the first two moments of the respondents' and markets' distributions are tested. To conduct tests of differences in means and variances, it is assumed that the degrees of freedom associated with the futures price distribution are given by the trading volume of the call option used to calculate the implied volatility. These volumes averaged about 1,000 for the options considered and are, thus, effectively infinite. Hence, the mean and variance of futures are taken as known parameters in the tests. In addition, all tests are conducted with logged values of the data to remain consistent with the lognormality of futures.

Results

The means of the aggregate distributions of survey respondents are reported for each survey group and forecast date in table 2 for both soybeans and corn. Table 2 also reports the settlement futures price quoted during the elicitation period (or average settlement price over the days within a multiday survey period) for each survey group and forecast date. Finally, table 2 presents the differences between the means of the aggregate distributions and the futures settlement prices. The test for significant differences in log means was conducted using the variances obtained from the IVs and averaged IVs under the assumption that these are the "true" parameters. Thus, the test statistic is a standard normal.[7]

Of the fourteen corn price differences between the respondents and the market, five are significantly different than zero at the 5% level (four using the averaged IV to calculate the variance). Only one of the fourteen soybean differences is significant. Four of the six significant differences are from the fall survey period, and fifteen of the sixteen differences for producers in this period are positive, indicating a tendency of farmers to overestimate future price levels relative to the futures market during this period.

None of the subjective means of the grain merchandisers (Group 6) significantly differs from the corresponding futures price. This group likely has greater exposure to market information than would farmers in general; thus, the general agreement of grain merchandisers with the current futures is not surprising. The only group of farmers with no significant disagreement with the current futures is Group 3, the relatives of University of Illinois College of Agriculture undergraduates. Perhaps this group's

[6] The average difference between the averaged IVs and the IVs based on the ending date of the survey period is 9.19% for soybeans and 3.5% for corn. Schmalansee and Trippi suggest that use of an average IV (such as our 5-day average) tends to eliminate the need for Latane and Rendleman's weighting scheme.

[7] The test is a standard normal. The test statistic is

$$Z_{kt} = \frac{\mu_k - \ln(F_t)}{(\sigma_t^2/n_k)^{.5}}$$

where μ_k is the sample mean of the logged responses for group k; $\ln(F_t)$ is the log of current futures for the relevant forecast date; σ_t^2 is the variance of current futures calculated using either the IV or the averaged IV; and n_k is the number of respondents in group k.

Note: Settlement futures prices are those quoted during elicitation period or average settlement price over the days within a multiday survey period.

[a] January futures settle price calculated by: ln *Jan* = ln *Dec* + ($r * s$), where r = (ln *March* − ln *Dec*)/t, where $s = 1/12$, and $t = .25$.

[b] Asterisk indicates significant at the 0.05 level using both the variance based on the IV from the survey day or the 5-day average IV. Values in parentheses are the p-values (1 − CDF) using variances based on the IV from the survey date; cross indicates significant at the 0.05 level using variance based only on the IV from the survey day but not using the variance based on the 5-day average. Significance tests were performed on the logged data.

[c] December futures settle price.

general agreement with the futures market is partly because of the length of time (Thanksgiving vacation) that respondents had to complete the survey. Respondents also may have taken extra care to complete the survey because their children asked for their participation.

Table 3 reports the subjective variances of the aggregate distributions of futures prices both as the variance of the ratio P_{t+1}/P_t, calculated assuming the lognormality of this ratio as described earlier and as annualized expected volatilities for both soybeans and corn. The annualized volatilities implied by the option premia are presented as well.

Although most respondents expected a larger price variance for the March distribution than for the nearby date, all respondents' annualized subjective volatilities are lower for March than for the nearby date. Similarly, the respondents' annualized subjective volatilities are higher for forecasts with shorter time horizons (e.g., December forecasts of March 1) than for longer time horizons (e.g., July forecasts of March 1). The market volatilities implied by option premia are not uniformly smaller for the more distant forecast date.

The annualized volatility estimates derived for the market as well as the respondents represent an average variance rate. If the variance rate is constant over the forecast period, then the average equals this constant rate. However, the actual variance rate may change over time, and the time period length over which a given rate level exists may change. For most option pricing models, including Black's, the theoretical solution can be based on any variance rate which is a continuous function of time (and/or underlying commodity price). For corn and soybean prices, fairly strong evidence of seasonality in variance rate has been found (Anderson, Hauser and Andersen, Kenyon et al.). At a point in time, if the longer horizon's annualized volatility is larger/smaller than the shorter horizon's, the simple average of the variance rate for the more distant horizon will also be greater/less than for the shorter horizon. The inverse relationshp in table 3 between forecast horizon and the respondents' annualized volatility suggests a perception of a decreasing variance rate over time.

Table 4 reports the results of chi-square tests of the ratios of the variances expected by the survey respondents to the variances implied by

[a] Because premia for the March option were not available during this time period, these annualized volatilities are based on the November option premia.
[b] Because January corn options do not exist, volatilities based on the March corn option are used for the January annualized volatilities.
[c] December corn options used to calculate November volatilities.

option premia. This test was used to test for differences between the survey and market variances. The chi-square tests were performed by converting annualized percentage standard deviations to variances.[8]

The subjective variance of survey respondents for soybeans is always significantly less than the implied variance, except for the near forecasts of the grain merchandisers with respect to the option premium of the survey date. For corn, subjective variances for near forecasts are not significantly different than implied variances for any group except the grain merchandisers. For the distant forecast, subjective variances for corn are all significantly less than implied variances.

Under many paradigms for measuring behavior under risk, these findings imply that respondents perceive a lower level of risk in soybean prices and in distant corn prices than does the market. This suggests that the IV as an estimate of the subjective variance (risk) is biased upward.

For corn, the greater agreement between survey and market near-horizon forecasts of variance is consistent with past studies that have found a high correlation between IVs and recently observed variance, or historical variance (e.g., Hauser and Andersen, Kenyon et al.). To the extent that the IV is a function of historical variance, the present analysis suggests that the respondents believe current volatility conditions will persist in the near term for corn but not in the long term.

Hauser and Eales provide a perspective on how the commodity hedger's subjective variance relative to the market's IV affects the risk and return of the hedging strategies as perceived by the hedger. In their framework, the results of table 4 suggest that the respondents believe the soybean options and distant corn options are overpriced. In these cases, producers would be reluctant to hedge through purchase of puts, though the sale of calls may be attractive.

[8] The test is chi-squared with degrees of freedom equal to the number of respondents. The test statistic is

$$X_{kt} = \frac{\sigma_k^2 n_k}{\sigma_t^2},$$

where: σ_k^2 is the variance of logged survey responses for group k; σ_t^2 is the variance of logged futures based on either IV or the averaged IV; n_k is the number of respondents in group k.

[a] Asterisk indicates significant at the 0.05 level. Note that since, a priori, either variance may be larger, the test is two-tailed.

Conclusions

The means of twenty-two of the twenty-eight survey distributions are not significantly different than the futures price. Of the six significant differences, four are significantly greater than the futures price. However, all four are from the same time period and probably indicate a disagreement between respondents and the futures market peculiar to that period rather than a systematic bias in the relationship between futures prices and individual expectations. For two groups, no significant difference occurred between the futures price and group means. The composition of these two groups suggests that agreement with the futures market is more likely the longer is the time given to express expectations and the greater is the familiarity with the prices quoted on futures markets.

There is strong evidence of systematic disagreement between the respondents and market with respect to variance forecasts. The differences between survey and market variance expectations always imply that the respondents (both farmers and grain merchandisers) expect a lower variance than the market.

Any lack of significant disagreement between futures prices and means of the subjective price distributions may occur because farmers and grain merchandisers consider the futures market when forming price expectations. Our results may have occurred because the futures price is readily observable, while IVs are not. This explanation is consistent with the finding that the subjective means of those people with more time and greater exposure to futures were most likely to agree with futures prices.

These findings suggest that in most instances the futures price is an appropriate proxy for expected price. However, market IVs do not appear to reflect accurately the subjective variances of producers and merchandisers. The difference between the survey and market variances imply (*a*) IVs are overestimates of variance perceptions; (*b*) an important factor determining the type and extent of hedging with options, futures, and other risk management tools may be the difference in perceived variances; and (*c*) observations about producer's risk aversion should consider these differences in perceived variances. Finally, the difference between survey and market price distributions is consistent with the phenomenon of overconfidence reported in psychology literature.

Imperfect Competition in Agricultural Markets and the Role of Cooperatives: A Spatial Analysis

Richard J. Sexton

Important characteristics of many agricultural markets are costly to transport raw products and relatively few processors, one or more of which is often a cooperative. This paper analyzes pricing behavior in these oligopsonistic, spatial markets and focuses specifically upon the conjecture that cooperatives may have a procompetitive effect on the behavior of rival non-co-op processors. The existence and magnitude of a procompetitive effect is shown to depend upon a number of structural and strategic factors including competitive relations among the non-co-op processors and a cooperative's membership and pricing policies.

Key words: agricultural markets, conjectural variation, cooperatives, imperfect competition, oligopsony, spatial markets.

In a typical agricultural market, raw product production is by a large number of spatially dispersed farmers who act as price takers. The raw product is bulky and/or perishable and, thus, costly to transport. Processing of the raw product is by a relatively few marketing firms, and one or more of the processors is a cooperative.[1]

The first three of these conditions jointly suggest that processors may exercise spatial oligopsony power over farmers, but the classic works on farm–retail price spreads (George and King, Gardner) have assumed nonspatial perfect competition or, in the case of Bressler and King, recognized the spatial dimension but for the most part failed to deal with the attendant implications for firm behavior. Previous analysis that have examined spatial market power [e.g., Capozza and Van Order (CVO) and Greenhut, Norman, and Hung (GNH)] have focused on seller market power in retail markets.

The trend toward fewer and larger processing facilities makes the spatial dimension of agricultural markets increasingly important over time. Given the concern about oligopsony power in these markets, an interesting question that provides the focus of this paper is the role cooperatives may play in mitigating the potentially adverse performance implications of structural oligopsony. The notion that a cooperative may have a salutary effect on its rivals' behavior is known as the "yardstick of competition" hypothesis. The merit of this hypothesis is crucial to understanding the implications of alternative market structures, measuring cooperatives' market performance, and evaluating the public policy implications of cooperatives, but, surprisingly, the topic has received little formal attention. Apart from Fulton's recent analysis of the Canadian fertilizer industry, studies of agricultural markets have not distinguished cooperatives from other marketing firms.[2] Moreover, analyses of marketing cooperatives have usually examined the cooperative in isolation as if it were a monopsony processor.[3] The industry norm, though, is that cooperatives coexist with other firms in markets that are structural oligopolies or oligopsonies (Cotterill, Fulton). For exam-

[1] Cooperatives aggregate market share in the United States measured at the farm gate is roughly 30%. The share is significant, moreover, across several industry groups, including dairy, 77%; cotton, 36%; grain and soybeans, 36%; fruits and vegetables, 20%; and livestock, 11% (Wissman). Cooperatives are also important market forces in many European and developing-country economies.

[2] For example, Just and Chern concluded that the California tomato-processing market exhibited oligopsonistic behavior but failed to consider that the market contains two cooperative processors and a cooperative bargaining association.

[3] See surveys of this literature by LeVay, Sexton, and also Staatz.

ple, raw product markets that generally satisfy these structural conditions include dairy, cotton, some grains, and many processing fruits and vegetables. A partial listing here would include apples, avocados, citrus, olives, peaches, pears, potatoes, and tomatoes.[4]

The goal of this paper is to characterize formally the pricing behavior of for-profit processors (i.e., processors that are not cooperatives) in these oligopsonistic spatial markets in the absence and presence of cooperative processors. These results are derived from a conjectural variations model of oligopsony competition in which the key consideration is the for-profit processor's rational conjecture of a cooperative's behavior in contrast to the conjectures it might plausibly entertain for the behavior of a rival for-profit processor.

In this manner we are able to derive and compare equilibrium processor-farm price spreads under alternative market structures and modes of co-op behavior. In so doing, this analysis establishes formally the conditions for which a yardstick effect does and does not exist, and develops conceptual measures of the magnitude and determinants of the effect.

The paper proceeds in the next section to develop a model of spatial competition in the marketing sector wherein the effect of alternative forms of competition on the farm-processor price spread is demonstrated. The analysis is then broadened to include cooperatives among the set of processors. The effect of cooperatives on noncooperatives' price spreads is demonstrated for alternative modes of cooperative behavior. The paper concludes by exploring implications of the results for antitrust policy and public policy towards cooperatives and by suggesting further research.

Spatial Competition in Agricultural Markets

This section derives the farm–processor price spread under alternative modes of spatial competition. These results are compared in the next section to price spreads for markets in which a cooperative is present. To simplify the analysis, it is assumed that processors are homogenous and are price takers in their selling markets. The analysis is easily extended, however, to handle imperfect competition in the selling markets (see footnote 7). Farmers are also assumed to be homogenous and distributed uniformly in space with density D.

An individual farmer's supply curve is denoted as

$$r_i = r_i(W_i),$$

$r_i' > 0$, where r_i is the quantity of raw product supplied and W_i is the net price received by the farmer. In turn, $W_i = w - tL_i$, where w is the mill price offered by the processor, t is the cost to transfer a unit of the raw product one unit of distance, and L_i is the farm-to-processor distance. Transfer costs are assumed to be borne by the farmer, although this point is not essential to the analysis. Thus a higher mill price calls forth an increased supply from each farmer.

In modeling supply to a processor, we follow conventional spatial theory and assume that competition occurs in n directions. Given homogeneity in technology and behavior among processors, a given firm's market radius will be identical in each direction and denoted by L. The representative processor's supply, R, is then

$$(1) \quad R(W, L) = nD \int_0^L r(W)d\tau, \; W = w - t\tau.$$

The purposes of this paper, it is convenient to rewrite the supply function to a processor in the following general inverse form,

$$(1') \quad w = w(R, L).$$

To further simplify the subsequent analysis, it is assumed that all processors produce a single product q and employ the same quasi-fixed proportions technology wherein no substitution is possible between the raw product and the vector of processing inputs $X = \{x_1, \ldots, x_n\}$, but substitution among the various x_k may be possible.[5] This technology may be written as

$$(2) \quad q = \min \{R/\lambda, h(X)\},$$

where $\lambda \le R/q$ indicates conversion possibilities between raw and processed product, and $h(X)$ is concave with positive and declining marginal products and continuous second derivatives. Given positive prices for R and X, cost minimization requires that $q = R/\lambda = h(X)$. In ad-

[4] Although this paper focuses on raw product markets, analogous concepts are applicable in farm input markets whenever spatial considerations are important as, for example, with bulky inputs such as fertilizer (Fulton) and petroleum.

[5] Dunn and Heien, for example, were unable to reject statistically the hypothesis that elasticities of substitution between farm and nonfarm inputs were zero.

dition to the costs associated with R and X, each processor must incur a fixed set up cost $f > 0$.

Given these conditions on technology, the processor cost function is

$$(3)\qquad c(q) = \begin{cases} 0 \text{ if } q = 0, \\ \lambda wq + m(q) + f, \text{ if } q > 0, \end{cases}$$

where λwq are raw product costs, and $m(q)$ are costs due to the processing inputs, where it follows that $0 < m' < \infty$, $m'' \geq 0$.

Equation (3) embodies economies of size over at least some range for $q > 0$. That is, the effect of spreading $f > 0$ over increasing outputs causes average cost to fall over some $q > 0$ even if $m'' > 0$. Economies of size in processing are necessary to generate a spatial distribution of processors rather than having a processor located at each farm site.

Without loss of generality, let product quantities be measured so that $\lambda = 1$ and $q = R$. Profits for a representative processor producing $q > 0$ are then

$$(4)\qquad Y = PR - m(R) - wR - f.$$

The first-order condition for maximization of (4) is

$$(5)\qquad dY/dR = P - m' - w - R(dw/dR) = 0.$$

To simplify notation, define $p = P - m'$ as the processed product price net of marginal non-raw product processing costs. If $m'' = 0$ as is typically assumed in spatial theory, p is a constant. If $m'' > 0$, p decreases in R.

From (1′) the term dw/dR in (5) can be written as

$$(6)\qquad dw/dR = \partial w/\partial R + (\partial w/\partial L)dL/dR.$$

The term $\partial w/\partial L$ in (6) can be reexpressed through use of the implicit function theorem on (1):

$$(7)\qquad \partial w/\partial L = -(\partial R/\partial L)/(\partial R/\partial w) < 0.$$

The inequality in (7) follows because both $\partial R/\partial L$ and $\partial R/\partial w$ are positive. That is, a higher mill price and a larger market area each call forth a greater raw product volume to the processor. The sign in (7) reflects that larger market areas diminish spatial competition among rival processors, increasing the monopsony power of a given firm and, thus, diminishing price.

Interpreting (6) in words, $\partial w/\partial R > 0$ measures the effect on a processor's price from increasing purchases within a given market radius. The magnitude of $\partial w/\partial R$ is determined from growers' supply curves. If, however, the processor believes he can expand market area, L, by raising R and, indirectly, w, then, given $\partial w/\partial L < 0$, it follows that the full price response, dw/dR, is less than the response predicted from examining only $\partial w/\partial R$. In other words, the greater is dL/dR the less flexible (more elastic) is the total raw product supply response facing the processor.

Converting (6) to elasticities obtains;

$$(8)\qquad \eta_{w,R} = \epsilon_{w,R} + \epsilon_{w,L} \cdot \eta_{L,R'}$$

where $\eta_{w,R} = (dw/dR)(R/w)$ is the total price flexibility of w (inverse elasticity of R), $\epsilon_{w,R} = (\partial w/\partial R)(R/w)$ is the corresponding partial flexibility (inverse elasticity), $\epsilon_{w,L} = (\partial w/\partial L(L/w)$, and $\eta_{L,R} = (dL/dR)(R/L)$. Substituting (8) into (5) obtains

$$(9)\qquad \frac{p - w}{w} = \epsilon_{w,R} + \epsilon_{w,L} \cdot \eta_{L,R}.$$

That is, the relative farm–processor price spread is determined by the raw product supply flexibility facing the firm and by the product of the flexibility of the mill price w with respect to market dimension L and the elasticity of L with respect to the quantity of the raw product purchased.

Examining the individual terms in (9), larger $\epsilon_{w,R}$ means a more flexible (less elastic) raw product supply and a larger price spread, *ceteris paribus*. As noted in (7), the term $\epsilon_{w,L} < 0$ measures the competitive effect of larger market areas. Its effect on the price spread is determined jointly with $\eta_{L,R}$, the key term for purposes of this paper.

$\eta_{L,R}$ is the spatial competition analog of the classical conjectural variation. It measures the processor's perception of competitive conditions in the market. For example, increasing R implies increasing w as a necessary condition to call forth greater raw product supply given $r_i' > 0$. How rapidly w increases depends on the extent to which the processor can attract supply from rival processors. That is, it depends on the magnitude of dL/dR. If the firm believes dL/dR is small or even zero, competitive behavior to raise R is less profitable than if dL/dR is large because w will rise relatively rapidly. For example, if $dL/dR = 0$, any increase in R must be generated solely from the growers in the area defined by L, and price must rise in accord with their aggregate supply flexibility. Small dL/dR

is equivalent to a perceived aggressive response from rivals attempting to preserve their market area. Such a perception discourages the firm from behaving competitively. Monopsony pricing and high margins are then the outcome.

Two alternative behavioral postulates have received primacy in spatial theory (CVO, GNH): Loschian competition, wherein each competitor behaves as if his market area is fixed, and Hotelling-Smithies competition, wherein each competitor believes his actions will not affect his rivals' prices. The Hotelling-Smithies conjecture is the Nash conjecture in a price-setting context, but an alternative conjecture, owing to Cournot, that a given firm's quantity changes will go unheeded by rivals, is the Nash conjecture in this quantity-setting model.

To elucidate the behavior implications of these alternative conjectures, note that equilibrium behavior (assuming all markets are served) requires the net prices of rivals to be equal at their common borders. Letting u_j denote the arc distance between a representative firm and its jth rival, $j = 1, \ldots, n$, and w_j, the jth rival firm's price, the equation defining the market boundary L_j between the two firms is

$$(10)\qquad w - tL_j = w_j - t(u_j - L_j), j = 1, \ldots, n.$$

Given symmetric rivals, let $u_k = u_j = u$, $w_k = w_j = \bar{w}$, and $L_k = L_j = L$. The market boundary is then symmetric in all n directions ($\bar{w}$, $\bar{R}$, are, henceforth used to denote a rival's price and output while w, R denotes the representative processor's price and output). Note that fixed u implies that plant locations and numbers are fixed, a condition equivalent to the usual oligopoly/oligopsony condition that number of firms in the market is fixed in the short run. Moreover, the market boundaries, L, are also known and treated as fixed in the short run with the crux of the subsequent analysis focusing on firms' perceptions of how their behavior will affect the market boundaries. Solving (10) for $L_j = L$ and differentiating obtains

$$(11)\qquad \frac{dL}{dR} = \left[\frac{dw}{dR} - \frac{d\bar{w}}{dR}\right]\frac{1}{2t}.$$

The Loschian conjecture is that $dL/dR = 0$. From (11), it implies $d\bar{w}/dw = 1$, any price change generated by the representative firm's behavior will be exactly matched by its rival. This is the collusive conjecture in nonspatial oligopsony theory and leads to the joint monopsony solution when all firms entertain this conjecture.[6] Loschian (LO) competition is, therefore, the spatial analog to collusive behavior in a nonspatial context, and from (9)

$$(9')\qquad \left(\frac{p - w}{w}\right)^{LO} = \epsilon_{w,R}.$$

The Hotelling-Smithies (H-S) conjecture is $d\bar{w}/dw = d\bar{w}/dR = 0$. Its nonspatial analog is Bertrand competition, which is known to generate the competitive solution where price equals marginal cost whenever markets have homogenous products and firms with nonbinding capacity constraints. Substituting (11) into (6) with $d\bar{w}/dR$ set equal to zero obtains

$$(12)\qquad \frac{dw}{dR} = \frac{\partial w/\partial R}{1 - (1/2t)\partial w/\partial L}.$$

Substituting (12) into (5) and rearranging as indicated in (9) gives the price spread when all rivals engage in Hotelling-Smithies competition:

$$(9'')\qquad \left(\frac{p - w}{w}\right)^{H\text{-}S} = \epsilon_{w,R}\left[\frac{1}{1 - (1/2t)(\partial w/\partial L)}\right].$$

Given $\partial w/\partial L < 0$ from (7) and $m'' \geq 0$, it follows from (9″) that *H-S* competition induces higher w and a lower price spread than Loschian competition, a result consistent with their respective analogs in nonspatial imperfect competition.

The Cournot-Nash (*C-N*) conjecture is $d\bar{R}/dR = 0$. Denoting the raw product supply facing a rival as $\bar{w} = \bar{w}(\bar{R}, u - L)$ and differentiating obtains

$$(13)\qquad \frac{d\bar{w}}{dR} = \frac{\partial \bar{w}}{\partial L}\frac{dL}{dR}$$

upon invoking the $d\bar{R}/dR = 0$ conjecture.

Given that processing firms are symmetric, it follows in equilibrium that

$$(14)\qquad \partial \bar{w}/\partial L = -\partial w/\partial L.$$

That is, each unit increase in L induces a unit decrease in $(u - L)$, a rival's radius. Therefore, a change in L will have an effect on w exactly opposite of its effect on $\bar{w}$. In particular, note that $\bar{R}/dR = 0$ implies $d\bar{w}/dR > 0$. That is, as $u - L$ shrinks in response to $dR > 0$, the rival

[6] Given that marginal costs are the same for all processors, the conjectures must be the same across firms in equilibrium (Appelbaum).

must raise price to call forth a constant supply from its diminished market area.

Substituting (13) and (14) into (11) and rearranging obtains

$$(11') \quad \left(\frac{dL}{dR}\right)^{C\text{-}N} = \frac{dw}{dR}\left[\frac{1}{2t - \partial w/\partial L}\right].$$

Substituting (11′) into (6) for dL/dR and then converting to the relative price spread as illustrated previously obtains

$$(9''') \quad \left(\frac{p - w}{w}\right)^{C\text{-}N} = \epsilon_{w,R}\left[\frac{2t - (\partial w/\partial L)}{2t - 2(\partial w/\partial L)}\right].$$

Comparing (9′), (9″), and (9‴), it is easy to show that

$$\left(\frac{p - w}{w}\right)^{LO} > \left(\frac{p - w}{w}\right)^{C\text{-}N} > \left(\frac{p - w}{w}\right)^{H\text{-}S}.$$

The preceding approach can be generalized by noting that the alternative conjectures can all be written in terms of dw/dR:

$$\text{Loschian: } dL/dR = (0)dw/dR;$$

$$H\text{-}S\text{: } dL/dR = (1/2t)(dw/dR);$$

$$C\text{-}N\text{: } dL/dR = (dw/dR)/(2t - \partial w/\partial L).$$

Thus, letting $dL/dR = \theta dw/dR$, we obtain from (6) and (9) the following general formulation of the price spread:

$$(15) \quad \frac{p - w}{w} = \epsilon_{w,R}\left[\frac{1}{1 - \theta(\partial w/\partial L)}\right].$$

From (15) $d((p - w)/w)/d\theta < 0$. That is, the greater the dL/dR conjecture, the higher is w and the lower the price spread for the reasons given earlier. If $m'' > 0$, rising incremental processing costs reinforce the effect of θ on margin behavior.

Note also that θ can be interpreted as an index of market structure ranging from 0 (collusion) to $1/2t$(H-S). From (9″) as $t \rightarrow 0$, $((p - w)/w) \rightarrow 0$ under H-S competition, affirming the equivalency of the H-S and Bertrand equilibria in the nonspatial world. Econometric estimates for θ may be used to test specific hypotheses about market structure (Appelbaum, Karp and Perloff).

The preceding results are summarized geometrically in figure 1, where $P - m'$ denotes the net marginal revenue product (*NMRP*) curve for R. (The curve labelled *NARP* in figure 1 is relevant to discussion of the co-op processor and is defined in the next section.) *NMRP* is the demand curve for the raw product for processors who are competitive in their selling market. Given the raw product supply curve $w(R, L)$ the price-quantity equilibrium is (w^{PC}, R^{PC}) if a processor behaves competitively in the raw product market as well.

However, profit-maximizing processors with spatial market power do not set $w = NMRP$ but, rather, equate *NMRP* with their perceived marginal cost of procuring the raw product. The Loschian, *H-S*, and *C-N* equilibria illustrated in the figure are each based upon different perceptions of this marginal cost function based, in turn, on firms' perceptions of how rivals would react to their changes in w and R.

The Effect of Cooperatives on Farm–Processor Price Spreads

Some concepts from the economic theory of cooperatives need to be introduced initially. The net average revenue product (*NARP*) of the raw product R is the revenue from processed product sales less processing costs, both divided by the quantity of raw product employed. Given $\lambda = 1$ and the processing technology set forth in (2) and (3):

$$(16) \quad NARP = [PR^c - m(R^c) - f]/R^c = P - AC(R^c),$$

where R^c is the cooperative's volume of raw product purchases as well as its output and $AC(R^c)$ is its average cost function for processing inputs.

As noted, the *NMRP* of R is the incremental contribution to net revenue of each successive unit of R employed:

$$(17) \quad NMRP = d[PR^c - m(R^c) - f]/dR^c = P - m'.$$

If $m'' > 0$, *NARP* has the usual inverted "*U*" shape illustrated in figure 1.[7]

Treating the raw product supply curve of its

[7] Another factor which will tend to create an inverted U-shaped *NARP* curve whenever $f > 0$ is the perception by the cooperative that it has market power in the sale of its processed products. The analysis of price spreads in this paper can easily accommodate these market conditions. For example, let $\Sigma^n q_i = Q$ and $P(Q)$, $P' < 0$, denote market demand for the homogenous product Q. Then $dP(Q)/dq_i = P + P'dQ/dq_i$, where dQ/dq_i is the ith firm's conjecture of its effect on total market output. The term $P'dQ/dq_i$ can be converted to elasticities and would appear on the right-hand side of the relative price spread formulations such as (9), with larger dQ/dq_i raising the price spread.

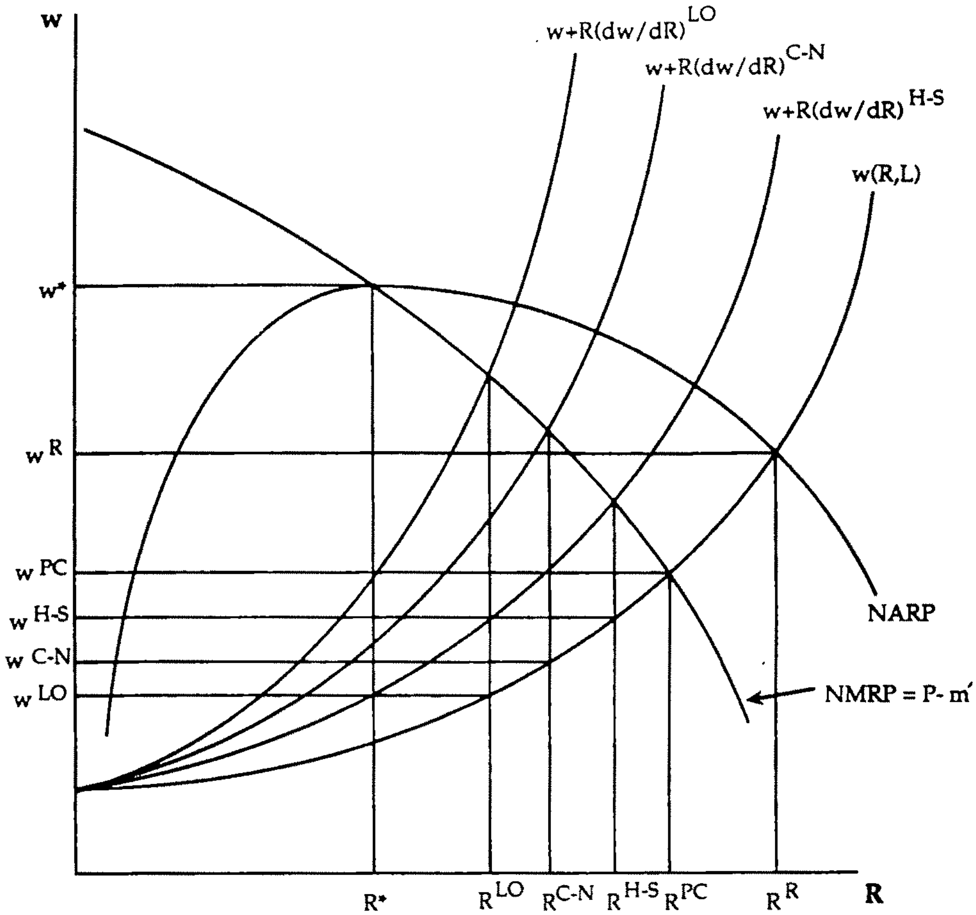

Figure 1. Price–quality equilibria for a for-profit processor and a co-op processor under alternative forms of spatial competition

members as given, it is well known that a cooperative maximizes its members' profit from jointly producing and marketing their product by setting raw product price, w^c, and purchasing quantity, R^c, where *NMRP* intersects member supply.[8] This behavior generates the competitive outcome (w^{PC}, R^{PC}) from figure 1. A problem is that the *NMRP* solution fails to satisfy the constraint that a cooperative break even unless member supply intersects *NARP* at its maximum where *NARP* = *NMRP*. Deficits or surpluses from *NMRP* pricing must be allocated to members as fixed charges or rebates, otherwise members will adjust their quantity supplied from the optimum level (LeVay, Staatz).[9]

The solution that maximizes members' profit subject to setting w^c to breakeven results from setting w^c at the intersection of member supply and *NARP*. As such *NARP* pricing is a Ramsey, second-best optimum—it maximizes member profit subject to the breakeven constraint. The Ramsey solution is denoted as (w^R, R^R) in figure 1.

The extent to which a cooperative plays a pro-

[8] Issues pertaining to the traditional price-output equilibrium have been extensively analyzed and debated. Summaries of the discourse are provided in survey papers by LaVay, Sexton, and also Staatz.

[9] Examples of fixed charges/rebates would be a lump sum levy or rebate per member or an allocation based on a fixed input such as acreage. Allocations, that can be linked back to patronage, e.g., patronage refunds, do not work in this regard because members rationally inpute the refund or levy as part of their net price and adjust their supply behavior accordingly. The ensuing equilibrium is not (w^{PC}, R^{PC}) but, rather, (w^R, R^R).

competitive role in an oligopsonistic market is shown here to depend on whether the cooperative (*a*) has an open or closed membership policy,[10] (*b*) is operating in the upward or downward sloping portion of *NARP*, and (*c*) sets price according to *NMRP* or *NARP*.

In considering these alternative scenarios, note that whenever a cooperative's *NARP* function is increasing over the range of growers' desired raw product supply, open membership is its optimal policy because adding new members makes existing members better off by raising *NARP*.

Restricted membership becomes an issue for a cooperative when its *NARP* declines within the range of desired grower supply. Some authors have argued that a cooperative will restrict membership and purchase only the quantity of raw product, R^*, that maximizes *NARP*, in which case members can be paid $w^* = NARP(R^*)$, the maximum per unit price possible. Others have argued that the cooperative will maintain open membership and expand purchases into the range of diminishing *NARP*, setting raw product price where growers' supply intersects either *NMRP* or *NARP*. See the references in footnote 8 for further discussion and figure 1 for an illustration of the alternative outcomes.

Our approach is to recognize that each of these scenarios may be descriptive of co-op behavior in various situations and to analyze each in turn. For ease of exposition, price spread behavior for a for-profit processor is derived in the ensuing subsections for the case when the processor faces only co-op rivals. Generalization is subsequently made to the typical real-world case involving both co-op and non-co-op competitors.

The Open Membership Cooperative

An open membership cooperative will attract members until at the market boundary L a grower's payoff as a co-op member equals his payoff from patronizing the neighboring firm—assumed to be a for-profit processor. For the cooperative that sets price according to $w^c = NARP$ and is located distance u from the representative for-profit processor, the boundary condition is simply

$$(10') \qquad w - tL = w^c - t(u - L).$$

Adapting from (11), we have

$$(11'') \qquad \frac{dL}{dR} = \left[\frac{dw}{dR} - \frac{dw^c}{dR}\right] \Big/ 2t.$$

From (16), we obtain

$$(18) \qquad \frac{dw^c}{dR} = \frac{dNARP}{dR^c}\frac{dR^c}{dR} = \frac{dR^c}{dR}\frac{1}{R^c}[AC - m'],$$

where *NARP* is increasing when $AC > m'$, decreasing when $AC < m'$, and a maximum when $AC = m'$. Noting that

$$(19) \qquad \frac{dR^c}{dR} = \frac{\partial R^c}{\partial w^c}\frac{dw^c}{dR} + \frac{\partial R^c}{\partial L}\frac{dL}{dR},$$

and using this result to substitute for dR^c/dR in (18) obtains

$$(18') \qquad \frac{dw^c}{dR} = \frac{(\partial R^c/\partial L)(dL/dR)(AC - m')}{R^c - (\partial R^c/\partial w^c)(AC - m')}.$$

Then substituting (18′) into (11″) obtains

$$(20) \qquad \frac{dL}{dR} = \frac{1}{2t}\frac{dw}{dR} \cdot \left\{\frac{R^c - (\partial R^c/\partial w^c)(AC - m')}{R^c - [\partial R^c/\partial w^c - (\partial R^c/\partial L)/2t](AC - m')}\right\},$$

or

$$(20') \qquad \left(\frac{dL}{dR}\right)^{OM} = \frac{\gamma}{2t}\frac{dw}{dR},$$

as the rational conjecture for a processor facing an open membership (*OM*), *NARP*-pricing cooperative, where γ is the term in curly brackets in (20).

Notice that (20′) embodies the cooperative's Ramsey optimal price response to dR in the sense that adjusting price in accord with *NARP* maximizes the cooperative members' welfare subject to satisfying the breakeven constraint. As such, the conjecture of the for-profit firm in (20) is a rational or consistent conjecture because it embodies a response that is optimal for the cooperative. (See, for example, Jacquemin, pp. 62–65 for a discussion of the concept of consistent conjectures in oligopoly theory.) Because $\partial R^c/\partial L < 0$ in the denominator of γ, it follows that

(21) $\gamma > 1$ when *NARP* is increasing

$\gamma = 1$ when *NARP* is a maximum

$0 < \gamma < 1$ when *NARP* is decreasing.

[10] Youde presented survey evidence to indicate that about three-fourths of "leading" marketing cooperatives and nearly 90% of all others have open membership policies.

Substituting (20′) into (6) for dL/dR and converting to the price spread as in (9) obtains

$$(22)\quad \left(\frac{p-w}{w}\right)^{OM} = \epsilon_{w,R}\left[\frac{1}{1-(\gamma/2t)\partial w/\partial L}\right].$$

The relative competitive effect of the *NARP*-pricing open membership co-op depends upon whether *NARP* is increasing, decreasing, or a maximum at the co-op's output level, R^c.

PROPOSITION 1. *The following relationships summarize the price spreads for a for-profit firm who competes only with open membership (OM) cooperatives versus only with technologically equivalent for-profit rivals conjectured to behave in either a Loschian (LO), Hotelling-Smithies (H-S), or Cournot-Nash (C-N) manner:*

a. Increasing NARP:

$$(23a)\quad \left(\frac{p-w}{w}\right)^{LO} > \left(\frac{p-w}{w}\right)^{C\text{-}N} > \left(\frac{p-w}{w}\right)^{H\text{-}S} > \left(\frac{p-w}{w}\right)^{OM}.$$

b. Maximum NARP:

$$(23b)\quad \left(\frac{p-w}{w}\right)^{H\text{-}S} = \left(\frac{p-w}{w}\right)^{OM}.$$

c. Decreasing NARP:

$$(23c)\quad \left(\frac{p-w}{w}\right)^{LO} > \left(\frac{p-w}{w}\right)^{C\text{-}N} > \left(\frac{p-w}{w}\right)^{OM} > \left(\frac{p-w}{w}\right)^{H\text{-}S}.$$

Proof. Most of the proposition is proved simply by comparing the alternative price spread equations in (9′), (9″), (9‴), and (22). Part (*a*) follows because from (21), $\gamma > 1$. The part (*b*) equality is apparent once $\gamma = 1$ is substituted into (22). For part (*c*), $((p-w)/w)^{OM} > ((p-w)/w)^{H\text{-}S}$ follows from substituting $\gamma < 1$ into (22). The other component of part (*c*), that $((p-w)/w)^{C\text{-}N} > ((p-w)/w)^{OM}$, is verified by noting that the Cournot conjecture, $d\bar{R}/dR = 0$ implies that the rival firm acts as if it has a perfectly inelastic raw product demand curve. That is, in response to $dR \geq 0$, the Cournot rival reacts by raising $\bar{w}$ sufficiently to hold $\bar{R}$ constant. *NARP* plays the role of raw product demand for the *NARP*-pricing cooperative. The assumptions set forth on the production technology in (2) preclude *NARP* from ever becoming perfectly inelastic. Thus, the *OM* cooperative always responds to $dR > 0$ and the subsequent shift inward in its raw product supply curve by decreasing R^c so that its price response, dw^c, is less than $d\bar{w}$, the Cournot rival's response. This result, in turn, elicits more competitive behavior and a lower price spread than from the equivalent Cournot rival. Q.E.D.

The results in proposition 1 are consequences of the behavioral differences between the for-profit and co-op entities. For example, when *NARP* is increasing, the cooperative rationally reduces its price offer as market area and volume decrease in response to $dR > 0$. Thus, not only does the co-op fail to match a for-profit rival's price change, the co-op's price movement is opposite its rival's when *NARP* is increasing. The *H-S* conjecture posits no change in competitors' pricing while *C-N* and *LO* behavior, respectively, involve partial and full price matching. Recall that the greater the extent to which a raw product price increase is expected to be matched, the less profitable such competitive activity becomes, leading to high margins.

Part (*c*) of the proposition is especially important because the Cournot conjecture generates the Nash equilibrium in the quantity-setting game. We are thus assured that the *OM* co-op generates a lower price spread than would be obtained in equilibrium under competition among only Cournot rivals.

Worth noting also is that if $t \rightarrow 0$, i.e., spatial considerations are unimportant, $\gamma \rightarrow 1$ (from L'Hopital's rule) and from

$$\left(\frac{P-w)}{w}\right)^{OM} = \left(\frac{P-w)}{w}\right)^{H\text{-}S} = 0.$$

That is, in the nonspatial world, the open membership cooperative drives its rivals to the competitive solution.

Results for an open membership cooperative that sets (w^c, R^c) at the intersection of member supply and *NMRP* are similar to those for the *NARP*-pricing cooperative, but there are some differences. *NMRP* now plays the role of raw product demand for the cooperative, so except when *NMRP* = *NARP* at $R^c = R^*$, the two pricing schemes generate different (w^c, R^c) equilibria. As indicated previously (footnote 9), *NMRP* pricing must be complemented by a set of allocations to handle the break-even constraint which is satisfied automatically by *NARP* pricing. This fact complicates derivation of the rational conjecture for a processor competing with

an *NMRP*-pricing co-op. Derivation of the conjecture is contained in the appendix. The key result, though, is a logical consequence of optimal, *NMRP*-pricing versus second-best, *NARP*-pricing.

PROPOSITION 2. *A cooperative that attains the NMRP-pricing equilibrium generates less competitive behavior from its for-profit rivals than an equivalent cooperative that attains the NARP-pricing equilibrium.*

Proof. The *NMRP*-pricing cooperative responds optimally to any change in its raw product supply caused by a rival's behavior. The *NARP*-pricing cooperative responds in a second-best fashion. Because the *NMRP*-pricing cooperative responds optimally to any $dR > 0$ its market area will shrink less rapidly than for an otherwise identical *NARP*-pricing counterpart. That is, except at $R^c = R^*$, dL/dR is less when the for-profit processor faces an *NMRP* rather than an *NARP*-pricing co-op. Q.E.D.

The Restricted-Membership Cooperative

This section examines the competitive effect of the cooperative that restricts purchases to R^* and sets $w^c = w^* = NARP(R^*) = NMRP(R^*)$. The immediate consequence of this behavior is that the equilibrium condition of net price (10′) or net welfare (appendix equation A1) equality at the market boundary need not hold. Instead the condition at the market boundary, L, is

$$(24)\qquad w^c - t(u - L) \geq w - tL,$$

with strict inequality holding for (24) if the co-op faces excess supply at R^*.

The restricted-membership cooperative's behavior introduces a kink in the supply facing its noncooperative neighbor(s). Specifically, for

$$w \leq w^c + t(2L - u),$$

the noncooperative's market boundary is fixed in the direction of its restricted membership cooperative neighbor. That is, $dL/dR = 0$, the Loschian conjecture, in which case the for-profit processor acts as a monopsonist within its boundary.[11] Only for $w > w^c + t(2L - u)$ can the noncooperative attract supply from the cooperative members, in which case the cooperative would react, as described in the previous subsection or the appendix, by reducing purchases along either its *NMRP* or *NARP* function. The following proposition, thus, applies for the restricted membership cooperative:

PROPOSITION 3. *The rational conjecture for the for-profit processor facing a restricted membership cooperative (RC) setting price according to NARP is*

$$(25)\qquad (dL/dR)^{RC} = \begin{Bmatrix} 0 & \text{if } w \leq w^c + t(2L - u) \\ (\gamma/2t)(dw/dR) & \text{otherwise} \end{Bmatrix}.$$

Equation (A6) is substituted for $(\gamma/2t)(dw/dR)$ in (25) if the cooperative sets price according to NMRP.

As previous results have demonstrated, the greater is the dL/dR conjecture, the greater is the perceived total elasticity of grower supply response facing the processor. Competitive behavior is more desirable when the processor believes (rationally) that he can encroach upon the cooperative's market area. That is, he need raise w by a lesser amount to obtain a given increase in R if raising w raises L as well as increasing quantity supplied among the processors in L. This fact causes a kink at the price $w = w^c + t(2L - u)$ in the for-profit firm's perceived raw product supply function. This kink causes the firm's perceived marginal cost curve for the raw product to be discontinuous, introducing the possibility of multiple equilibria for the firm, depending upon where its net price, $P - m'$ intersects its perceived marginal costs of procuring raw product.

Competition with Both Cooperatives and For-Profit Rivals

Cooperatives and for-profit firms operate together in the typical agricultural market. Given different behavior between cooperative and for-profit processors, market areas need not be symmetric in the n directions of competition. Denote a representative for-profit processor's market area by the vector $L = \{L_1, \ldots, L_n\}$. Equation (6) can be rewritten to reflect heterogenous competitors as follows:

$$(6')\qquad \frac{dw}{dR} = \frac{\partial w}{\partial R} - \frac{1}{n}\sum_{j=1}^{n}\left[\frac{\partial R/\partial L_j}{\partial R/\partial w}\right]\frac{dL_j}{dR},$$

where (7) is used to substitute for $\partial w/\partial L$ in (6).

[11] The possibility that farmers excluded from the closed membership cooperative may form their own cooperative is explored in Sexton and Sexton.

Let n_1 of the rival processors be identical cooperatives and $n_2 = n - n_1$ be identical for-profit processors. Again denoting conjectures with θ, let $dL_k/dR = \theta^C(dw/dR)$, $k = 1, \ldots, n_1$ denote the rational conjecture for a firm faced with a cooperative competitor, where θ^C is defined in (20′), (25), or (A6) depending on the cooperative's behavior.

Let $dL_s/dR = \theta^{FP}dw/dR$, $s = n_1 + 1, \ldots, n$, denote the conjecture for a for-profit (*FP*) competitor's behavior, the magnitude of which depends on the perceived competitiveness in the market. Then substituting for dL_j/dR in (6′) and converting to the price spread obtains

$$(26)\quad \frac{p-w}{w} = \epsilon_{w,R}\left[\frac{1}{1 + (n_1/n)[(\partial R/\partial L_k)/(\partial R/\partial w)]\theta^C + (n_2/n)[(\partial R/\partial Ls)/(\partial R/\partial w)]\theta^{FP}}\right].$$

Clearly, if $\theta^C > \theta^{FP}$, competing with some cooperatives rather than all for-profit firms reduces a noncooperative's price spread. The likelihood of observing $\theta^C > \theta^{FP}$ has been shown here to depend critically on the structure of the market as manifest in the behavior of the cooperative's *NARP* and *NMRP* functions and on the membership policy of the cooperative.

To summarize, when *NARP* is increasing over the range of grower supply, open membership is the optimal policy, and proposition 1 indicates that a cooperative elicits more competitive behavior (a lower price spread) from its rivals than would a comparable for-profit processor conjectured to behave in a Loschian, Cournot-Nash, or Hotelling-Smithies fashion.

Conversely, a cooperative that fixes membership to maximize *NARP* provides a range of prices indicated by proposition 3 whereby a rival for-profit processor can rationally entertain Loschian conjectures and act like a monopsonist within its market area. A cooperative that maintains an open membership policy in spite of a diminishing *NARP* is predicted to have a more salutary effect on spatial competition than its closed-membership counterpart. From proposition 1, the *NARP*-pricing cooperative elicits a lower price spread from rivals than a comparable for-profit processor conjectured to pursue Cournot-Nash behavior.

Conclusions

Although the possible existence of a competitive yardstick effect for cooperatives has long been considered (e.g., see Cotterill), this paper is the first to document in a rigorous oligopsony model the membership, market structure, and technological conditions that determine the existence and magnitude of such an effect. The work offers a number of implications for public policy wherein agricultural cooperatives have traditionally held a favored position. Beneficial tax treatment, limited exemption from antitrust statutes under the Capper-Volstead Act, below-market interest rates, and free technical assistance through the USDA and extension services are among the most-cited examples of policy favorable to cooperatives.

Underpinning these policies is the presumption that cooperatives have an overall favorable impact on the economy. This belief is often challenged. For example, cooperatives have been criticized in respect to their use of marketing orders (Ippolito and Masson). And recently, Daniel Oliver, the chairman of the Federal Trade Commission (FTC), has called for elimination of cooperatives' antitrust exemption (American Institute of Food Distribution). Also important is recent criticism based on the results of econometric research that suggests cooperatives may be less efficient than other organization forms. Porter and Scully (pp. 511–12) conclude, for example, that "tax breaks, interest subsidies and the gratis services of The Department of Agriculture presumably compensate cooperatives for higher per-unit costs. These public resources provided to cooperatives foster and promote an inefficient form of organizing production. . . . To the extent that government policy promotes the emergence of and subsidizes the survival of, the inefficient cooperatives . . . more technically efficient for-profit proprietary firms may be prevented from emerging and developing."

The results described in this paper help justify favorable policies toward open membership cooperatives as procompetitive forces whose presence mitigates for-profit firms' opportunities to exercise monopoly or monopsony power. Any reexamination of policy should be limited to the minority of cooperatives that restrict membership and for which similar procompetitive effects cannot be claimed. Moreover, performance evaluations of cooperatives must be made carefully, recognizing that direct comparisons to rival for-profit enterprises may be misleading because the market presence of a cooperative likely causes its for-profit rivals to perform better than they otherwise would.

Further policy implications are in the area of antitrust, where the U.S. Justice Department merger guidelines explicitly recognize the importance of spatial factors in fomenting market power. This work indicates that opportunities to exercise spatial market power are diminished where one or more of the spatial competitors is an open membership cooperative, and, thus, it is less likely that horizontal mergers in these markets would have a significant anticompetitive effect. These procompetitive effects of cooperatives need to be considered when contemplating FTC Chairman Oliver's suggestion to dismantle the Capper-Volstead Act.

Profitable avenues for future research will be to develop and implement empirical models to test for the exercise of oligopsony power and the existence and magnitude of cooperatives' yardstick effect in specific markets. Methodologies to conduct parametric tests of market power have been developed in recent years (e.g., Appelbaum, and Karp and Perloff). These methodologies typically estimate the magnitude of a conjectural variation as part of a time-series econometric model of the industry under study. These models may be extended to also conduct tests of the procompetitive effect of cooperatives. For example, conjectural variations may be expressed as functions of the extent and magnitude of co-op competition as suggested by (26). The incremental data required to implement this generalized model are one or more variables, such as co-op market share, to measure the extent of co-op competition over time in the market.

Appendix

The NMRP-Pricing Cooperative

Members of an *NMRP*-pricing co-op necessarily face a two-part pricing schedule, and the market boundary condition can no longer be stated as equality of net prices as in (10′). Rather, denoting as $\pi(W)$ a representative grower's well-behaved profit function, we have the boundary condition:

$$\text{(A1)} \qquad \pi(W^c) - \pi(W^n) = k$$

where W^c and W^n are, respectively, the grower's net price from the cooperative and noncooperative, and $k = k(R^c, L)$ is the fixed charge to the grower located on the market boundary L. If $m' > AC$, $k < 0$ is a rebate, and $W^c < W^n$ at the boundary.

The total deficit or surplus to the cooperative is $K = (AC - m')R^c$. It is assumed that K is allocated among members in proportion to their patronage. That is, for the boundary farm

(A2) $$k = (r^c/R^c)K,$$

where r^c denotes the quantity supplied by the boundary farm if it patronizes the cooperative. Consistent with the discussion in footnote 9, it is further assumed that the allocation is based on a fixed proxy for patronage so that members cannot influence the level of k by altering their volume of patronage.

Equation (A1) is an equilibrium identity that can be totally differentiated to obtain

(A3) $$\pi'(W^c)dW^c - \pi'(W^n)dW^n = dk.$$

This equation can be rewritten by using (A2) to express the differential dk as

$$dk = (r^c/R^c)dK + (K/R^c)dr^c - (r^cK/R^{c2})dR^c,$$

and by noting also the following:

$$dW^c = dw^c + tdL,$$

$$dW^n = dw - tdL,$$

$$\pi'(W^c) = r^c,$$

$$\pi'(W^n) = r^n,$$

where r^n denotes the quantity supplied by the boundary firm if it patronizes the for-profit processor. The latter two equalities are consequences of the envelope theorem. Substituting these expressions into (A3) and dividing by dR obtains

(A3′) $$r^c(dw^c/dR + tdL/dR) - r^n(dw/dR - tdL/dR) = (r^c/R^c)(dK/dR) + (K/R^c)(dr^c/dR) - (r^cK/R^{c2})dR^c/dR).$$

Equation (A3′) can be solved for the rational conjecture dL/dR for a firm competing with an *NMRP*-pricing open-membership cooperative. This is accomplished by first noting that K is just the inverse of the cooperative's "profit." Thus, it follows from the envelope theorem that

(A4) $$\frac{dK}{dR} = \frac{\partial K}{\partial w^c}\frac{dw^c}{dR} = R^c dw^c/dR.$$

Considering jointly the terms involving dr^c/dR and dR^c/dR on the right-hand side of (A3′), we obtain after expanding these derivatives:

(A5) $$\frac{K}{R^c}\frac{dr^c}{dR} - \frac{r^cK}{R^{c2}}\frac{dR^c}{dR} = \frac{K}{R^c}\left\{\frac{dw^c}{dR}\left[\frac{\partial r^c}{\partial w^c} - \frac{r^c}{R^c}\frac{\partial R^c}{\partial w^c}\right] + \frac{dL}{dR}\left[\frac{\partial r^c}{\partial L} - \frac{\partial R^c}{\partial L}\frac{r^c}{R^c}\right]\right\}.$$

The first bracketed term in (A5) vanishes due to homogeneity among farmers. Substituting (A4) and (A5) into (A3′) obtains the rational conjecture:

(A6) $$\frac{dL}{dR} = \frac{dw}{dR} \cdot \left\{\frac{r^n}{t(r^c + r^n) - (AC - m')[\partial r^c/\partial L - (r^c/R^c)\partial R^c/\partial L]}\right\}.$$

The expression $[\partial r^c/\partial L - (r^c/R^c)\partial R^c/\partial L]$ in the denominator of (A6) measures how the boundary farm's share of any co-op deficit or surplus changes in response to dR. The expression is always positive because raising L reduces $u - L$, the cooperative's market area, in turn causing $\partial R^c/\partial L < 0$. However, lower $u - L$ reduces transportation costs and raises supply for the border farm so that $\partial r^c/\partial L > 0$.

To evaluate behavior for the *NMRP*-pricing cooperative, consider the case where $R^c = R^*$ and $NMRP = NARP$. The two pricing schemes generate identical behavior and the identical, Hotelling-Smithies conjecture for a rational for-profit rival: $dL/dR = (1/2t)(dw/dR)$. (This result is verified from (A6) by noting that at R^*, $r^c = r^n$ and $AC - m' = 0$.)

When $R^c > R^*$, the *NMRP*-pricing cooperative generates a surplus and $r^c < r^n$. As R and w rise causing R^c to fall, the cooperative increases its total payout to members which is always monotonically increasing in *NARP*. This fact, as in the *NARP*-pricing case, makes $(dL/dR)^{OM} < (dL/dR)^{H\text{-}S}$ and, hence, discourages procompetitive behavior by the for-profit rival relative to the Hotelling-Smithies conjecture.

The opposite is true when $R^c < R^*$. Here the co-op incurs a deficit and $r^c > r^n$ for the border firm. Increases in w and R force the cooperative to diminish its total payout to members under *NMRP* pricing. Once again this fact makes $(dL/dR)^{OM} > (dL/dR)^{H\text{-}S}$, which induces more procompetitive behavior by the rational for-profit rival and a lower farm–processor price spread relative to the Hotelling-Smithies benchmark.

Investment Potential of Agricultural Futures Contracts

T. Randall Fortenbery and Robert J. Hauser

Investment benefits from trading live cattle, hog, corn, and soybean futures contracts are considered under the assumption that the investor's risk/return evaluation is relative to a highly diversified stock portfolio. A mean-variance approach is used to find the "optimal" mix of investments for the initial stock portfolio and for portfolios which may include both stocks and futures. The addition of futures contracts to the portfolio rarely increases the portfolio return. This finding is consistent with risk-premium results of previous studies. However, investment benefits from agricultural futures are found in the form of a reduction in the portfolio's nonsystematic risk.

Key words: futures contracts, investment, mean-variance analysis, risk premium.

What determines benefits from a position in the futures market? Keynes argued that a systematic risk premium is gained by speculators for offsetting hedgers' positions. A different but commonly used concept of "risk premium" involves the degree to which the variability of the returns to an instrument or activity cannot be diversified away. This perspective on risk is the foundation of the standard capital asset pricing model (CAPM) developed by Sharpe and by Lintner. As the level of systematic risk of an activity increases, the risk premium increases. That is, the market will compensate an investor for risk that can not be eliminated.

Keynes' notion of risk and its premium is only a function of the price return for an individual futures contract. The Sharpe/Lintner definition of risk and its premium relies on the return behavior of the completely diversified portfolio. The objective of our study is to identify and measure the investment benefits of agricultural futures contracts to investors or speculators whose concept of risk/return may fall between these extremes.[1]

The speculator's evaluation of risk/return is relative to his current portfolio. In contrast, the CAPM approach considers the perfectly diversified portfolio. However, the CAPM concept has at least two practical problems. First, an individual may make the evaluation relative to his own portfolio, regardless of whether the market is determining risk premiums based on the market portfolio. Our approach, through mean-variance (EV) analysis, recognizes that speculative rewards are a function of the specific investor and investment set considered, emphasizing that investors may hold portfolios which contain nonsystematic risk. The second problem with the CAPM approach involves the definition and measurement of the market portfolio. Dusak, for example, was criticized for her market-portfolio proxy by Carter, Rausser, and Schmitz, who in turn were criticized for their choice by Marcus and by Baxter, Conine, and Tamarkin. These and other debates reflect the fact that the CAPM approach requires an a priori assumption about the optimal portfolio mix. The present analysis determines the "optimal" mix of investments in the initial portfolio given a set of investments from which to choose.

Methodology

To measure the investment potential of futures contracts, efficient EV frontiers are estimated for portfolios with and without futures contracts as an investment option. If investment benefits from futures contracts exist, then the frontier that includes the futures contracts will attain a higher level of risk-efficiency, as illustrated in figure 1. The increase in risk efficiency is measured

The authors are an assistant professor, Division of Economics and Business, North Carolina State University; and an associate professor, Department of Agricultural Economics, University of Illinois.

This research was supported by Hatch Project No. 05-0354.

[1] The terms speculator and investor are used interchangeably here because the analysis considers the portfolio effects of a stock investor who expands his investment set to include futures speculation.

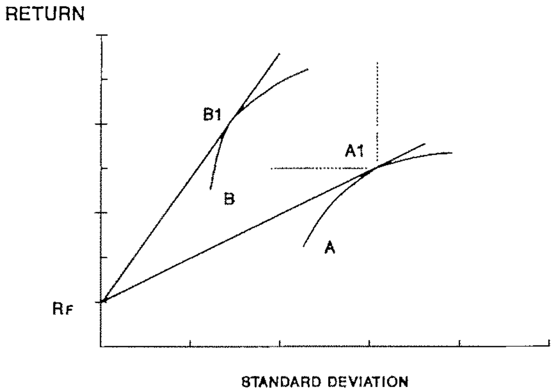

Figure 1. Illustration of return and risk management benefits

by defining optimal risky portfolios in each EV frontier. Following Elton and Gruber, these portfolios are found at the tangency between the EV frontier and the capital market line, represented by points $A1$ and $B1$.

Two types of benefits are created by an upward shift in the EV frontier. The first type is represented by the difference between expected returns, while the second is reflected by the difference in the standard deviations of returns. An increase in expected return is a "return benefit;" a decrease in standard deviation is a "risk management benefit." Both types of benefit are represented in figure 1 because the optimal portfolio of frontier B lies inside the quadrant defined by the dashed lines.

EV analysis allows empirical measurement of benefits which are unique to the investor, depending on the initial portfolio mix. The approach used here is similar to that used by Howard and D'Antonio, except that the focus is on speculators rather than on hedgers, and the value of the futures contract is measured differently.

The initial investment set is assumed to consist solely of stocks traded at the New York Stock Exchange. The stock frontier is found with the following quadratic programming (QP) specification:

$$\text{(1)}\quad \text{Minimize } V(Z)^{1/2} = \left[\sum_{i=1}^{n}\sum_{j=1}^{n} q_i \sigma_{ij} q_j\right]^{1/2},$$

subject to

$$\sum_{i=1}^{n} q_i U_i \geq M,$$

$$\sum_{i=1}^{n} q_i = 1,$$

$$q_i \geq 0 \text{ for } i = 1,2,\ldots,n,$$

where $V(Z)$ is the variance of the portfolio return, q_i is the proportion of each risky investment i in the portfolio, σ_{ij} is the variance-covariance matrix of expected rates of return, U_i is the expected rate of return for investment i, and M is the minimum acceptable rate of portfolio return. The model is solved iteratively with parametric variations in M of 0.01% per month.

A highly diversified stock portfolio is found by using the four individual indices of the Standard and Poor's 500 Stock index. The indices represent utility, industrial, financial, and transportation stocks.[2] While the EV approach does not require a well-diversifed portfolio, a diversified portfolio is used here so that the results are comparable to those found by Bodie and Rosansky, Dusak, and Lee and Leuthold. These studies measure risks and benefits of futures under the assumption that the Standard and Poor's 500 index represents a completely diversified portfolio.

Using data from July 1976 to December 1985, monthly returns to stock portfolios are computed as the percentage change in average monthly index values plus the average monthly rate of dividend returns to each index. An EV frontier is then estimated using the four stock indices as the investment set. The resulting capital market line is defined by the highest linear function between the risk-free rate of return (represented by the 90-day treasury bill rate) on the vertical axis and the tangency on the EV frontier. The tangency point between the capital market line and the EV frontier represents the optimal risky portfolio.

Individual futures contracts are then added to the investment set and the EV frontier is reestimated. The optimal portfolio for the new EV frontier is identified, allowing measurement of the return and risk management benefits.[3] Following Bodie and Rosansky, the return to the futures positions is calculated as the monthly percentage changes in the futures prices plus the risk-free rate of return. They argue that returns to futures contracts can be measured and compared to returns to stocks in two ways. The first is to calculate returns to futures as the proportional change in futures price:

$$R_{1t} = (P_{t+1} - P_t)/P_t,$$

[2] Each stock of the Standard and Poor's 500 is weighted such that changes in its price influence the index in proportion to the stock's relative market value. The individual indices of the Standard and Poor's 500 are comprised of the 500 stocks categorized by industry.

[3] An equilibrium framework is not employed, and thus portfolio adjustments are not evaluated on the basis of risk attitude, wealth, and/or new investment opportunities.

where R_{1t} is the futures return, P_{t+1} is the futures price in period $t + 1$, and P_t is the futures price in period t. Bodie and Rosansky use this measure for comparison against the net return of stocks. The stocks' net return is the return to a stock position in excess of the 90-day treasury bill rate (i.e., in excess of the risk-free rate of return).

The second method for computing returns to futures accounts for the ability of speculators to post treasury bills as margin. To avoid problems associated with marking futures positions to market daily (i.e., settling all futures gains and losses at the end of each business day), Bodie and Rosansky consider the treasury bill interest earned on average equity in futures over the investment period. This led to the following measure of futures return:

$$R_{2t} = ((P_{t+1} - P_t) + R_{ft}(P_t + P_{t+1})/2)/P_t,$$

where R_t and P_t are as before, and R_{ft} is the 90-day treasury bill rate in period t. This return was then compared to the gross stocks' return. Note that when P_{t+1} and P_t are close in value, R_{2t} will be approximately equal to the proportional change in futures price plus the 90-day treasury bill rate:

$$R_{2t} \approx R_{1t} + R_{ft}.$$

We use this approximation of R_{2t} by defining R_{ft} as the average 90-day treasury bill rate for period t.

The investment benefits of four agricultural futures contracts are examined: live cattle, hogs, corn, and soybeans. Combinations of the contracts also are considered. Finally, positions in the Commodity Research Board's Commodity Futures Index (CFI) are examined to reflect a diversified holding of futures positions.[4] The mean return and standard deviation of a long position is reported by futures contract in table 1. Correlations between the futures and index returns are also presented. The return levels relative to their standard deviations suggest that Keyensian risk premiums are not present. However, the small correlation coefficients indicate that agricultural futures may provide diversification benefits.

Several trading scenarios are modeled for each contract. The first is a routine buying strategy where the investor trades long in the nearby contract. Because futures contracts do not expire every month, positions are opened and closed only in those months preceding contract expiration. Monthly observations are calculated by dividing the gross return of a futures trading strategy by the number of months the position is held. For example, gross returns for live cattle contracts are divided by two because these contracts expire every other month; thus, a position is opened and closed every two months.[5]

The second trading scenario is the same as the first, except the investor takes a short position in the nearby contract. The third and fourth strategies are the same as the first and second, respectively, except that a position is taken in a contract that is approximately six months from maturity. This position is offset and a position is taken in the next distant contract when that contract is six months from maturity. These last two strategies are employed to evaluate potential differences in the risk or return characteristics that are attributable to contracts of different maturities.

[4] Similar in construction to a stock index, the CFI is based on 27 commodities which include both agricultural and nonagricultural futures contracts.

[5] The assumption that the return to a position held for two months can be equally divided between the two months ignores compounding. This is not considered critical, however, because an average is never computed for more than a two-month investment period.

Table 1. Relationships between Futures and Stock Returns

			Correlation Coefficients			
Futures[a]	Mean	Standard Deviation	Financial	Transportation	Utility	Industrial
N. Cattle	0.39	3.84	.018	−.066	−.148	.021
N. Hogs	0.53	5.19	−.056	.091	.016	.116
N. Corn	−0.36	4.06	.001	.150	−.029	.200
N. Soybeans	−0.73	5.77	.067	.226	.019	.199
D. Cattle	0.03	2.78	−.046	−.005	−.179	.053
D. Hogs	0.38	4.88	−.142	−.017	−.143	−.003
D. Corn	−0.50	3.57	.019	.160	.011	.186
D. Soybeans	0.22	5.14	.057	.228	.062	.231
CFI	−0.09	2.85	−.023	.227	−.032	.254

[a] "N." signifies nearby contract; "D." is distant contract.

Results

EV frontier *A* in figure 2 represents the estimated set of risk-efficient portfolios attainable by an investor who views his investment alternatives to consist solely of the four stock indices. Given a risk-free rate of return equal to the 90-day T-bill rate, the optimal risky portfolio has an expected monthly rate of return of 1.29% and a standard deviation of 2.47% per month.[6]

The effects of adding long nearby live cattle contracts to the stock investment set are also shown in figure 2. The addition of the cattle contract causes the EV frontier to move to the left, indicating that trading benefits are available for the nearby live cattle contract traded long. These benefits as well as those for other contracts are quantified in table 2.

When measured at the points of the optimal risky portfolio, the live cattle futures contract does not provide return benefits for any of the trading strategies. However, risk management benefits are indicated. The greatest risk management benefit is derived from trading the live cattle contract long. Trading the nearby contract long reduces risk by 0.28% per month with no change in the expected rate of return, while trading the distant contract long results in a risk reduction of about 0.52% per month and a reduction in the expected rate of return of about 0.12% per month.

The risk efficiency results for hog futures are similar to those for live cattle (table 2). For nearby live cattle traded long, the futures contract represents 26.19% of the portfolio; for hogs, it is 17.92%. In the CAPM framework, Bodie and Rosansky argue that agricultural futures should comprise 40% of the optimal market portfolio, whereas Marcus contends that 10% is more appropriate. For the investor considered here the optimal percentage of individual livestock futures in the portfolio falls between these two estimates.

The results from including corn contracts in the feasible investment set are similar to those for livestock except that the largest risk management benefit is derived from trading corn short rather than long. When corn is traded short on the nearby contract, frontiers similar to those for nearby live cattle traded long are generated. As shown in table 2, trading the nearby corn contract short yields no return benefit, but a measurable risk management benefit exists. This same result is generated when the distant corn contract is traded short. When either corn contract is traded long, trading rewards are negligible.

For soybean futures, long positions in either the nearby or distant contracts yield no return benefits, although some risk management benefit occurs if the distant soybean contract is traded long. The nearby contract traded long is not even on the efficient frontier.

[6] The standard deviation of expected returns is used here as a proxy for risk. A risk level, for example, of 3% per month is equivalent to a standard deviation of expected monthly returns of 3%.

Near long	1.29	2.4727	0.0000
Near short	1.33	2.3355	16.735
Distant long	1.27	2.2211	3.4799
Distant short	1.27	2.2211	3.4799

[a] Measured as percent per month.

Figure 3 shows the frontier derived by including the nearby soybean futures contract traded short in the investment set compared to the original all-stock frontier. At the maximum rate of return, 1.36% per month, the frontier that includes soybeans lies to the left of the all-stock frontier. In all other cases this rate of return was a point of convergence between the frontiers including and excluding futures contracts. Moreover, only when trading the nearby soybean futures contract short does the expected rate of return to the optimal portfolio increase when an individual futures contract is included in the investment set. However, the increase in return is only 0.04% per month, and the risk management benefit in this case is small relative to the risk management benefit identified for other strategies.

Table 3 presents the results of including combinations of futures contracts in the portfolio. Increased speculative benefits are associated with diversifying in either the livestock or grain futures markets. When both grains are held short, a return benefit is realized. The portfolio return is 1.35% per month with a risk level of 1.84%.

Results are also generated under the assumption that the investor holds either a long or short position in the CFI to proxy the effects of being totally diversified in the futures market. A nearby strategy is considered. As table 3 indicates, little difference occurs between trading the CFI index short or long. Some portfolio risk reduction is available from either strategy but at a substantial reduction in expected portfolio return. Thus, several strategies for both individual and combined contracts represent superior investments to the CFI index.

Concluding Comments

The EV model used in this study is useful for identifying investment potential or speculative rewards of futures contracts. The methodological approach differs from previous work in two fundamental ways. First, it allows measurement of both the "return benefit" and "risk management benefit" of future market investments. Previous analyses focus primarily on return benefits in the form of risk premiums. However, the absence of futures market "risk premiums" does not imply an absence of speculative rewards. To conclude that no speculative rewards exist for a given speculator, one must also show that portfolio risk is not reduced by the addition of a future position. The second difference is that the EV model allows return and risk management benefits to vary across investors and across commodities. Rewards to futures speculation may be a unique function of a specific

portfolio's risk and return characteristics. Previous studies have often assumed that the existence and magnitude of risk premiums are market phenomena. Thus, all speculators were expected to receive identical rewards from similar futures market positions.

Return benefits are generally not found for the investor characteristics and strategies considered here. This finding is consistent with the risk premium results of Dusak, Lee and Leuthold, and others. However, our study suggests that trading benefits associated with including some futures contracts in the investment set occur as reductions in portfolio risk. This finding supports previously untested hypotheses that futures contracts can diversify the nonsystematic risk components of stock portfolios (Dusak, Lee and Leuthold, Bodie and Rosansky).

The RLS Positive-Part Stein Estimator

Lee C. Adkins and R. Carter Hill

The RLS Stein-rule estimator of the classical normal linear regression model is formed by taking a linear combination of the least squares and restricted least squares estimators. Using a simple analytical device, we prove that the convex combination known as the RLS positive-part Stein estimator dominates the conventional version under weighted quadratic loss. Possible uses for the positive-part estimator in economic and agricultural economic research are discussed.

Key words: biased estimation, restricted least squares estimator, Stein-rule estimator.

Although it is well known that positive-part Stein rules dominate ordinary versions in many general settings, such a result has not been obtained for an important family of Stein estimators. We respond to the conjectures of Hill, Ziemer, and White; and Mittelhammer and Young, who claim that the Stein rule, which is formed by taking a linear combination of OLS and RLS estimators, is dominated by the convex combination called the positive-part Stein rule. By using a simple analytical device, we prove that the positive-part rule dominates the conventional version under weighted quadratic loss.

In the next section the classical normal linear regression model and its estimators are presented. Then the canonical form for the Stein-rule estimator is derived and the desired result is deduced using the canonical form and results given in Judge and Bock. Finally, the properties and potential uses of the positive-part Stein rule are discussed.

The Model and Its Estimators

The classical normal linear regression model (CNLRM) is represented by

(1) $$y = X\beta + e \quad e \sim N(0, \sigma^2 I_T),$$

where y is a $T \times 1$ vector of observable random variables, X is a nonstochastic $T \times K$ matrix of rank K, β is a $K \times 1$ vector of unknown parameters, and e is a $T \times 1$ vector of unobservable normally and independently distributed random variables having zero mean and finite variance σ^2. The ordinary least squares (OLS) and maximum likelihood estimator of β is $b = (X'X)^{-1}X'y \sim N(\beta, \sigma^2(X'X)^{-1})$, and the minimum variance unbiased estimator of σ^2 is $\hat{\sigma}^2 = (y - Xb)'(y - Xb)/(T - K)$, with $(T - K)\hat{\sigma}^2/\sigma^2 \sim \chi^2_{T-K}$ and independent of b.

Judge and Bock (pp. 240–42) proposed a family of Stein-rule estimators which dominates the MLE of β in the CNLRM under weighted quadratic loss with weight matrix W. Their estimator is a linear combination of the unrestricted and restricted MLEs and has the form

(2) $$\delta(b) = (1 - c/u)b + (c/u)b^*,$$

where $u = (Rb - r)'(RS^{-1}R')^{-1}(Rb - r)/J\hat{\sigma}^2 \sim F_{J,T-K,\lambda}$ is the conventional F-statistic used to test the hypothesis restrictions H_0: $R\beta = r$, $S = X'X$; R is a known $J \times K$ nonstochastic matrix of rank J; r is a $J \times 1$ vector of known constants; $b^* = b - S^{-1}R'(RS^{-1}R')^{-1}(Rb - r)$ is the restricted least squares estimator (RLS); $\lambda = (R\beta - r)'(RS^{-1}R')^{-1}(R\beta - r)/2\sigma^2$ is the noncentrality parameter; and $c = a(T - K)/J$. The estimator is minimax if the scalar a is chosen to lie within the interval $[0, a_{\max}]$, where

(3) $$a_{\max} = [2/(T - K + 2)] \cdot \{\lambda_L^{-1} \operatorname{tr}[(RS^{-1}R')^{-1}RS^{-1}WS^{-1}R'] - 2\},$$

and λ_L is the largest characteristic root of $[(RS^{-1}R')^{-1}RS^{-1}WS^{-1}R']$. The value of the constant a which minimizes quadratic risk is the interval's midpoint.

Lee C. Adkins is an assistant professor, Department of Economics, Oklahoma State University, and R. Carter Hill is a professor, Department of Economics, Louisiana State University.

The authors would like to thank Ron Mittelhammer for his careful reading of our original manuscript and for kindly suggesting a more elegant transformation which we used in the proof.

In many circumstances, the usual Stein estimator is dominated by a simple modification called the positive-part rule. The positive-part rule associated with (2) is denoted

$$(4)\qquad \delta^+(b) = \begin{bmatrix} b^* & \text{if } c > u \\ \delta(b) & \text{if } c \le u. \end{bmatrix}$$

Both Hill, Ziemer, and White; and Mittelhammer and Young correctly claim that the usual Stein rule is dominated by its positive part. Below, we will prove that their conjecture is true by showing that (4) dominates (2) under arbitrary quadratic loss using a simple analytical device which can be easily applied in many similar circumstances.

The Canonical Form

To show dominance of (2) by (4), the model and the hypothesis restrictions are written in their canonical forms. Let

$$(5)\qquad y = X\beta + e = XPP^{-1}\beta = Z\theta + e,$$

where $Z = XP$, $\theta = P^{-1}\beta$, and P is such that $P'X'XP = I$. Under the same transformation the restrictions $R\beta = r$ become $RPP^{-1}\beta = H_1\theta = r$. The rank of H_1 is J; therefore, there exists a nonsingular matrix, C, such that $CH_1 = [I_J\ 0]$; hence the restrictions can be written $CH_1\theta = Cr = H\theta = h$, where $H = CH_1\theta$ and $h = Cr$. The model is now $y = Z\theta + e$ subject to the simple equality restrictions $H\theta = [I_J\ 0]\theta = \theta_J = h$. The least squares estimator, restricted least squares estimator, and test statistic are $\hat{\theta} = Z'y \sim N(\theta, \sigma^2 I_K)$, $\theta^{*\prime} = (h', \hat{\theta}'_{K-J})$, and $u = (\hat{\theta}_J - h)'(\hat{\theta}_J - h)/J\hat{\sigma}^2$, respectively, where $\hat{\theta}_{K-J} = [0\ I_{K-J}]\hat{\theta}$ and $\hat{\theta}_J = [I_J\ 0]\hat{\theta}$.

For the problem at hand, the analytical advantages of this canonical form are substantial. The regression model subject to linear constraints has been transformed into the problem of estimating the mean of a multivariate normal distribution subject to simple equality restrictions $\theta_J = h$. It is a simple matter to derive the desired result in this context.

Result

The goal is to prove that (2) is dominated by the positive-part Stein rule given in (4). To obtain this result, we use the transformation described in the previous section along with a known result from the literature on Stein estimation.

Judge and Bock (pp. 245–48) prove that b_g^+ dominates b_g under arbitrary quadratic loss functions where

$$(6)\qquad b_g = [1 - c/u]b + (c/u)b_0,$$

$$(7)\qquad b_g^+ = \begin{bmatrix} b_0 & \text{if } c > u \\ b_g & \text{if } c \le u, \end{bmatrix}$$

$J = K$, and b_0 is a $K \times 1$ vector of known constants.

The Stein estimator (2) defined in terms of the transformed parameter space is

$$(8)\qquad \delta(\hat{\theta}) = [1 - (c/u)]\hat{\theta} + (c/u)\theta^*, \text{ or}$$

(9)

$$\delta(\hat{\theta}) = \begin{bmatrix} [1 - (c/u)\hat{\theta}_J + (c/u)h \\ \hat{\theta}_{K-J} \end{bmatrix} = \begin{bmatrix} \delta(\hat{\theta}_J) \\ \hat{\theta}_{K-J} \end{bmatrix}.$$

Because $\hat{\theta}_J$ is statistically independent of $\hat{\theta}_{K-J}$ and $E[\hat{\theta}_{K-J}] = \theta_{K-J}$, the quadratic risk of using $\delta(\hat{\theta})$ to estimate θ is

$$(10)\qquad R(\delta, \theta) = R(\delta(\hat{\theta}_J), \theta_J) + R(\hat{\theta}_{K-J}, \theta_{K-J}).$$

The risk of using least squares, $\hat{\theta}$, to estimate θ is

$$R(\hat{\theta}, \theta) = R(\hat{\theta}_J, \theta_J) + R(\hat{\theta}_{K-J}, \theta_{K-J}).$$

Thus, $\delta(\hat{\theta})$ dominates $\hat{\theta}$ if

$$R(\delta(\hat{\theta}_J), \theta_J) \le R(\hat{\theta}_J, \theta_J).$$

Similarly, the positive-part rule, $\delta^+(\hat{\theta})$, which is equal to θ^* if $(c/u) > 1$ and $\delta(\hat{\theta})$ otherwise, will dominate $\delta(\hat{\theta})$ if

$$R(\delta^+(\hat{\theta}_J), \theta_J) \le R(\delta(\hat{\theta}_J), \theta_J).$$

As given, $\delta(\hat{\theta}_J)$ is equivalent to (6) with $K = J$, and the Judge and Bock result can be applied to this expression directly.

In the context of the transformed model the quadratic loss function associated with use of an arbitrary estimator of θ, call it $\tilde{\theta}$, is

$$\begin{aligned} L(\tilde{\theta}, \theta, W^*) &= (\tilde{\theta} - \theta)'W^*(\tilde{\theta} - \theta) \\ &= (\tilde{\beta} - \beta)'P^{-1\prime}W^*P^{-1}(\tilde{\beta} - \beta). \end{aligned}$$

Squared error loss in the θ-space is equivalent to mean square error of prediction loss in the original β parameter space, i.e., $L(\tilde{\theta}, \theta, I_J) = L(\tilde{\beta}, \beta, X'X)$. For squared error loss in the β-space, let $W^* = P'P$. The constant $a_{\max}$ in the transformed model is obtained by substituting $R = [I_J\ 0]$, $S = I$, and $W = W^*$ into (3) and the Stein-rule or positive-part Stein-rule estimator is minimax if the number of restrictions (J) is strictly greater than two.

The mean, covariance, and risk of the RLS Stein rule and its positive part may be obtained similarly using existing results for (6) and (7) in conjunction with the canonical form. The usefulness of these results is limited in practice because they depend on the unknown parameters, β and σ^2. Replacing the unknown parameters in the moment expressions with consistent estimators like the unrestricted MLEs or Stein rules yields statistics and interval estimators with unknown sampling distributions. Though biased, the Stein rule (2) has lower risk than the unrestricted MLE, and the positive-part rule (4) has lower risk than the usual Stein rule; these are sufficient reasons to use the positive-part rule for point estimation in applications. Work is under way on procedures to evaluate the small-sample precision of (2) and (4) and on interval estimation techniques based on the Stein rules. See, for example, Adkins; Adkins and Hill; and Ullah, Carter, and Srivastava.

Discussion

The positive-part rule takes a convex combination of the unrestricted and restricted MLEs; geometrically, this means that (4) lies between b and b^*. The positive-part rule is intuitively appealing because it draws, or "shrinks," the unrestricted estimates toward, but not past, the restricted estimates. The usual Stein estimator (2) is less attractive because it changes the sign of the unrestricted MLEs whenever the value of the test statistic, u, is smaller than the constant, c.

The positive-part Stein rule can be used whenever one has uncertain nonsample information involving three or more linear parameter restrictions. These situations are common in agricultural economics and a wide range of potential applications can be found. Consider the following. First, one may have panel data consisting of multiple observations on several cross-sectional units and suspect that the dependent variable responds similarly to changes in the exogenous variables, X, across units. The (uncertain) equality of coefficients across units can be represented by a set of linear parameter restrictions. Second, Almon polynomial distributed lag models require one to choose lag length and polynomial degree which impose linear restrictions on coefficients of the distributed lag. These exact restrictions on the parameters are only approximately true at best. Third, principal components regression is sometimes recommended for models estimated using poorly conditioned data (i.e., in the context of near multicollinearity). The deletion of principal components from the model imposes exact, sample specific, linear constraints on the model's parameters which are often difficult to interpret and evaluate. Once again, these restrictions are only approximately true and the positive-part RLS Stein rule can be used to obtain a risk improvement.

Additional examples can be found in production theory in which under certain circumstances production functions are homothetic in the inputs. Depending on the functional form used, homotheticity often implies restrictions of the form $R\beta = r$. Similarly, in demand equations Engle aggregation or homotheticity restrictions can often be expressed in the $R\beta = r$ form and used with the linearized equation.

Another possibility to consider when faced with uncertain linear parameter restrictions is to assume that the information they embody is correct and to impose the restrictions on the model's parameters using the RLS estimator. Unfortunately, the risk of the RLS estimator is unbounded and increases with the value of the noncentrality parameter, λ, which measures the specification error implicit in the restrictions. A common econometric practice is to treat the restrictions as a hypothesis and employ them if they cannot be rejected by conventional tests. The resulting pretest estimator, which selects either the MLE or RLS estimators based on the outcome of the hypothesis test of the restrictions $R\beta = r$, has greater risk than the MLE (or the Stein rules) over large regions of the parameter space. The positive-part Stein rule, which combines the MLE and RMLE, has uniformly lower risk than the MLE under arbitrary quadratic loss and may be used in any of these situations.

In the presence of uncertain nonsample information an appealing alternative to pretesting is to adopt a Bayesian procedure which uses a prior distribution on the parameters (or the sampling "equivalent," mixed estimation). The Stein rules have been shown to be empirical Bayes rules (Judge, Hill, and Bock); consequently, they are formal as well as intuitive alternatives to pretesting which have desirable statistical properties.

Concluding Comments

In general, most researchers should use positive-part Stein rules rather than the usual ones

because they are known to have smaller quadratic risk under general circumstances. In this article, we have shown that a general family of Stein rules mentioned in Judge and Bock, extended by Mittelhammer and Young, and generalized by Mittelhammer (1984, 1985) is in fact dominated by the positive-part rule which sets the Stein estimator equal to the RLS estimator whenever the shrinkage factor $(c/u) > 1$. In addition, some possible uses for the positive-part rule in economic and agricultural economic research have been discussed.

The Effects of Food Stamps on Food Expenditures: Comment

Phillip S. Kott

In a recent issue of the *Journal*, Devaney and Fraker compared weighted and unweighted regression analyses performed on data from a complex sample the 1977–78 Nationwide Food Consumption Survey, (NFCS) low-income sample. The authors had some difficulty interpreting their findings. Perhaps this comment can be of some assistance.

Suppose an analyst wants to perform a regression with sample survey data. Suppose further that the sample has been drawn with unequal probabilities of selection reflecting a design variable which is not incorporated into the analyst's regression model.

Holt, Smith, and Winter have noted that probability weighting appears to control for the bias in ordinary least squares when both the dependent and independent variables of the regression are correlated with the design variable. This suggests that when weighted and unweighted regression yields meaningfully different values for a particular coefficient (in Devaney and Fraker's case, MFC_f), the model may be underspecified. That is to say, a more complete model would include some function (or functions) of the design variable.

Adding dummies for stratification variables in an unweighted analysis (the authors consider such dummies in a weighted context) may sometimes address the underspecification problem, but not always. One possibility in the authors' example is that a separate MPC_f for households in low-poverty areas is needed.

It should be noted that the rationale for weighting given above is much different from that in generalized least squares (GLS) theory. As a result, GLS-based estimated standard errors—like those derived using SAS and most conventional regression programs—are meaningless in this context.

There are regression packages designed specifically for use with data from complex samples. Two that I like are PC CARP (Fuller et al.) and SURREGR (Holt).

The Effects of Food Stamps on Food Expenditures: Reply

Barbara Devaney and Thomas Fraker

In his comment on our recent article in *AJAE* (Devaney and Fraker), Kott notes that GLS-based standard errors are biased when generated by standard regression packages from complex sample survey data. While it is true that the standard errors of the estimates of the marginal propensity to consume food (MPC_f) out of food stamp benefits that are given in tables 2 and 3 of our article are incorrect, there remains statistically sound evidence in support of the central thesis of our article: the estimates of the MPC_f out of food stamps that are generated by conventionally specified models of food expenditures on the basis of data from the Nationwide Food Consumption Survey (NFCS) are highly sensitive to whether the sample weights are used in the estimation process.

Let us assume that Y is the dependent variable in a regression equation, X is a row vector of explanatory variables, W is a variable which holds the values of the sample weights associated the units of observation in the survey data file, and Z is a row vector of the sample-weighted explanatory variables ($Z = X'W$). DuMouchel and Duncan observe that the t-statistics associated with the coefficients on Z in an unweighted regression of Y on X and Z are good approximations to the t-statistics for the difference between corresponding coefficients in weighted and unweighted regressions of Y on X. We used that relationship to test whether there is a difference between the weighted and unweighted estimates of the MPC_f out of food stamps that are generated by our food expenditure model. Our results show that the weighted and unweighted estimates of this parameter are different at the 7% level of statistical significance. Furthermore, the difference between the two estimates is very large from the perspective of policy makers who, on the basis of such estimates, must draw conclusions regarding the efficiency of the food stamps in augmenting food expenditures.

We agree with Kott's observation that the large difference between the weighted and unweighted estimates of the MPC_f out of food stamps is symptomatic of an underspecified model; however, we wish to point out that our model is very similar to those used in previous studies of the effects of food stamps on food expenditures. Indeed, our discovery that the variation in the estimates of the MPC_f found in previous studies was due primarily to the use or nonuse of sample weights, rather than to more complex statistical issues, suggested model specification bias and prompted us to alert other researchers to this finding. As reported in our article, we attempted to improve the specification of the model by adding dummy variables for NFCS sample stratifiers. We used both weighted and unweighted data to estimate the expanded model; and, following Method A on page 539 of DuMouchel and Duncan, we conducted an F-test for equality between the two vectors of regression coefficients. On the basis of that test, we were unable to reject the null hypothesis of equality. Thus, the test indicates that the expanded model is not underspecified; nevertheless, the difference between the weighted and unweighted estimates of the MPC_f that are generated by that model is nearly as large as the difference obtained using the base model. The importance of this finding is that researchers cannot be complacent regarding the choice between weighted versus unweighted data simply because their models satisfy this test for misspecification.

Kott speculates that both the base model and the expanded model may be underspecified in that they do not allow for the possibility that the MPC_f out of food stamps may be different in low-poverty areas than in medium- or high-poverty areas. Support for his hypothesis is provided by our own preliminary analysis, which indicates that the MPC_f may in fact be much larger for food stamp recipients who reside in low-poverty areas than for other recipients. Additional research on this aspect of the model specification problem is needed.

In conclusion, we encourage all researchers to note carefully Kott's warning regarding the limitations of standard regression packages when applied to sample survey data. We also believe that his suggestion that the MPC_f out of food stamps may vary across poverty strata warrants further investigation. However, neither of these points detracts from the validity of the principal conclusions that can be drawn from our analysis: (*a*) estimates of the MPC_f out of food stamps that are generated by applying a conventionally specified model of household food expenditures to data from the NFCS are very sensitive to whether or not the sample weights are used; (*b*) much of the variation in published estimates of the MPC_f may be due to the use or lack of use of the NFCS sample weights rather than to more complex modeling and statistical issues.

Expenditure Constraints and Profit Maximization in U.S. Agriculture: Comment

Barry T. Coyle

In a recent (1986) paper, Lee and Chambers (hereafter LC) developed a model of expenditure constrained profit maximization. A single constraint was specified for the purchase of all variable inputs, and the competing hypotheses of unconstrained and constrained profit maximization were tested in terms of corresponding nonnested homogeneity conditions. LC proceeded in terms of a profit function with prices normalized on the predetermined level of expenditure.

In this comment, an alternative formulation of the expenditure constrained profit function is presented. The advantages over the LC approach are twofold. First, the nested relationship between the hypotheses of unconstrained and expenditure-constrained profit maximization is apparent. This permits simple nested tests of the full consequences of the alternative models. Second, this alternative formulation can readily incorporate situations whereby expenditure constraints are input specific. For example, farmers typically negotiate separate loans for the purchases of operating inputs and capital inputs. Different expenditure constraints may have different impacts on incomes. Furthermore, input-specific foreign exchange constraints on production are easily incorporated into this formulation of the expenditure-constrained firm. The importance of modeling the effects of foreign exchange constraints on production in developing countries is well recognized (Dervis, de Melo, and Robinson); however, to date, econometric models of producer behavior have not incorporated the impacts of foreign exchange constraints in a consistent manner (e.g., Kohli, Diewert and Morrison).

Theoretical Background

We begin with a formulation of the expenditure constrained profit function that is similar to LC:

$$(1) \qquad \pi^o(p^o, w^o, E) = \max_{(x,y)\epsilon T} p^o y - w^o x \quad \text{s.t. } w^o x \leq E,$$

where $y = (y^1, \ldots, y^M)$ is a vector of outputs, $x = (x^1, \ldots, x^N)$ is a vector of variable inputs, p^o is an M-dimensional vector of output prices, w^o is an N-dimensional vector of variable input prices, T is the set of feasible (x, y), and E is the predetermined level of expenditure which the farmer cannot exceed in purchasing variable inputs. LC also assume a vector q of fixed inputs; but, in order to simplify notation, we will omit q from the list of arguments of the profit function.[1] LC observe that equilibrium input and output levels $x^* = x(p^o, w^o, E)$, $y^* = y(p^o, w^o, E)$ solving (1) are homogenous of degree zero in (p^o, w^o, E) and (if the expenditure constraint is binding) homogenous of degree zero in the vector of output prices p^o. This implies the following homogeneity restrictions on the profit function:

$$(2) \qquad \pi^o(\lambda p^o, \lambda w^o, \lambda E) = \lambda p^o y^* - \lambda w^o x^* = \lambda \pi^o(p^o, w^o, E),$$

and, if $w^o x^* = E$,

$$(3) \qquad \pi^o(\lambda p^o, w^o, E) = \lambda p^o y^* - w^o x^* = \lambda \pi^o(p^o, w^o, E) + (\lambda - 1)E,$$

where (x^*, y^*) denotes an equilibrium (x, y) at initial parameter levels (p^o, w^o, E), and λ is any positive scalar.

LC further impose the normalization $p = p^o/E$, $w = w^o/E$ and $\pi^o/E = \pi^o(p, w, 1)$ implied by (2). Analogous normalizations have been commonly employed in the specification of indirect utility functions, where there is little concern with testing hypotheses about the marginal utility of income (Christensen, Jorgenson, and Lau). However, in the producer case, this normalization obscures the nested relation between the hypotheses of constrained and unconstrained profit maximization.

In contrast we develop further properties of the profit function (1) without imposing this normalization. Expressing (1) in Lagrange form,

Barry T. Coyle is an assistant professor in the Department of Agricultural Economics and Farm Management, University of Manitoba.

The author thanks Robert Chambers, Hyunok Lee, Scott Jeffrey, and Thomas Hertel for helpful comments.

[1] Weaker restrictions on technology are required in the case of an expenditure-constrained profit function than in the case of an unconstrained profit function. In particular, increasing returns to scale can be consistent with an expenditure-constrained equilibrium. By combining standard proofs of existence for a cost function (McFadden) and of equivalence of solutions to utility maximization and expenditure minimization problems (e.g., Varian), we can show that existence and continuity of the profit function are implied by the following assumptions:

$$V(y) = \{x: y^1 = f(y^2, \ldots, y^M, x); (x, y) \geq 0\}$$

is closed and nonempty; $f(\cdot)$ is continuous; and $P = \{(p^o, w^o, E)\}$ is compact. Differentiability of $\pi^o(p^o, w^o, E)$ can be established as in Blackorby and Diewert.

$$(4)\quad \pi^o(p^o, w^o, E) = \max_{\gamma,(x,y)\epsilon T} p^o y - w^o x + \gamma(E - w^o x),$$

and applying the envelope theorem yields

$$\partial\pi^o(p^o, w^o, E)/\partial p^{jo} = y^{j*} \qquad j = 1, \ldots, M;$$

$$\partial\pi^o(p^o, w^o, E)/\partial w^{io} = -x^{i*} - \gamma^* x^{i*}, \qquad i = 1, \ldots, N;$$

where $\gamma^* = \partial\pi^o(p^o, w^o, E)/\partial E$ (Takayama, pp. 137–39). Thus

$$(5)\quad y^j(p^o, w^o, E) = \partial\pi^o(p^o, w^o, E)/\partial p^{jo} \qquad j = 1, \ldots, M;$$

$$(6)\quad x^i(p^o, w^o, E) = \frac{-\partial\pi^o(p^o, w^o, E)/\partial w^{io}}{1 + \partial\pi^o(p^o, w^o, E)/\partial E} \qquad i = 1, \ldots, N.$$

These equations can be viewed as a generalization of Hotelling's lemma and Roy's identity. If the shadow price of the budget constraint, i.e., $\partial\pi^o(p^o, w^o, E)/\partial E$, is equal to zero, then these equations reduce to Hotelling's lemma. This occurs if the budget E is at the profit-maximizing level of expenditure.

The derivation of further restrictions on the Hessian matrix of second derivatives of the profit function is more complex. Suppose that the expenditure constraint $w^o x \leq E$ is satisfied as an equality and the profit function is twice differentiable. Define the gain function

$$(7)\quad g(p^o, w^o, x, y) = \pi^o(p^o, w^o, E(w^o, x)) - [p^o y - w^o x] \qquad (x, y)\epsilon T,$$

where $E(w^o, x) = w^o x$. It can be shown that $g(p^o, w^o, x, y)$ takes the minimum value of 0 when $(p^o, w^o, x, y) = (p^o, w^o, x^*, y^*)$ where $x^* = x(p^o, w^o, E)$ and $y^* = y(p^o, w^o, E)$ solve (1).[2] In turn, the $M + N$ dimensional matrix of second derivatives $g_{p^o w^o}(p^o, w^o, x^*, y^*)$ is symmetric positive semidefinite, i.e.,

$$(8)\quad d' g_{p^o w^o}(\cdot) d \geq 0 \qquad \text{for all } d$$

[Hatta, lemma 2 and equation (17)]. Using (7) the elements of this matrix are evaluated as follows:

$$(9)\quad \partial^2 g(p^o, w^o, x^*, y^*)/\partial p^{io}\partial p^{jo} = \partial^2\pi^o(p^o, w^o, E)/\partial p^{io}\partial p^{jo} \qquad i, j = 1, \ldots, M$$

$$\partial^2 g(p^o, w^o, x^*, y^*)/\partial p^{jo}\partial w^{io} = \partial^2\pi^o(p^o, w^o, E)/\partial p^{jo}\partial w^{io} + x^{i*}\partial^2\pi^o(p^o, w^o, E)/\partial p^{jo}\partial E \qquad i = 1, \ldots, N; j = 1, \ldots M$$

$$\partial^2 g(p^o, w^o, x^*, y^*)/\partial w^{io}\partial w^{jo} = \partial^2\pi^o(p^o, w^o, E)/\partial w^{io}\partial w^{jo} + x^{j*}\partial^2\pi^o(p^o, w^o, E)/\partial w^{io}\partial E + x^{i*}\partial^2\pi^o(p^o, w^o, E)/\partial w^{jo}\partial E + x^{i*}x^{j*}\partial^2\pi^o(p^o, w^o, E)/\partial E^2 \qquad i, j = 1, \ldots, N.$$

Equations (5)–(6) suggest the following procedure for estimating a producer's output supply and factor demand equations when there is an exogenous expenditure constraint as in model (1). First, specify an appropriate flexible functional form for the producer's profit function $\pi^o(p^o, w^o, E)$. Second, differentiate this functional form with respect to prices p^o, w^o and budget E in order to obtain output supply and factor demand equations, as indicated in (5)–(6). Third, estimate this system of equations and test or check whether these equations satisfy the restrictions listed above. Imposing appropriate homogeneity and symmetry restrictions on the model will increase efficiency of the estimators.

A model of unconstrained profit maximization is easily embedded within this model of expenditure constrained profit maximization. The standard competitive profit maximization problem of the firm can be defined as

$$\pi^o(p^o, w^o) = \max_{(x,y)\epsilon T} p^o y - w^o x,$$

or, equivalently,

$$(10)\quad \pi^o(p^o, w^o) = \max_{E\geq o} \pi^o(p^o, w^o, E).$$

In other words, unconstrained profit maximization can be decomposed logically into two stages: first profits are maximized for given levels of expenditure E (problem 1); and then the level of expenditure E is chosen so as to maximize profits (problem 10). This two-stage procedure is equivalent to unconstrained profit maximization.

Thus, profit maximization when total expenditure E is unconstrained implies the same restrictions on $\pi^o(p^o, w^o, E)$ as indicated above plus the first- and second-order conditions for an interior solution to (10):

$$(11)\quad \partial\pi^o(p^o, w^o, E)/\partial E = 0$$

$$(12)\quad \partial^2\pi^o(p^o, w^o, E)/\partial E^2 \leq 0.$$

This characterization of the standard maximization problem in terms of the expenditure constrained profit function $\pi^o(p^o, w^o, E)$ leads to relatively simple procedures for testing the hypothesis that expenditure on inputs is unconstrained.[3]

The above analysis is easily generalized to characterize particular cases where expenditure constraints are input specific. For example, suppose that expenditures on inputs $x^B = (x^{1B}, \ldots, x^{NB})$ draw upon

[2] The envelope relations (5)–(6) can also be derived directly from this property of the gain function (7) (Hatta, theorem 5).

[3] The basic implication of this nested relation $\pi^o(p^o, w^o) = \max_E \pi^o(p^o, w^o, E)$ for testing the hypothesis of unconstrained profit maximization is not discussed in Lee and Chambers (1986) nor in the comments by Färe and Sawyer, Lee and Chambers (1988).

an exogenous budget or credit constraint E, whereas expenditures on other inputs $x^A = (x^{1A}, \ldots, x^{NA})$ are unconstrained. Alternatively, inputs x^B may be imports drawing upon the firm's ration of foreign exchange E. The corresponding profit function $\pi^o(p^o, w^o, E)$ is now defined as

$$\pi^o(p^o, w^o, E) = \max_{(x,y)\epsilon T} p^o y - w^{Ao}x^A - w^{Bo}x^B \quad \text{s.t. } w^{Bo}x^B \leq E.$$

Applying the envelope theorem to the corresponding Lagrange function, equations (5)–(6) are modified as follows:

$$y^k(p^o, w^o, E) = \partial\pi^o(p^o, w^o, E)/\partial p^{ko} \quad k = 1, \ldots, M$$

$$x^i(p^o, w^o, E) = -\partial\pi^o(p^o, w^o, E)/\partial w^{io} \quad i = 1A, \ldots, NA$$

$$x^j(p^o, w^o, E) = \frac{-\partial\pi^o(p^o, w^o, E)/\partial w^{jo}}{1 + \partial\pi^o(p^o, w^o, E)/\partial E} \quad j = 1B, \ldots, NB.$$

In order to derive restrictions on $\pi(\cdot)$ that are analogous to (8)–(9), define the gain function

$$h(p^o, w^o, x, y) = \pi^o(p^o, w^{Ao}, w^{Bo}, E(w^{Bo}, x^B)) - [p^o y - w^o x] \quad (x, y)\epsilon T,$$

where $E(w^{Bo}, x^B) = w^{Bo}x^B$. Then the Hessian matrix $h_{p^o w^o}(p^o, w^o, x^*, y^*)$ is symmetric positive semidefinite (Hatta), where derivatives are evaluated in a manner analogous to (9). The nested relations (10)–(12) between constrained and unconstrained profit maximizaton models still apply in this case. The analysis can also be generalized in an obvious manner to cases of multiple expenditure constraints $w^{Ao}x^A \leq E^A$, $w^{Bo}x^B \leq E^B$.[4]

Functional Forms

In choosing appropriate functional forms for empirical models of expenditure constrained producer behavior, the constrained profit function $\pi^o(p^o, w^o, E)$ as in (1) must satisfy both homogeneity conditions (2) and (3).

In the case of a single output, substitution of $\lambda = 1/p^o$ into (3) yields the following restriction on functional forms for $\pi^o(p^o, w^o, E)$:[5]

$$\pi^o(p^o, w^o, E) = p^o\pi^o(1, w^o, E) + (p^o - 1)E = p^o\phi(w^o, E) + (p^o - 1)E.$$

The additional homogeneity condition (2) implies that the profit function can be expressed equivalently in the following normalized form:

$$\pi^* = \pi^*(p^*, w^*, E^*),$$

where $\pi^* \equiv \pi^o/w^{1o}$, $p^* \equiv p^o/w^{1o}$, $w^* \equiv (w^{2o}/w^{1o}, \ldots, w^{No}/w^{1o})$, $E^* \equiv E/w^{1o}$. Imposing homogeneity condition (3) on this normalized profit function,

$$\begin{aligned}\pi^*(p^*, w^*, E^*) &= \pi^o(p^*, 1, w^*, E^*) && \text{by (2)}\\ &= p^*\pi^o(1, 1, w^*, E^*) + (p^* - 1)E^* && \text{by (3)}\\ &= p^*\phi^*(w^*, E^*) + (p^* - 1)E^*.\end{aligned}$$

In the case of multiple outputs, the following class of functional forms for $\pi^o(p^o, w^o, E)$ satisfy homogeneity conditions (2) and (3):

$$\pi^*(p^*, w^*, E^*) = h(p^*)\phi^*(w^*, E^*) + [h(p^*) - 1]E^*$$

where $h(p^*)$ is linear homogenous in p^*.

The following variation on a normalized quadratic profit function with a single output satisfies these conditions:

$$\pi^* = p^*\left(a_o + \sum_{i=2}^{N} a_i w^{*i} + a_e E^* + \frac{1}{2}\sum_{i=2}^{N}\sum_{j=2}^{N} a_{ij}w^{*i}w^{*j} + \sum_{i=2}^{N} a_{ie}w^{*i}E^* + a_{ee}E^{*2}\right) + (p^* - 1)E^*.$$

This implies the output supply and factor demand equations, using (5)–(6),

$$\begin{aligned}y &= \phi^*(w^*, E^*) + E^*\\ &= a_o + \Sigma_i a_i w^{*i} + (a_e + 1)E^* + 1/2\Sigma_i\Sigma_j a_{ij}w^{*i}w^{*j} + \Sigma_i a_{ie}w^{*i}E^* + 1/2a_{ee}E^{*2}\end{aligned}$$

$$\begin{aligned}-x^i &= \frac{\partial\phi^*(w^*, E^*)/\partial w^{*i}}{1 + \partial\phi^*(w^*, E^*)/\partial E^*} \quad i = 2, \ldots, N.\\ &= \frac{a_i + \Sigma_j a_{ij}w^{*j} + a_{ie}E^*}{1 + a_e + \Sigma_i a_{ie}w^{*i} + a_{ee}E^*}\end{aligned}$$

Alternatively consider the following normalized translog profit function:

$$\log \pi^{**} = a_o + \sum_{i=1}^{N} a_i \log w^{**i} + a_e \log E^{**} + \frac{1}{2}\sum_{i=1}^{N}\sum_{j=1}^{N} a_{ij}\log w^{**i}\log w^{**j} + \sum_{i=1}^{N} a_{ie}\log w^{**i}\log E^{**} + \frac{1}{2}a_{ee}(\log E^{**})^2$$

[4] Lee and Chambers (1988) also note that the predetermined expenditure may be only a fraction (λ) of total expenditure. They suggest that their model be modified by treating E/λ rather than total observed expenditure E as exogenous expenditure, where λ is a parameter to be estimated. However, this ad hoc specification is inappropriate whenever the predetermined expenditure is associated with a specific subset of purchased inputs.

[5] Note that in the case ot a single output ($M = 1$) and $w^o x \leq E$ binding, expenditure-constrained maximization of profit reduces to expenditure-constrained maximization of output.

where $\pi^{**} \equiv \pi^o/p^o$, $w^{**} \equiv w^o/p^o$, $E^{**} \equiv E/p^o$. This satisfies both homogeneity conditions (2)–(3). Equations (6) imply the factor demand equations

$$-sx^j = \frac{a_j + \sum_{i=1}^{N} a_{ij} \log w^{**i} + a_{je} \log E^{**}}{1 + \left(a_e + \sum_{i=1}^{N} a_{ie} \log w^{**i} + a_{ee} \log E^{**}\right) \pi^o/E} \quad j = 1, \ldots, N,$$

where $sx^j \equiv w^{jo}x^j/\pi^o$.

Hypothesis Testing

This section illustrates two simple procedures for testing the hypothesis that expenditure on inputs is at profit-maximizing levels. The null hypothesis H_o is that expenditure E solves the unconstrained profit maximization problem $\max_{E \geq o} \pi^o(p^o, w^o, E)$, and the alternative hypothesis H_1 is that the firm is at an expenditure-constrained, profit-maximizing equilibrium. Given the nested relation between these hypotheses, an obvious approach is to test the first-order condition (11) for unconstrained profit maximization and then to check or test for the second-order condition (12) within the context of a particular specification for $\pi^o(p^o, w^o, E^o)$.

A t-test of the first-order condition (11) for unconstrained profit maximization can be formulated as follows from estimates of the system of output supply and input demand equations (5)–(6). Assuming normally distributed disturbances the statistic

$$(13) \qquad t_o \equiv \pi_E^*/V(\pi_E^*)^{1/2}$$

has a t-distribution under H_o, where π_E^* denotes the estimate of the shadow price. Linear approximations to the variance of the estimates π_E^* can be calculated essentially as in Kulatilaka. Suppose that the profit function $\pi^o(p^o, w^o, E)$ has a functional form of the type $\pi^o = f(p^o, w^o, E, \beta) + \epsilon$, as in the generalized Leontief or normalized quadratic case. Then $\pi_E^* = \partial f(p^o, w^o, E, \beta^*)/\partial E$, and in turn the variance of π_E^* can be approximated linearly as

$$(14) \qquad V(\pi_E^*) = \pi_{E\beta}^* V(\beta^*) \pi_{E\beta}^*,$$

where $\pi_{E\beta} \equiv \partial^2 f/\partial E \partial \beta$. Thus, given a normalized quadratic or generalized Leontief functional form for $\pi^o(p^o, w^o, E)$, the t-statistic t_o can be approximated directly from the estimates of output supply and factor demand equations (5)–(6). In the translog case, calculation of t_o would require direct estimation of the profit equation (Kulatilaka).

Alternatively a Hausman specification test can often be constructed for the first-order condition $\partial \pi^o(p^o, w^o, E)/\partial E = 0$ (11). Let $\hat{\beta}_1$ denote estimates of the coefficients of equations (5)–(6) obtained by three-stage least squares estimation of (5)–(6) alone, and let $\hat{\beta}_o$ denote estimates of the same coefficients obtained by three-stage least squares estimation of (5)–(6) plus (11). At the industry level, output prices p^o as well as expenditure E generally should be treated as endogenous. Then under the hypothesis H_o of unconstrained profit maximization, the following statistic is distributed asymptotically as chi-square:

$$(15) \qquad m \equiv (\hat{\beta}_1 - \hat{\beta}_o)\hat{V}^{-1}(\hat{\beta}_1 - \hat{\beta}_o),$$

where the variance-covariance matrix $\hat{V}$ is calculated as $\hat{V} = \hat{V}(\hat{\beta}_1) - \hat{V}(\hat{\beta}_o)$ (Hausman, Schankerman and Nadiri).

International Financial Markets and Agricultural Adjustment in North America (G. Edward Schuh, Humphrey Institute of Public Affairs, presiding)

Exchange Rate Effects on Inputs and Outputs in Canadian Agriculture

Colin A. Carter, Richard S. Gray, and W. H. Furtan

In a seminal piece of work, Schuh demonstrates, using a single market partial equilibrium model, that exchange rates have a large impact on the price received for farm products. He argued that the overvalued U.S. dollar reduced export demand and the domestic price of U.S. grains. Since then, much of the work on estimating the impact of exchange rate changes on agriculture has implicitly assumed that inputs to the agricultural sector come from the nontraded sector.[1] We argue this assumption can result in an error in the estimation of the effects of exchange rates. In an examination of the pass-through of changes in the $US/CDN exchange rate, we find the data from 1975 to 1989 are consistent with the hypothesis of a complete pass-through of exchange rates for many important variable inputs to Canadian agricultural production. This analysis indicates that, while exchange rates may have had significant impacts on the return to fixed factors and farm income, they have had little effect on grain production. In the case of livestock feeding in Canada, exchange rate devaluations may actually reduce production and reduce the return to fixed factors because inputs (especially grain) are more tradeable than outputs. Finally, we examine the potential welfare impact on nontradeables (such as land) from changes in the exchange rate.

Theoretical Model

The framework in which to analyze the aggregate effects of exchange rates has been developed by Salter. In the Salter model goods in the economy are aggregated into two sectors, tradeable and nontradeable. The economy can produce different combinations of the two types of goods, given available technology and resources. The production possibilities can be represented by a concave hull *AB* as shown in figure 1. The economy also has a defined set of preferences over these goods which can be represented by a set of convex indifference curves, $u_1, u_2, \ldots, u_n$. The tangent of the indifference curve and the production possibility curve, i.e., point *C*, represents the equilibrium in the economy where the balance of trade requirement is met and where there is zero excess demand for nontradeables. The real exchange rate (or the ratio at which these conditions are met) is represented by the slope of line *RR*′. A change in exchange rates moves this point of tangency. A devaluation in the exchange rates means an increase in the nominal and real prices in the tradeable sector. This increases production in the tradeable sector.

Within the parameters derived in this general equilibrium setting it is possible to examine the effects of exchange rate changes on small specific industries using a simple model of the firm and partial equilibrium analysis. First, we assume exchange rates are set exogenously to the sector.[2] Second, we assume the two countries

Colin A. Carter is a professor of agricultural economics, University of California, Davis. Richard E. Gray is a Ph.D. candidate, Department of Agricultural and Resource Economics, University of California, Berkeley. W. H. Furtan is a professor of agricultural economics, University of Saskatchewan.

This is Giannini Foundation Paper No. 929.

[1] Recognizing the importance of traded inputs, Carter and Hamilton estimate the impact a change in the Canada–U.S. exchange rate would have on the price of farm inputs used in Canadian wheat production.

[2] Rausser et al. argue the assumption of exogenously determined exchange rates is inappropriate for agriculture. This would rule out the use of partial equilibrium analysis. However, because agriculture in the United States and Canada is a very small part of the overall economy and accounts for a small part of total exports, the exogeneity assumption is considered appropriate. In addition, we are examining subsectors (e.g., wheat, livestock) within agriculture, and the exchange rate is truly exogenous to these subsectors.

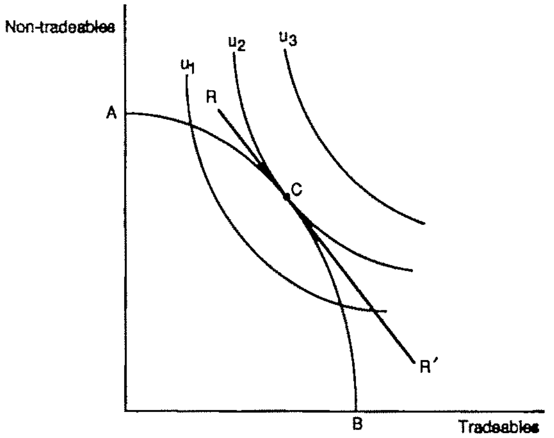

Figure 1. Real exchange rates in the Salter general equilibrium model

are both large countries (i.e., both countries impact on world prices). Lindert develops a similar model for the small country case. Finally, we do not incorporate any imperfect competition arguments.[3]

In figure 2, Country 1 (Canada) is the exporting region, while Country 2 (United States) is the importing region. The excess supply from Country 1 and excess demand from Country 2 are shown in panel b of figure 2—the international market. Initially the exchange rate between the two countries is par (shown in panel c of fig. 2 as the 45° line OA). The volume of trade is initially equal to OQ (shown in panel b).

The excess supply and demand condition for commodity i can be written

$$D_i = g(P_i) \tag{1}$$

$$S_i = \mathrm{h}(\delta_i, r) \tag{2}$$

$$D_i = S_i, \tag{3}$$

where r is a vector of input prices, P_i and δ_i are the output prices in each country's domestic currency.

If e is the exchange rate (units of the exporter's currency per unit of the importer's currency), the law of one price states: $e{*}P_i = \delta_i$. For a more complete analysis of the equilibrium conditions see Chambers and Just. If a change in e causes the value of the importer's currency to appreciate such that OA rotates to OA' in figure 2(c), the excess demand curve rotates upward from ED to ED' in figure 2(b). This results in an expansion of trade by an amount equal to QQ_1 as well as an increase in the exporter's price by an amount equal to PP_1. Chambers and Just argue that if the exchange rate also changes the price of substitute goods this would reduce the effect of the exchange rate on the demand for good i.

Inputs may also be traded. If Country 1 is assumed to import at least some inputs from Country 2, the excess supply curve will rotate from ES to ES' in figure 2(b) with an appreciation of Country 2's currency (e.g., Canada imports agriculture inputs from the United States, such as machinery and agriculture chemicals). This increased cost of production in the exporting country (Country 1) reduces the volume traded between the two countries and raises the commodity price from OP_1 to OP_2. The magnitude of the net change in trade and price depends upon the elasticity of excess demand and

[3] Others (Giovannini and Feenstra) have explored exchange rate pass-through using imperfect competition models.

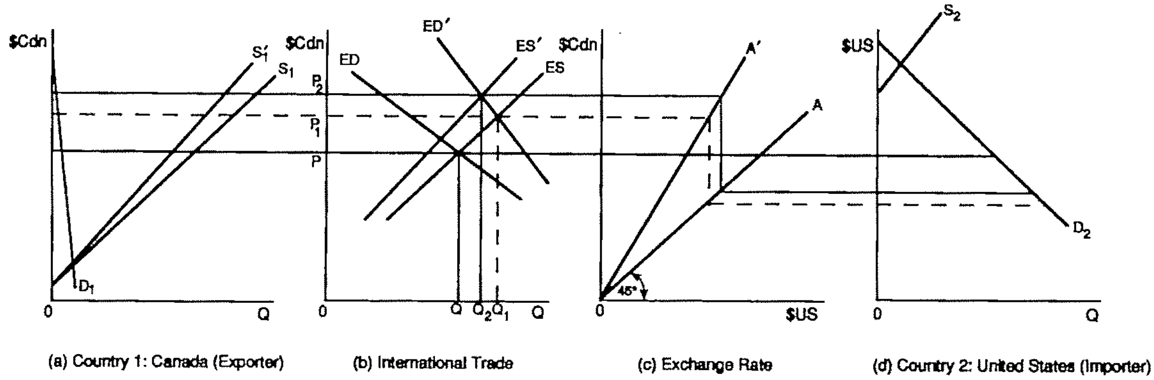

Figure 2. Exchange rate pass-through in a partial equilibrium model

supply and the proportion of traded inputs in total cost of production.

The welfare impacts in the exporting country may be large even though there is little change in the volume traded. As shown in figure 3, because of the increased cost of production (due to traded inputs), there may be little increase in commodity trade but a substantial gain in welfare in the exporting country. This results from an increase in the rent earned by those inputs which are not traded but used in the production of the exported commodity. In the case of agriculture, such inputs include land and labor. Producers in the exporting country gain area P_3deP_1 (fig. 3) and lose area *eba*, which may/may not represent a welfare increase depending upon the elasticity of the excess supply curve. The less elastic the excess supply, the greater the likelihood of producer gains. The volume traded may be unrelated to the welfare gains for the exporting country. Much of the analysis on exchange rates and agricultural trade between developed countries has focused on the volume of trade and price, ignoring these important welfare impacts.

Estimating Exchange Rate Pass-Through

An examination of exchange rate pass-through is one way of measuring whether or not inputs and outputs are tradeable. The estimation of the exchange rate pass-through has focused on the law of one price. The law of one price states that, in the presence of market arbitrage, the price of the same good in two locations will differ

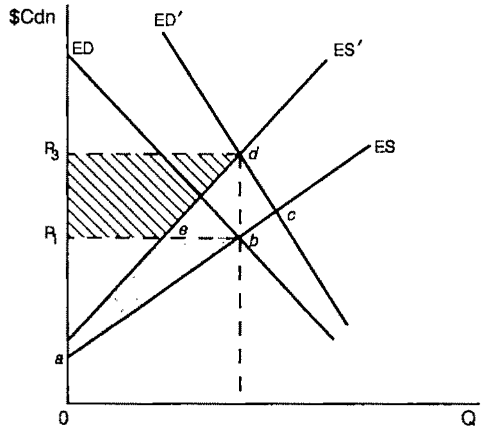

Figure 3. Welfare effects of an exchange rate depreciation

only by the transaction cost in moving the commodity from one market to another.

The law of one price is derived from the no arbitrage condition. The no arbitrage condition be written as

$$P_t^1 = P_t^2 e + \Phi, \tag{4a}$$

where P_t^1 and P_t^2 are the commodity prices, Φ is equal to the anticipated transaction cost in moving from market 2 to market 1, and e is the exchange rate.[4] Alternatively, equation (4a) can be written as

$$P_t^1/P_t^2 = e \cdot \Phi \tag{4b}$$

when Φ is proportional to the value of the products. The transaction cost Φ is made up factors including the direction of trade flows, transportation, storage, interest, tariffs, and a normal rate of return to the arbitrager. Because data on transaction costs are difficult to obtain, most studies ignore these costs and estimate the following equation:

$$P_t^1/P_t^2 = e \cdot \Phi + \epsilon. \tag{5}$$

Ardeni suggests that this type of behavior is consistent with the law of one price, which states that, in the long run, commodity prices in two countries must be the same. In his analysis he finds the law of one price fails as a long-run relationship, and deviations from the pattern are permanent.

This rejection of the law of one price in the long run may result from the omission of transaction costs in the analysis. An implicit assumption in equation (5) is that transaction costs were stationary and varied about some underlying mean over time. However, one would expect that, in the long run, transaction costs will change in a permanent fashion. Changes in income, tastes, technologies, and trade flows all tend to be permanent phenomena. Given the permanent nature of the shocks which effect transaction costs, it may be reasonable to assume that transaction costs vary over time in the following fashion:

$$\Phi_t = \Phi_{t-1}(1 + \gamma), \tag{6}$$

where γ is a random variable with mean μ and some variance σ.

If these innovations arrive in a continuous

[4] This pure relationship holds for a trade flow in a specific direction. If the trade flow direction changes, the sign of Φ would also change. There will also be a range of relative prices in which no trade will take place.

fashion, then by the central limit theorem the proportional change in transaction costs is lognormally distributed. Given this specification for the stochastic process, then first differencing equation (5) yields the estimating equations:

$$(7)\quad \ln\frac{P_t^1}{P_t^2} - \ln\frac{P_{t-1}^1}{P_{t-1}^2} = \ln e_t - \ln e_{t-1} + \ln\Phi_t - \ln\Phi_{t-1},$$

$$(8)\quad \ln\frac{P_t^1}{P_t^2} - \ln\frac{P_{t-1}^1}{P_{t-1}^2} = \ln\left(\frac{e_t}{e_{t-1}}\right) + \mu + \ln z,\ \ln z \sim N(0, \sigma^2),$$

$$(9)\quad \ln\frac{P_t^1}{P_t^2} - \ln\frac{P_{t-1}^1}{P_{t-1}^2} = \beta_0 + \beta_1 \ln\left(\frac{e_t}{e_{t-1}}\right) + \epsilon.$$

If $\beta_1 = 1$, then there is complete exchange rate pass-through. If β_1 does not equal 1.0, then the transaction cost must be a function of the exchange rate, which means there are sticky prices for some institutional reasons. For example, one such institution in agriculture would be a stabilization program complete with border controls. If prices are sticky, it is important to examine the period of time for which they are sticky. Unless prices were changed on a daily basis, one would expect some lag time to fully reflect unanticipated changes in exchange rates. As Ardeni points out, in models employing first differences the error structure of the model is not fully specified. Thus, the rate at which the exchange rate changes are fully transmitted through to commodity prices must be studied. This can be done within this framework by adding lagged exchange rates to the regression analysis to capture the lagged effect of exchange rates on prices. the more general model to estimate is of the form:

$$(10)\quad \ln\frac{P_t^1}{P_t^2} - \ln\frac{P_{t-1}^1}{P_{t-1}^2} = \beta_0 + \beta_1 \ln\left(\frac{e_t}{e_{t-1}}\right) + \beta_2 \ln\left(\frac{e_{t-1}}{e_{t-2}}\right) + \beta_3 \ln\left(\frac{e_{t-2}}{e_{t-3}}\right) + \epsilon.$$

Data and Results

In order to estimate exchange rate pass-through for Canadian agriculture, equation (10) was estimated using ordinary least squares for three outputs and five inputs for Canadian and U.S. agriculture. The relative prices of wheat, oilseeds, and livestock were estimated using published quarterly average cash prices at a specific locations in each country. The relative prices of petroleum, fertilizer, pesticides, and machinery were calculated from aggregate farm input price indexes in each of the two countries. All regressions included data from 1975 to the second quarter of 1988 which, given the two quarter lagged variables, yielded fifty-two observations. Seasonal dummies were estimated for all of the equations but were significant only in the feeder cattle equation.

The results of the regressions are reported in table 1. In addition to the standard results, student t-values are reported for the tests that: (a) the contemporaneous quarter plus the two lagged effects sum to one, which is consistent with complete pass-through; and, alternatively, (b) the exchange rate elasticities sum to zero, which is consistent with no pass-through. The data strongly support a contemporaneous pass-through for wheat, canola, and petroleum, a one-quarter lagged pass-through for feeder steers, fat steers, and pesticides, and a two-quarter (3/4) lagged pass-through for fertilizer and no pass-through for farm machinery. Given these high pass-through rates on the major variable inputs in Canadian agricultural production, exchange rates should have had little effect on allocative decisions within the grain sector.

However, the beef sector is a different story. The immediate pass-through on grains and the one-quarter lag effect on fat prices should mean a reduction in the feeding margins when the Canadian dollar devalues. This relationship is consistent with a negative contemporaneous pass-through with respect to feeder prices. The increased feeding costs are reflected in a drop in the price of feeder steers. It is this industry which may be adversely affected by devaluations in the dollar.

The low R-squared in each of the equations indicates that exchange rate changes only explain a small part of the changes in the relative Canadian/U.S. prices. This result is not that unreasonable because exchange rate changes were rather small during the sample period. Exchange rates ($Cdn/$US) slowly increased during the period from a low of .97 near the beginning of the period to a high of 1.4.

Another interesting aspect of the data is the strong seasonal effect on pass-through in the price of feeder steers. The seasonal variable indicates that pass-through is much greater in the second and fourth quarters of the year than in the first and third quarter of the year. This seasonal pattern is consistent with the time of year feeders

Table 1. The Exchange Rate Pass-Through for Canadian Agricultural Inputs and Outputs

Commodity	β_0 (t)	β_{1t} (t)	β_{1t-1} (t)	β_{1t-2} (t)	F D-W	R^2 r: $\Sigma\beta = 1$	r: $\Sigma\beta = 0$

are actively traded. In the first quarter the calves are wintering on feed. In the second quarter they are being put on grass. In the third quarter they remain on pasture, and in the fourth quarter they come off the grass to be fed. Thus, one would expect a substantial trade in the animals only in the second or the fourth quarters of the year. The data support this seasonal pattern.

The lack of exchange rate pass-through on new machinery prices appears inconsistent with the lack of trade barriers and the relatively low transport costs for machinery. A reasonable explanation for this lack of pass-through is that a change in exchange rates is consistent with a difference in nominal interest rates in the two countries.[5] Thus, an increase in the exchange rate which lowers the purchase price of a new machine will be correlated with increases in the interest cost. Machinery dealers respond to the decreased demand for their product (and higher inventory costs) by lowering margins. The farmer is precluded from buying in the other country by the inability to have the machine serviced by the local dealer in the event of a breakdown. A similar, but somewhat weaker, story involves fertilizer markups. In this case the local dealer often provides service in terms of timely delivery and occasionally the rental of application equipment.

[5] Carter and Hamilton found a strong correlation between the change in exchange rate and nominal interest rates in Canada, which one would expect given arbitrage in financial markets.

Conclusions

This paper presents a framework for evaluating exchange rate effects when both inputs and outputs are tradeable. The impacts of exchange rates on input and output prices, volumes traded, and welfare were described. The important effect on input prices and welfare has been previously ignored in the literature.

Empirically, we found exchange rate pass-through on the major variable inputs used in Canadian agriculture to be significant. A difference occurs in the rate of pass-through that may be explained by institutional factors such as price pooling and localized dealer markups. A major conclusion is that the input prices as well as commodity prices are affected by exchange rates. This may reduce the short-run effect of exchange rates (in the case of wheat producers) or even reverse the impact (as in the case of feeder cattle).

Given the large pass-through on many of the variable inputs and outputs, the exchange rates will have a small impact on the quantity produced. Given the small production effect, rents or returns to fixed factors should change approximately in proportion to the change in exchange rates. Finally, the small production effect of exchange rates reduces the impact of agricultural trade in determining exchange rates. Under these conditions a partial equilibrium analysis is appropriate.

Performance of Mexican Agriculture: The Effects of Economic and Agricultural Policies

Manuel R. Villa-Issa

Mexican agriculture is having difficulties for several reasons. Especially important was the need in 1989 to import 9.5 million tons of basic food, mainly corn, wheat sorghum, beans, and milk. Much needs to be done in order to return agriculture to a profitable activity.

In this paper I will analyze the relationship between macroeconomic factors, mainly foreign exchange, investment, and prices, and the performance of the farm sector. Three time periods are considered: (*a*) from 1910, when the Mexican Revolution started, to 1940 when agriculture began to exist in a peaceful environment; (*b*) from 1940 to 1970, when the agricultural growth rate surpassed the population increase, exports were in progress, and the farm sector was contributing effectively to the whole economy, although the conditions for a poor sector performance were developing; and (*c*) from 1970 to the present, when, as a result of past and current policy conditions, the rural sector moved to a point where it was unable to contribute as effectively to the economy. Food imports increased, trade was nearly balanced, and the strength of agriculture generally deteriorated.

The Period from 1910 to 1940

Early in this century, Mexico depended mostly on agriculture. More than 90% of the population was involved in agriculture. However, land was concentrated in a few hands. Before the 1910 Revolution, about 97% of the land in Mexico was owned by 830 people or corporations. Approximately 3.5 million peasants were landless.

During 1910 to 1930, internal war dominated the country. Many people left agriculture; whatever was produced was devoted to feed the fighting groups, and little investment in agriculture occurred. In general, capital outflow from the farm sector was mainly the result of social instability.

During the 1930s many agricultural policies were initiated to stimulate development in the farm sector. Land distribution began; credit, roads, irrigation developments, and research also began to appear in the sector. Agriculture production began to increase again from a very low point, at an increasing rate. This situation, thus, characterized the early 1940s.

During the late 1930s, conditions to foster further expansion of raw material exports and growth of consumer goods were created. Landowners' economic power was undermined, and agrarian reform widened the agricultural boundaries upon redistribution of 18.8 million hectares. For comparison purposes, consider that the annual average area under cultivation was less than 6 million hectares. In addition, the institutional framework aimed at facilitating economic expansion was created.

In 1934 (National Financiera was established in 1937) the National Foreign Trade Bank was founded; in 1938, the Tariff Act was passed, and in 1939 the New Industry Support Act was adopted. Other state-run companies created at that time that were vital for the economy were Pemex (the oil monopoly) and CFE (the Federal Electricity Commission). The financial system, which had deteriorated during the armed conflict, was given further strength. By 1940, credit had more than doubled compared to the 1925 level.

The Period from 1940 to 1970

This period is divided into two parts for better understanding: (*a*) 1940 to 1955 was a period of growth with inflation, and (*b*) 1955 to 1970 was a stabilizing development period.

At the end of World War II, the Mexican gov-

Manuel R. Villa-Issa is a professor, Centro de Economia, Colegio de Postgraduados, Mexico, and adviser to the Secretary of Agriculture and Hydraulic Resources.

ernment became involved in an industrial input substitution model in order to increase the rate of development. Because most of the international resources were devoted to the reconstruction of Europe, the main source to finance this model was the agricultural sector. Under this condition agriculture had to generate resources for its own development as well as industrial and commercial development.

The federal public investment, which in 1940 was 4% of the gross domestic product (GDP), increased to 5% by 1955. The investment structure was also modified in 1940: 52% was devoted to railways, roads, and bridge construction; 36% went to hydraulic works for the agricultural sector and industrial development.

The exchange rate was another policy instrument. Because the Mexican peso was overvalued at the beginning of World War II, substantial imports of intermediate and capital goods occurred. By 1955, the Mexican currency had a 33% overvaluation (equilibrium base 1950). Imports of goods were curbed by levying tariffs, permits, and duties.

Within this framework, the Mexican economy began to expand. Sustained growth was accompanied by relatively high inflation and exchange instability. The GDP increased at an annual rate of 6% in real terms. This growth came primarily from commercial manufacturing and the agricultural sector. These activities accounted for about 70% of the GDP growth rate in this period. Economic policy and agriculture in particular were successful: employment grew, income rose, and the nation began to improve its economic and social well being.

The agrarian reform substantially widened agricultural boundaries. The area under cultivation increased at an annual rate of 2.9%. Furthermore, 1.6 million hectares were added to the irrigation system, which represented 18% of the area under crop by 1955.

The agricultural trade balance recorded a surplus. From 1950 through 1955, the farm sector accounted for 54% of the overall exports while representing only 7.6% of imports. Although exports of agricultural products were encouraged by international demand, domestic policies, such as the exchange rate and the protection policy, had a negative effect ranging from −2% to −6% level, respectively. Under these circumstances, the resource transfers from the agricultural sector to the rest of the economy were estimated to average 1% of the agricultural GDP annually.

During this period relative prices in the internal market favored the agricultural sector. However, the relationship changed over time. The ratio of farm prices relative to the general index fell from 1.23 in 1940 to 0.93 in 1970. The price relationship between agriculture and industry fell from 1.18 in 1940 to 0.89 in 1970. This decline represents a real decrease of 25% in a thirty-year period.

The economic growth and the international trade recovery resulted in imports outgrowing exports in the early 1950s. The balance of trade deficit accounted for an average of 3.5% of the GDP on a five-year basis. Furthermore, in spite of long-term capital inflows, Banco de Mexico's (the Central Bank) international reserves shrank to a yearly average rate of 8% between 1950 and 1954. In view of balance-of-payment difficulties and a 10% annual inflation rate, the federal government decided to change its development strategy.

The new strategy gave rise to a "stabilizing development" period. It was based on urban-industrial expansion. Industrial growth was fostered by an import-substitution system encouraged by protective tariffs followed by quantitative controls on manufacturers, mainly durable consumer goods. Manufacturing industry grew at an annual real rate of 8.4%. The nondurable consumer industry was no longer the most dynamic, despite a real annual growth of 6.4%. It was replaced by the durable consumer goods industry, with an annual growth rate of 13%.

The exchange rate was fixed and currency conversions were free. The peso/dollar parity was contained at 12.50 from 1954 to 1976, involving a large peso overvaluation strategy to foster imports required in the industrial sector.

Economic policies aimed at backing urban-industrial development had a positive impact on the economy as a whole; however, the impact on agricultural sector development was negative and getting worse. Agricultural activities rose at 3% between 1955 and 1970. However, by 1965 agricultural output value trends declined. The farm sector's annual growth rate was 3.1% during the 1955–60 period, 5.8% during 1960–65, and 1.0% during 1965–72. By the end of the stabilizing development period, agricultural activities showed complete stagnation.

Following 1965, the Mexican farm sector no longer fulfilled certain key roles. The drop in foodstuffs and raw material output caused large imports of basic crops by the end of the stabilizing development period. A partial explanation for the change in farm sector performance is as follows.

In spite of the annual 4% increase in gross agricultural investments 1960–72, a substantial share (about 32% of gross investment) was devoted to maintenance and replacement of irrigation works carried out during the two previous decades. The pricing policy adopted was a negative one. Thus, from 1955 through 1972, farm prices lagged by 19% with respect to the implicit deflator. The drop in real prices as well as the increase in the cost of farm imports brought about by the closing of borders discouraged private investment in the rural sector. The response was increasing allocations of public funds.

In spite of the public sector's ever-increasing allocation of resources to farm activities, private investment was discouraged, mainly because of the sector's negative pricing policy and to the exchange rate policy. The exchange rate was overvalued by about 22% from 1954 through 1972. Between 1960 and 1972, public investment grew from 2.6% of the agricultural GDP to 8.6%, while private investment declined from 20.9% of the agricultural GDP to 17.7%.

Various interventions in the market had an overall negative effect on the farming sector. The net rates of nominal and effective protections for 1970 were minus 10.3% and minus 13.1%, respectively. On the one hand, prices received for domestic production were about 10% below international prices and, on the other hand, the sector experienced a 13% decline in value added relative to the absence of market interventions.

A strong contrast exists between the agricultural sector protection rates and those relative to durable consumer goods and capital goods. The latter were about 12.7% and 34.6%. In addition, the fertilizer and insecticide programs exhibited protection rates of 15.5% and 197.1%, respectively.

In summary during the first decde of the stabilizing development period, the farming sector fulfilled its role of supplies of foodstuffs and raw material. Subsequently—from 1965 to 1972—food supply became increasingly difficult, giving way to massive cereal imports.

During this period, the farm sector's capacity to provide net transfers of foreign currency to the rest of the economy gradually eroded. The trade balance surplus dropped by 1.1% annually. Agricultural exports maintained a 52% share of overall exports. Agricultural imports, on the other hand, increased relative to overall imports. By 1972 imports reached 10.1%, basically because of corn and wheat purchases abroad.

The Period from 1972 to 1986

The 1971 and 1972 years represent the end of the stabilizing development period and the beginning of a new economic policy. In 1971, the stabilizing development reached a turning point: GDP grew 3.4%, and per-capita product rose 1.7%, compared to previous annual rates of 7.2% and 3.7%, respectively. The slower growth was reflected by several indicators: gross investment fell by 5.1% (public investment diminished 26.6%), and domestic savings dropped 6%, the credit flow declined by 28.5%, and merchandise exports declined 3.1% (in spite of the rise in grain imports).

This situation forced the federal government to reorient the economic policy. In 1972, the government attempted to reactivate the economy through government expenditure and an increase in demand. Federal current expenditure rose by 22.9%, and capital expenditure increased 81.9%; banking credit grew 7.5%, and the money supply increased by 21.2%.

Industry, building, and mining (including oil) increased at annual rates of 7.2%, 8.3%, and 11.7%, respectively. The oil sector was the most active during the period and, together with mining, reached a share of 6.3% of the GDP in 1981, up from 2.1% in 1971. Modern manufacturing continued to expand compared to the traditional industrial activity, although the difference between those rates was less than during the stabilizing development period. Therefore, modern industry had a 53% share of the industrial GDP in 1981, up from 49% in 1972.

Such economic development, mainly in the oil sector, caused a greater need for capital good imports. Import substitution of durable goods essentially ended.

Imports were favored by an exchange policy that overvalued the exchange rate. From August 1970 to August 1976, the currency was overvalued by 13.4%. In 1976 the peso was devalued, but by December 1981, overvaluation (compared to September 1976) had reached 35.3%.

Imports recorded a real growth rate of 27.1% a year, and exports (mainly oil) grew 24.5% annually. The trade deficit accounted for a major part of the current account deficit, amounting to US$12,544.3 million in 1981. The current account deficit was offset by the capital account surplus, mainly long-term net capital of the public sector.

From 1972 to 1981 the farming sector benefited from the government expenditure policy.

Government gross investment in agriculture rose at a real annual rate of 13.1% and averaged 14.8% of agricultural GDP. Furthermore, it benefited from both the price control on products generated by the public sector and the subsidies policy. For example, the implicit price index increased by 478.8%, while the price of gasoline, farming tractors, and fertilizers grew by only 148.6%, 185.7%, and 171.5%, respectively. Subsidies through loans granted by agricultural trust funds (FIRA) were estimated at 0.2% of the agricultural GDP in 1975 and increased to 2.3% in 1981.

Other public investment also benefited the agricultural sector. Fertilizers and seed production, both concentrated in the public sector, increased 15.4% and 17.1% annually from 1972 to 1981.

On the other hand, price policy, although erratic throughout the period, had negative effects overall. Agricultural product prices deteriorated against the implicit price index by 3.4% from 1972 to 1982. In particular, the real price of corn and beans decreased 16.1% and 23.4%, respectively, in this period. The overvalued exchange rate policy resulted in the stagnation of agricultural exports and the fostered imports of consumer and capital goods.

In the 1970s, the growth rate of basic food (corn, beans, and wheat) production was lower than the population growth rate. Corn production increased at a 0.4% annual rate and beans and wheat grew at (−0.9) and 2.9% annually. Meanwhile, crops for livestock feed and edible vegetable oils reached high rates of growth. Sorghum, soybean, alfalfa, and safflower achieved annual rates of 9.4%, 11.3%, and 7.7% a year. This period was marked by increasing imports of agricultural food and raw material. Raw material imports increased as a result of the greater consumption of meat, eggs, milk, and vegetable oil by medium- and high-income consumers in the mid-1970s.

The sector's role as foreign currency supplier also slowed down. The balance-of-trade surplus decreased from 1972 to 1975. As mentioned above, this situation was influenced by the foreign exchange policy. After the 1976 devaluation, the surplus again grew until 1979. For the first time, the slight exchange rate flexibility during 1980–82 resulted in an agricultural trade deficit. Consequently, the agricultural sector's role as a foreign currency supplier came to an end in the last five-year period of the 1970s; it has been a net currency receiver since 1980.

Consider next the performance of the farm sector during the period 1982 to 1986, when economic policy was instituted mainly to control inflation, reduce the burden of foreign debt, and to avoid social unrest. This period was characterized by a decline in oil price, decreasing rates of public and private investment, and attempts to undervalue the exchange rate in order to stimulate exports.

During the early 1980s, aggregate demand accelerated because of the increase in the government expenditure based on income from oil exports. It reached \$US9.4 billion in 1980 compared to \$US3.8 billion in 1979. This situation resulted in an increase of real subsidies because this mechanism was used to partially transfer the oil resources to the rest of the economy. Furthermore, government expenditure was backed by a larger indebtedness.

Unfortunately, a foreign exchange policy holding the proper relationship between the spread of internal and external prices and the difference between inflation in Mexico and that of its trading partners was not implemented. The peso overvaluation was sustained, estimated at 35.5% by December 1981 compared to September 1976, when the last devaluation occurred. The result was a stagnation of nonoil exports and an acceleration of imports of luxury consumer goods that had a little impact on economic growth. Tourism, too, experienced drastic income reduction because of the peso overvaluation.

In short, at the beginning of 1982, the country's economic and financial situation was unfavorable: strong inflationary pressures on the supply and the demand side, a drastic reduction in government revenues, the lagging of public sector prices and tariffs, and the burden of debt servicing. The effect of the problems outlined above was felt in economic activity: GDP decreased by 0.5% in 1982, and none of the sectors recorded a higher growth than the previous year. Gross fixed investment dropped almost 16%.

The agricultural situation was not different from the rest of the economy and was aggravated in 1982 by an unusual drought. The favorable performance of agriculture in 1980 and 1981, strongly supported by subsidies from the SAM, became a serious decline in 1982: agricultural GDP fell 2.9%, and gross fixed investment declined 16.8%; cultivated land diminished 14.6%, and the average agricultural wage decreased 3.8%. The sharp decline in agricultural imports, −54.6%, exceeded the 16.7% drop of exports resulting in a positive trade balance.

The agricultural sector had an adequate per-

formance in 1983. Agricultural GDP rose 4.1%, cultivated land increased 17%, and production increased 4.2%. Balance of trade recorded a deficit of $US452 million, mainly because of import growth (54.7%). Exporters could not benefit from undervaluation (−30.7% from February 1982 to December 1983) because of the impact of the 1982 drought on the autumn-winter export crops harvested at the beginning of 1983. Therefore, agricultural exports grew only 1.2%.

The deficit reduction policy meant lower subsidies for the agricultural sector, and the exchange policy (undervaluation) increased production costs. The public sector adjusted guarantee prices to counterbalance rising costs (132%); however, this adjustment did not offset inflation because the real price fall was 7.4%. Nevertheless, guarantee price deterioration slowed compared to the 16.8% drop in 1982. In 1984, the agricultural GDP reached a growth rate of 2.6%, despite the bad weather. Cultivated land diminished 2%, but production increased 2.5%. Exports increased 17% in response to undervaluation. The decline in grain and forage production resulted in an increase of imports by 10.5%.

Going back to the policy of subsidies reduction, agricultural output costs continued increasing in real terms. Guaranteed prices were increased over the costs rate in order to offset the negative impact on this sector. Thus, guaranteed prices rose 21% above raw material costs, 22% in real terms.

In 1985, the area under cultivation increased by 2.6%. Wheat crops grew at 16.0% compared to the previous year. Sorghum, rice, and corn had high growth rates as well. The large availability of these and other products because of good weather conditions substantially reduced imports (14.5%), while exports declined 3.5%. Thus, the agricultural trade deficit declined from US$419 million in 1984 to US$197 million in 1985. Compared to the previous year, the growth rate of guarantee prices exceeded the inflation implicit index (3.6%), and the price policy was favorable because prices rose above production costs.

Bad weather conditions and drought prevailed in 1986, completely damaging 500 thousand hectares. Output in the agricultural sector drastically fell (4.2%). Cultivated land diminished by 8%. Sorghum and corn output declined by 65% and 14%, respectively. Storage water declined by 44% compared to the previous year. Fertilizers, in the form of nitrogen, phosphorus, and potassium products diminished by 9.3%, 8.8%, and 2.2%, respectively. Besides weather conditions, agriculture was seriously affected by the resulting negative price policy. Input costs increased 17% above the increase in guarantee prices, resulting in a substantial drop in the sector's profitability. Nonetheless, a combination of increases in exports and a decline in imports caused the previous year's trade deficit (US$197 million), to become a surplus of over US$1 billion. This year is a good example of the way exports may be fostered despite an adverse economic atmosphere and unfavorable weather conditions.

Concluding Comments

An important thrust of the argument in this paper is that farm sector performance depends a great deal on policy decisions taken outside the sector. Policies focusing on exchange rates, investment for the economy and for the rural sector, and product and input prices explain much of the sector's performance. The Mexican case is a good example, especially for the post-World War II era, when the farm sector was powerful and could fulfill its role in the economy. Since World War II, the economy essentially followed an industrial-urban development model and economic forces tended to move against the farm sector.

As development occurs, the relative importance of the rural sector is expected to decline; however, this does not imply economic stagnation in agriculture. On the contrary, the smaller the sector over time, the stronger it must be.

The challenge for the future is to better coordinate agricultural and macroeconomic policies. Much research is needed to understand what the key relationships are for making the right decisions.

International Capital Markets and Structural Adjustment in U.S. Agriculture

David Orden

The problem of foreign investments, or more generally of international movements of capital, has come very much to the fore during the last few years. Financial and general economic interests of the widest bearing are intimately connected with this problem . . . and the whole subject is more and more drawn both into the internal political controversies of the various countries and into the sphere of international discussion.

—Gustav Cassel, June 1928

Sixty-one years after Professor Cassel addressed the Harris Foundation about problems of trade and foreign investments, we again find international capital movements at the center of international trade discussions. The objectives of this paper are to place recent experience—in which the effects of trade and capital flows on agriculture have been widely recognized—in historical context and to draw on this review to offer some conclusions about the current U.S. trade deficits and agriculture.

International Capital Movements: 1900–88

Figure 1 presents data that places the recent prominence of international capital movements in perspective. U.S. international debt near the turn of the century (1897) is estimated to have approached 18.0% of annual national output. Over the next seventeen years, the United States maintained a positive balance on merchandise trade, with exports averaging 6.5% of gross national product (GNP). Still, we remained a debtor nation (around 6% of GNP) on the eve of World War I.

During the war, exports rose to almost 11% of GNP, and the trade surplus to about 5%. Europeans drew down their foreign investments and the United States emerged as a major international creditor. Private loans to the Allies amounted to $2.5 billion (about equal in value to our net pre-war debt), and the U.S. Treasury extended additional credit of $9.4 billion.

Emergence as a creditor nation shifted the international flow of investment income across the U.S. border. Prior to 1914, net annual payments to foreign investors had been on the order of $50–$100 million (0.2% of GNP). By 1919, income on private U.S. investments abroad exceeded income on foreign investments in the United States by 0.5% of GNP. Thus, the United States could have sustained substantial trade deficits during the 1920s. However, while exports fell to less than 6% of GNP, the United States remained a net exporter by making large private transfers and providing extensive new loans.

Following the stock market crash in 1929, both American invesetments abroad and foreign investments in the United States were reduced. World income and trade collapsed during the depression, but the net creditor status of the United States rose to almost 20% of GNP, a complete reversal of the situation at the turn of the century. Subsequently, as war approached, U.S. and foreign capital moved out of Europe. This capital movement again could have been associated with U.S. trade deficits, but was not, as official reserve asset accumulation more than offset other capital flows.

During the second world war, a large trade surplus was financed by transfers instead of loans. The war is then followed by a long period of relative calm in international capital and goods markets. The values of private investments abroad and foreign investments in the United States both grew at about the rate of nominal GNP through

David Orden is an assistant professor, Department of Agricultural Economics, Virginia Polytechnic Institute and State University, and is currently on leave as a visiting fellow, Department of Economics, University of New South Wales, Australia.

John Robertson provided assistance with the figures, and Ralph Monaco offered helpful comments during several conversations. The author also benefited by suggestions from Harold Breimyer and Paxton Marshall.

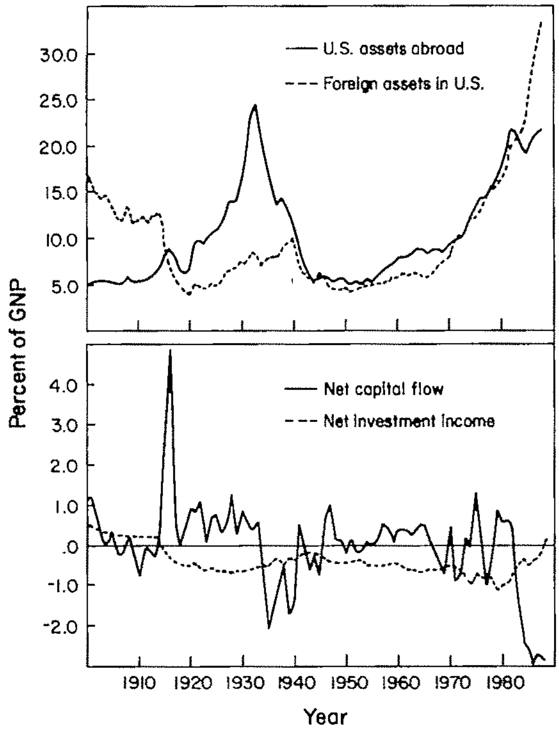

Figure 1. Stock of private U.S. assets abroad and foreign assets in the United States and net annual capital flows and investment income, as a percent of GNP, 1900–88

1970, and exports fell below 4% of GNP in the 1950s and 1960s. The net value of international asset holdings (U.S. private investments abroad minus foreign investments in the U.S.) remained less the 2% of GNP throughout this period.

After the devaluation and floating of the dollar in the early 1970s, there is a reemergence of international capital markets. This reemergence has been cited by Schuh and others as a crucial development affecting U.S. agriculture. Capital outflows from the United States increased almost sevenfold in a decade, and exports (total) again reached 6.5% of GNP. Foreign investments in the United States matched the rapid increase in our investments abroad. For the first time during this century, the United States sustained a significant trade deficit, more than offset until 1980 by a positive balance-of-investment income.

Since 1980, private capital outflows have collapsed, and the stock of U.S. investments abroad has stagnated. Foreign capital inflows have continually grown, and the United States is a debtor nation for the first time in seventy years. The change in direction of net capital flows of almost 3.5% of GNP during 1981–83 was larger than at any time except during World War I, and U.S. net debt is now around 10% of annual output.

Agricultural Prosperity and Collapse: 1910–29

Further perspective on the impact of international capital markets on agriculture comes from an examination of the policy debates and economic adjustments that occurred during the period 1910–29, when the United States first emerged as a major world creditor. Particularly relevant are the effects of investment income and new capital flows on agricultural exports and the emergence of postwar agricutural policy in the context of monetary policy, tariff policy, and war-debt policies that generally discriminated against agriculture.

To set the stage for this discussion, one needs to remember that the agricultural sector was relatively prosperous in the period before World War I (Hansen). The export-oriented war economy then created both real growth and inflation. Nominal net farm income rose from a 1912–14 average of $4.1 billion to $8.9 billion in 1918. Prices received by farmers for crops and livestock rose 102.2% and 79.4%, respectively, and the parity index rose from 99 to 120.

The armistice in late 1918 created uncertainty about the economic expansion, export markets, and prices. Stimulative fiscal deficits continued through 1919, and the Federal Reserve Board deferred a contraction of domestic credit to allow the treasury to float its last war bond issue at low interest rates (Crabbe)—a sort of unpleasant monetarist arithmetic. These monetary and fiscal policies were particularly effective with respect to agriculture. The nominal value of agricultural exports rose 57% in 1919, and farm income rose to $9.1 billion, although the parity index fell to 110.

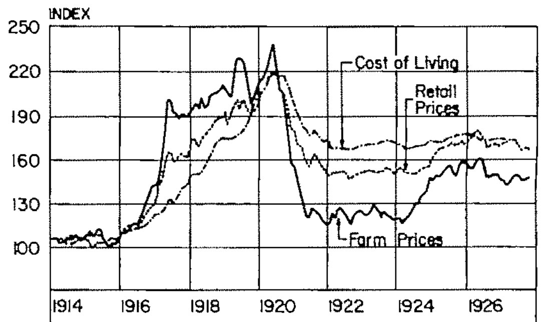
The postwar boom was also short lived. Nominal GNP dropped by almost one-quarter during 1920–21 and real GNP fell 8%. The parity index fell below 80 as prices received for crops dropped 41% during the second half of 1920. Possibly this was the worst collapse yet experienced by American farmers, and throughout the rest of the decade agriculture remained depressed relative to the nonfarm economy (Benedict).

Policy Issues

At the end of World War I, farmers and agricultural statesman shared the general uncertainty about the prospects for maintaining peacetime prosperity. G. E. Warren focused his January 1919 address to the American Farm Management Association on programs for making farm life more attractive. He asserted that food was "almost certain to continue to call for a larger share of the workers' income" (p. 14), a long-term view with which E. G. Nourse cautiously took issue (1920). Ten months later, Warren concluded that there would be a general deflation affecting agriculture, but that it would be "more gradual" than after the Civil War. J. R. Fain, the president of the association, posed the question of whether farm prices falling below cost of production during a period of adjustment could be "restricted to a short period or avoided altogether" (p. 8).

With these moderate views prevalent, a heated debate over the causes and the appropriate responses by farmers and government followed the collapse of prices in 1920. Farm groups focused their ire on the Federal Reserve System (Shideler). It was held responsible for fueling speculation during 1919 and for the general deflation collapse of farm prices during 1920–21. It was also accused specifically of restricting credit to agriculture, a claim that proved false but which contributed to a crisis atmosphere as prices fell (Link).

The argument that the 1920–21 deflation caused relative prices to shift against agriculture was pursued in studies by Warren (1920, 1928). His conclusions, which became a basis for policy efforts to raise the general price level in the 1930s, are illustrated in figure 2. G. W. Dowrie, of the University of Minnesota, also evaluated the effects of monetary deflation on agriculture. Dowrie agreed with Warren that FED policy intensifed the farm collapse but rejected Warren's main conclusion, finding instead that the factors primarily responsible for the postwar price deflation were overstimulated agricultural production resulting from high prices during the war, good crop conditions in 1920, and the collapse of "abnormal and unsound" sources of demand. Dowrie took issue with Henry A. Wallace (editor of *Wallace's Farmer* and soon to be the secretary of agriculture) and others who urged "farm activity to support a law instructing the Federal Reserve Board to take such steps as necessary to reach and maintain a price level 70% above pre-war" (Dowrie, p. 75).



INDEX NUMBERS OF PRICES OF FOOD AND THE COST OF LIVING, 1914 - 1927

The amount by which retail food prices are below the cost of living may be taken as a measure of the overproduction of food. The amount by which farm prices are below their usual ratio to retail prices is a measure of price disparity brought about by the failure of distributing charges to decline when prices fall. The present low farm prices of food are due to the latter cause rather than to overproduction.

Figure 2. Warren's analysis of prices

The effects of international capital movements on the demand for U.S. agricultural products also played an important role in the debate over postwar agricultural policy. The emergence of the United States as a net creditor during World War I was widely perceived to be of importance because agriculture had provided exports to service U.S. foreign debts throughout the nineteenth century (Holmes). Wallace put the argument succinctly: "The hard fact is that many of the nations of Europe are now in debt, and in the long run, debtor nations find it impossible to import goods as freely as creditor nations can" (pp. 81–82). Max Sering, of the University of Berlin's Agrarian and Land Settlement Research Institute, concluded more generally that it was difficult to see how a contraction of U.S. cultivated area and an extensive migration of farmers could be avoided if Europe was "not permitted a return to normal conditions" (p. 240).

However, the prospects for restoration of normal conditions in Europe were complicated in the aftermath of the war by demands for German reparations and repayment of U.S. war loans. Despite extensive negotiations to reduce these obligations, in his 1928 lecture Cassel viewed the remaining intergovernmental war debts as "the greatest problem the world has been confronted with in regard to international movements of capital" (p. 63). To the extent that reparations and debt repayments were feasible, they rested on the reemergence of competitive private international capital markets. American loans

to Germany during the 1920s financed reparation payments that in turn serviced war debts of the Allies. The private loans cycled back through reparation and debt payments did not provide large markets for U.S. exports, but the capital outflow was sufficient to finance a small U.S. trade surplus. Cassel concluded that this cycle could not go on indefinitely, and he expressed fear that the world would be faced with the real problem of reparation payments when private lending to Germany ceased.

Cassel recognized that in the absence of new loans, European repayment of war debts necessitated a U.S. trade deficit. But American interests, including many farm groups, were myopic on trade issues and resisted importation of European goods. Emergency legislation restoring tariffs to their high prewar levels was enacted in June 1921. Permanent legislation, increasing tariffs from an average of 27% to around 40%, was enacted fifteen months later (the Fordney-McCumber Tariff).

The postwar tariff legislation raised domestic nonfarm prices and, arguably, choked off agricultural exports. These effects became essential factors shaping agricultural policy. B. H. Hibbard, of Wisconsin, characterized agriculture's dilemma as being that "another world war would put food at a premium, a government subsidy might bring relief, a revision of the tariff downward would do likewise. Two of these remedies would be worse than the disease, the third measure would be a miracle" (p. 202).

In the absence of tariff reductions, the view which prevailed was to seek relief in specific measures of support for agriculture. Farmers were seen as the least organized group in an economy becoming affected more and more by collective action. Wallace argued that "farmers have just as much right to organize to control their output as union labor has to organize for the purpose of shortening hours and increasing wages" (1923, p. 16). This view gained support as demand adequate to raise prices for existing supplies failed to materialize (Holmes, Nourse 1927).

To obtain higher prices and incomes, farmers sought improved credit agencies, lower costs for farm-to-market transportation, strengthened cooperative marketing, and extension of the War Finance Corporation to provide export credits and credit assistance to farmers. Farmers also engaged in a contentious and prolonged battle for an export subsidy plan similar to the current policies of the European Community. The basic idea of the plan was to maintain prices at "parity" levels equal to those of the prewar period for output absorbed in the domestic market. Production in excess of domestic absorption would be sold at whatever prices the world market would bear, and individual farmers would receive an average price based on total national sales. The debate over farm policy centered on this proposal and alternatives to it. Legislation based on the plan was brought before Congress five times between 1924 and 1928 (Benedict). If failed to obtain majorities in the first three attempts. Subsequently, closely related legislation passed in both the House and Senate. Although they were vetoed on each occasion, these bills were the forerunners of the agricultural legislation enacted in 1933.

Implications

There are some important similarities between the 1910–29 period and the period since 1970. Initial prosperity in agriculture during inflationary years is followed in both periods by falling relative prices, collapse of export markets, increased international competition, asset-deflation and financial crisis, and failure of the sector to recover from a recession as quickly or as well as the overall economy. In the 1920s, the severity of the recession in agriculture was shared by sectors such as cotton manufacturing, coal mining, shipbuilding, and the shoe and leather industries. In the 1980s, some manufacturing sectors, such as apparel and primary metal products, have also remained relatively depressed and have faced intense international competition.

In this context, it is interesting to speculate about currency values and trade in the 1920s under alternative policies. The small U.S. accumulation of official reserves that occurred suggests that the dollar was slightly undervalued. Appreciation of the dollar would have brought the current and capital accounts into balance, given the debt repayment requirements and evident private investment decisions. Had the war debts been forgiven, then, all else being equal, the dollar would have been overvalued. To restore balance would have required depreciation of the dollar and an expansion of exports. Conversely, had international capital markets not functioned, repayment of the war debts would have resulted in a greater accumulation of official reserves or required a much stronger dollar, depressing exports further. Thus, war-debt policy served to increase the value of the dollar compared to what it otherwise would have been. The available private capital outflows facilitated

implementation of the fiscal policy by easing its effects on the exchange rate and trade sectors.

One can draw a comparison between the capital inflow required by the war debt repayments in the 1920s and the capital inflow induced partly by federal budget deficits in the 1980s. Fiscal policy has had a depressing effect on exports in both periods. The fiscal policies have also been feasible in both periods largely because of private international capital mobility.

A second comparison can be made between the inflation and capital movements during and after World War I, and the oil crises in the 1970s and extensive loans to the governments of hard-pressed developing countries. The strain on European recovery associated with war reparations and debts underscores the importance of resolving the current LDC's debt, and the tenacity of the U.S. position in the earlier debt-reduction negotiations, with eventual repudiation of their war debts by the Europeans, is sobering.

One dissimilarity between international capital markets in the two periods arises from the United States being a net source of credit in one period and a net borrower in the other. In the 1920s, capital movements enhanced the U.S. ability to export compared to the situation if new capital flows had not occurred, while the rising net asset position of the United States augered for eventual deterioration of exports relative to imports. In the 1980s, exactly the opposite is the case. Contemporaneous capital movements are a cause of poor U.S. export performance, while the deteriorating net asset position augers for eventual improvement of exports relative to imports.

Moreover, the magnitude of the recent capital inflows to the United States is unprecedented in this century, and the U.S. level of net foreign debt is on the verge of surpassing its level in 1900. This raises the question of whether we, like Cassell and Wallace, should be concerned that a country cannot borrow indefinitely, as we now know was infeasible for Europe in the 1930s. More specifically, it raises the question of whether the high level of U.S. debt foreshadows expanded agricultural exports to service the debt load, in a manner analogous to the pre-World War I period?

It appears that interest payments resulting from the current trade deficits will not necessarily lead to trade surpluses by themselves, at least not over the next decade. The current balance of net investment income barely favors foreigners despite the U.S. foreign indebtedness (see fig. 1). Net capital inflows of 2% of GNP—high by historical standards but less than recent net capital movements—imply that annual trade deficits will stay on the order of \$100–\$150 billion until the year 2000. But annual net interest payments due to foreign investors may rise to only 0.5% of GNP. This situation need not force a swing to a trade surplus.

Of greater issue is that new capital inflows of even 2% of GNP for another decade would continue to be unprecedented. Net U.S. debt to foreign investors would rise to 20% of GNP. Such an increase might heighten public sentiment about foreign takeover of the economy and could threaten free capital markets.

This is where the real concern arises. The relevant question is whether net capital inflows can be reined in while avoiding the sharp recession and drop in trade that accompanied both the end of Treasury financing after World War I and the shift in private capital flows in the early 1930s. Unification of the European market and revitalization of the centrally planned economies could stimulate world income growth and are important to the United States in this context. So, too, is easing of the debt burden of the developing economies and progress in the GATT negotiations. On the other hand, even modest capital market restrictions, say a foreign investment tax, might pose more of a threat to continued prosperity than the burden of servicing growing net interest obligations. Ironically, restrictions on capital movements also would pose a threat to U.S. agricultural exports by endangering world income growth.

A final remark concerns the interface of agricultural policy with monetary policy, international capital flows, and trade policy. In his seminal paper on exchange rates and agriculture, Schuh demonstrated the effects of the overvalued dollar on the development of agricultural policy during the 1950s and 1960s. Similarly, a lesson one can draw from the interwar period is that relatively free capital markets, which Cassel called "the only illuminating point" in a dark picture of economic relations among countries after World War I, cannot compensate for other distortions. The agricultural policies that originated in the 1920s, and were adopted in the 1930s, were consequences, perhaps inevitable, of the monetary policies, tariff policies, and war reparation and debt policies that were implemented. We can only speculate how agricultural policy would have evolved under the liberal trade regime and more adequate restoration of the European economy that were advocated as an alternative in the 1920s. But we

are right to be asking in forums such as GATT whether reform of agricultural policies is overdue in light of other policy changes that have occurred in the United States, Europe, and elsewhere.

International Financial Markets and Agricultural Adjustment in North America: Discussion

Terry L. Roe

I begin with a discussion of the Carter, Gray, and Furtan paper and then turn to Orden's paper. I conclude with only a few remarks on Villa-Issa's paper.

First, I take exception to the conceptual framework in CGF, not because the framework is incorrect, nor does it necessarily alter the conclusions drawn from their empirical results. Instead, the approach (their fig. 1) ignores the importance of capital markets in exchange rate determination, while the others, figures 2 and 3, illustrate the problem of casting questions of exchange rates into a partial equilibrium framework. The Slater model is a model of the current account. Their point C, figure 1, is characterized by a small country where expenditure equals income and the excess demand is zero at relative prices RR'. A disequilibrium is generated when, for example, a monetary authority increases the money supply causing actual cash balances to exceed desired balances. Then, an excess demand is generated for home and traded goods as expenditures exceed income. To satisfy excess demand, the authority must sell foreign exchange for domestic currency at some given rate of exchange or draw upon reserves. The new and temporary equilibrium lies to the right and above C denoting higher relative price for home goods and increased consumption of both home and traded goods. The deficit in the trade balance is something less than the increase in the money supply because some portion of it will be absorbed by voluntary increases in money holdings. In a two-country model, a devaluation causes consumers to reduce real expenditures in the devaluing country and to increase spending in the other country. Changes in the terms of trade depend on differences in the country's marginal propensity to consume traded goods. Changes in reserves are not dealt with directly and these flows have no direct impact on income.

As Krueger and Chipman (1989) point out, current account models are necessarily disequilibrium theory and questions of the consequences of altering the exchange rate cannot be answered without considering how it is altered; some other variable, notably capital market variables, must change to alter portfolio balances and influence trade flows, which together determine currency values. The causation is often from changes in capital market variables to a change in the exchange rate. Stylistically, a reduction in the home country's budget deficit will tend to decrease its excess of expenditures over income and hence increase the supply of exports and reduce the demand for imports, which in turn may alter the country's terms of trade. But this change alone may not be sufficient to induce the foreign country to reduce its export surplus, i.e., its excess of income over expenditure. The reduction in the devaluing country's budget deficit will lower its demand for loanable funds from the foreign country. The decreased demand for loanable funds in the home country will tend to release the funds in the foreign country for use in its consumption expenditures. It is through this capital market transaction that the foreign country is induced to reduce its export surplus.

Models of the interaction between the current and capital accounts tend to treat exchange rate equilibrium as a balance compatible with home country time preferences relative to investment opportunities at the world interest rate. The fractions of wealth held in various assets are functions of nominal and real interest rates and expected rates of currency depreciation. These variables link country's asset markets. For instance, individuals in a devaluing country may change their portfolio balance by selling assets abroad, lowering their prices and increasing interest rates, thus calling forth the requisite cash

Terry L. Roe is a professor and Co-Director, Economic Development Center, University of Minnesota.

from abroad. At any point in time, the asset market determines the exchange rate, which impacts on wealth through current account imbalances; this wealth, current account, capital account mechanism determines the path of the long-run exchange rate (Krueger, p. 105).

The next point to emphasize relates to the misleading insights that can come about from misinterpreting the partial equilibrium diagrams, figures 2 and 3 in CGF. To illustrate, suppose the diagrams depict economies composed only of traded goods. Then, in terms of these diagrams, changes in the nominal exchange rate will appear to yield the indicated effects. However, this is an illusion. The general equilibrium restricted profit function is homogenous of degree one in prices. Hence, changes in the nominal exchange rate equal the product of the nominal exchange rate and variable profits evaluated at world market prices; supply and factor demand are homogenous of degree zero in prices so no change in production or factor use levels occur. Moreover, the indirect general equilibrium utility function is homogenous of degree zero in prices, so changes in the nominal exchange rate yield no change in utility. If there are home net puts, or fixed factors of production, then changes in utility will depend on whether the prices of home net puts, and the shadow prices of the fixed factors, are functions of the prices of traded goods. There are special circumstances where changes in the prices of trade goods will have no impact on net put prices (Chipman 1974), although this is unlikely the case of fixed factors. But then, the wealth implications of changes in the shadow prices of fixed factors are also not accounted for in figures 2 and 3.

The empirical content of the CGF paper is interesting, and the conclusions seem appropriate to the extent that inferences based on either the Slater or the partial equilibrium diagrams are conditioned by the weaknesses of these constructs. I do feel that exchange rates are not exogenous to changes in prices, particularly when both countries are large so that changes imply income effects. In any case, the exogeneity of exchange rates is an empirical question; the conceptual one is clear: for the domain of price changes observed in their data, and ignoring other contemporaneous correlations, a violation of the exogeneity assumption may not alter the key insights obtained to the empirical questions posed.

The version of the Orden paper I received required several readings. The paper has many insights that are not easily organized. Orden first discusses international capital movements for the period 1900 to 1989. He then focuses on the cycles in agricultural prices and incomes for the period 1914 to 1921. The review version of the paper also contained a table of current and capital account data for the entire period, which helped to enrich this discussion. With the aid of the table, merchandise trade and investment income balances and corresponding capital account balances help to depict the adjustments that occurred over the period. It is clear, for example, that capital market flows were large relative to the trade imbalances in the 1920s and again in the 1980s, and that foreign capital flows relative to GNP are becoming more important in the 1980s. Had Orden provided a historical perspective on the nominal and real exchange rate adjustments over the period, it is likely that a stronger association could have been made between the increased demand for the U.S. dollar following World War I (because of European debt) and the depressed conditions in agriculture during the 1920s.

The third section of the paper focuses on the 1919–29 period. There are a number of interesting insights form this discussion. First, the recognition that intergovernmental debt affected the capacity of European countries to import U.S. commodities. Another insight is the political economy induced by changes in the 1920s. Special interest groups in agriculture were motivated to seek protection from declining export demand and increased import substitution in foreign countries. Still another: had capital markets not functioned in the 1920s so that no reverse capital flows from the United States to Europe occurred, then, to maintain the observed import levels, Europe would have had to increase its exports of goods and services (including agricultural products) to the United States, thereby making conditions in U.S. agriculture even worse then those realized. Put another way, the U.S. dollar would have had to appreciate even farther to restrict U.S. exports and to induce European imports in order for Europe to meet debt payments.

In the fourth section, analogies are made between the experience of the 1920s and the 1980s. The analogies between European debt in the 1920s and the U.S. fiscal deficit and developing country debt suggest further insights into the role of capital markets and trade in goods and services. The analogies also suggest a number of "what if" questions. Perhaps more attention might have been given to key differences between the two periods. These include the extent to which

world trade is now dollar based relative to the 1920s and the large proportion of international capital flows that in the 1980s were controlled by the private sector relative to the public sector. Another is the demand for U.S. dollars that is stimulated by both the U.S. fiscal deficit and LDC debt, which is also largely denominated in dollars.

I leave the review of Villa-Issa's paper to the other discussant, except to point out that the Mexican experience is not different from a number of the other countries included in the World Bank's study of the political economy of agricultural price policy in eighteen countries (Krueger, Schiff and Valdes). Essentially, import substitution and cheap urban-based food policies led to direct taxes on agricultural exports for many countries. In response to declining foreign exchange earnings, some countries subsidized the production of import-competing crops. In many cases, the indirect effects of industrial protection and an overvalued currency served to increase the taxes on agriculture by magnitudes exceeding direct taxes. Reform in many countries was forestalled when rising world prices for either petroleum or some other exportable permitted countries to maintain these implicit tax regimes. If reform occurred, it often came as increased farmgate prices or subsidizing inputs while maintaining low retail-level prices for staples. These policies made many countries vulnerable to the world market shocks of the early 1980s. The constituencies of these policies became entrenched, so that when adjustment was needed, negotiations between the various interest groups and the realignment of coalitions either did not occur fast enough or waited until a country faced a liquidity crisis. Then, the choice was to retreat to barter trade or undergo stabilization and structural readjustment policies supported by the World Bank and the International Monetary Fund. In either case, the old policies had to be discarded. What is particularly interesting is the extent to which the adverse adjustment costs faced by Mexico might have been decreased if increases in private capital flows lessened the need to shrink absorption and expand exports to meet the minimal demands of debt repayment. Hence, we once again turn to questions of how international capital markets influence trade flows.

Performance of Mexican Agriculture: Discussion

Odin K. Knudsen

The importance of macroeconomic events and policy in influencing the incentives to agriculture has become one of the stylized facts of modern agricultural economics. Schuh's papers, beginning in 1974 on the relation between exchange rates and agriculture, are one of the major contributions in establishing this fact for North American agriculture. The recent World Bank studies guided by Krueger, Schiff, and Valdes provide additional evidence for developing countries by showing that indirect taxation of agriculture through maroeconomic policy has overwhelmed the positive protection given import-substituting agriculture through direct interventions on pricing and trade.

The papers presented in this session reaffirm this growing evidence of the importance of macroeconomic phenomena in determining the incentives to agriculture. In particular, Villa-Issa's paper outlines how changes in government policy in Mexico affected agriculture in particular from the postwar period. He implicitly hypothesizes that these linkages occurred through import-substituting protection and macroeconomic policy as reflected by changes in the real exchange rate and the internal terms of trade between agriculture and industry. In this note, I will elaborate on this linkage in the case of Mexico from 1965 to the present.

The Agricultural Real Exchange Rate

Although the real exchange rate is supposed to influence agricultural incentives through changing relative prices of tradable to nontradables, in the case of Mexico this transmission was imperfect because of government interventions. Although most agricultural products produced in Mexico are tradable, quantitative restrictions (including prohibitions) on exports and imports and price guarantees and controls tended to insulate agriculture from international prices and softened price transmissions to the domestic economy. Therefore, the real exchange rate alone is an imperfect indicator of overall agricultural incentives versus nontraded goods. What is needed is a more specific indicator that links agricultural prices of tradable commodities to the prices of nontraded goods (one could consider the real exchange rate as a weighted average of these sector-specific real exchange rates). To do this, we define the agricultural real exchange rate E_a as the price of agricultural tradables P_a to the price of general nontradables P_n,

$$(1) \qquad E_a = P_a/P_n = (P_a/P_t)E_r,$$

where P_t is the price of tradables and E_r is the real exchange rate.

Therefore, the agricultural exchange rate depends on the price ratio of agricultural tradables to general tradables times the real exchange rate for the economy as a whole. Defining TT as the external terms of trade of agriculture versus tradable commodities, t_a as the rate of protection of agriculture, and t_t as the protection offered tradables in general, we get from (1),

$$(2) \qquad E_a = TT(1 + t_a)/(1 + t_t)E_r.$$

Thus, the agricultural exchange rate is a function of the external terms of trade of agriculture, the differential protection offered agriculture versus other tradables, and the real exchange rate. This agricultural exchange rate enables us to find how the incentives to Mexico's agriculture were changing.

In figure 1, we plot this sector-specific exchange rate along with the economy-wide exchange rate and the rate of agricultural GDP growth. It is immediately evident that agricultural growth has been considerably more volatile than real exchange rate movements in the 1960s and 1970s and that there is no apparent correlation between the two.

The agricultural real exchange rate moved more or less in parallel with the economy-wide real exchange rate until the 1980s, when they di-

Source: World Bank data.

Figure 2. Effective protection and growth

verged by nearly 30%. The economy-wide real exchange rate remained remarkably stable until the nominal devaluation in 1976, while the agricultural exchange rate slowly appreciated until the commodity boom of the mid-1970s. After 1976, both real exchange rates appreciated until 1981, with the agricultural exchange rate appreciating even more than its economy-wide counterpart. With the onset of the debt crisis in 1982, both exchange rates rapidly depreciated; but, with import licensing reaching 100% of trade in 1983, the depreciation of the agricultural exchange rate was less severe. Following this widening between the exchange rates in 1981 and 1982 and the collapse of many agricultural interventions, especially after 1985, the agricultural exchange rate reconverged to the economic-wide exchange rate, with both depreciating by about a third. Nevertheless, agricultural growth faltered.

If, as in figure 2, we examine real protection for grains, defined as the weighted nominal protection corrected for the real exchange rate, the volatility of incentives is evident. Plotted against the agricultural growth rates, it appears that part of the instability in agriculture results from this volatility in the incentives, caused in part by direct interventions and macroinfluences.

In conclusion, it is clear that agriculture in Mexico has experienced particularly unstable incentives in the late 1970s and 1980s. Except in the early 1980s, these incentives *vis-à-vis* nontradables have followed the macroinfluences reflected by the real exchange rate, despite heavy direct intervention in agricultural trade and markets.

Federal Support to Farm Lending (Marc Johnson, Kansas State University, presiding)

Imperfect Information and the Theory of Government Intervention in Farm Credit Markets

Robert D. Innes

This paper describes some possible economic motivations for government intervention in farm credit markets. These motivations are made possible by explicit departures from the perfect information and complete market assumptions that underlie both the neoclassical competitive paradigm and the fundamental theorems of welfare economics. To be more precise, the analysis focuses on three types of asymmetric information between farmers and prospective outside investors, both of whom are assumed to be risk neutral. Arguably, the three informational asymmetries examined here represent natural departures from "perfect markets" in that, unlike the unencumbered neoclassical model, each elicits farmers' optimal use of debt contracts (rather than equity instruments or other contractual forms) to raise investment capital. Despite their consistency with observed contractual choices, all three of the models analyzed below yield free-market equilibria that diverge from first best/perfect information outcomes. Given the inefficiency of these market equilibria, the key question raised and discussed here is: Can government improve upon the derived competitive outcomes and, if so, how?

Despite the enormity of the credit rationing literature, only a few extant studies address this question in models that are consistent with debt contracts. Among them are DeMeza and Webb (1987, 1988, 1989) and Innes (1988), which focus on the third type of informational asymmetry considered below. The other two information structures posited in this paper have been studied in several analyses of credit markets, but with attention focused on positive attributes of the unfettered competitive equilibrium rather than on prospective implications for welfare-enhancing government intervention. In what follows, this literature is surveyed and, for the first two information structures, some new policy results are presented. A critical discussion of the paper's limitations concludes the article.

The One-Period Model

Consider a population of risk-neutral farmers, each of whom can invest in his farm today and realize a net worth (also called profit) tomorrow of $\pi = \pi(A, \varepsilon; x)$, where A denotes the total farm investment today, $\varepsilon \in [0, \bar{\varepsilon}]$ is a random variable with continuous density (distribution) $h(\varepsilon)(H(\varepsilon))$, and x is a nonstochastic variable to be defined later. The total farm investment, A, is financed by external (nonfarmer) funds of I, and a given amount, $A - I$, of the farmer's own wealth. In all of the model variants analyzed below, it can be shown that a farmer will invest all of his own financial resources in the farm. Therefore, $A - I$ can be treated as fixed. Moreover, when relevant (and without loss in generality), the population of farmers will be defined to have a common level of initial wealth/collateral, $I - A = W_0$. The external investment, I, will then determine A, and we can define the probability density and distribution functions for π by $f(\pi; I, x)$ and $F(\pi; I, x)$, respectively; $f(\ )$ is assumed to be strictly positive on $[0, K(I, x)]$ and zero elsewhere.

External investors are assumed to be risk neutral, rational, and competitive in the sense that they are willing to sign financial contracts which yield them an expected return of ρ, the return on a risk-free bond. The farmer/investor financial contract specifies both the external investment level, I, and the farmer's payment to the external investors for each possible realization of π, $B(\pi)$. Because of the farmers' limited li-

Robert D. Innes is an assistant professor, Department of Agricultural Economics, University of California, Davis.
Giannini Foundation Research Paper No. 928.

ability, $B(\pi)$ cannot exceed π, a constraint which rules out a fixed payment contract.

In a first-best world without any information problems, an optimal $B(\pi)$ can take any form that satisfies limited liability and that yields the investors their required expected return, ρ. Further, a first-best setting will yield an investment level, I, which solves the following maximization:

$$(1) \qquad \max_{I} E(\pi; I, x^*) - (1 + \rho)I,$$

where E is the expectation operator for π, x^* will be defined appropriately in what follows, and $E(\pi; I, x)$ is concave in (I, x). The solution to (1) will be denoted by I^*, which is assumed to be positive.

We now turn to an analysis of three different imperfect information structures. For each of these structures, relevant properties of the equilibrium farmer/investor financial contracts will be presented and the welfare effects of prospective government credit market interventions will be described. In evaluating welfare effects of policy interventions, two different criteria will be applied:

Criterion 1. Can the sum of all agents' expected payoffs be increased by the intervention?

Criterion 2. Can the intervention, together with an appropriate compensation scheme, elicit a Pareto improvement?

Because compensation has allocative effects in the models analyzed here, the answers to these questions often diverge.

Model 1: *Ex-Post* Asymmetric Information

Following the development in Gale and Hellwig (also see Townsend, Diamond, and Williamson), suppose that external investors cannot observe *ex-post* farm profit, π, or the state of nature, ε, unless they incur an observation cost of $c(I, \varepsilon)$, where $\forall(I, \varepsilon) \gg 0$, $c > 0$, $c_I \geq 0$, $c_\varepsilon \geq 0$, and $c_{II} \geq 0$. *Ex-post* profits here are simply $\pi(A, \varepsilon)$ (without x), with $\pi(\ )$ assumed to have the following properties: $\pi_A > 0$, $\pi_\varepsilon > 0$, $\pi_{AA} < 0$, and $\pi_{A\varepsilon} > 0$.

After profits are realized (i.e., after the value of ε is determined), the farmer will report a profit (or ε) level to the external investors. In principle, the farmer's report may or may not be honest. However, from the revelation principle, a contract which sometimes elicits dishonest reports is equivalent to another which always elicits honest reports (e.g., see Harris and Townsend). Restricting attention to the latter incentive compatible contracts, the farmer/investor financial agreement will specify the set of profit (or ε) reports for which investor observation occurs. If N represents the set of ε realizations wherein investors do not observe π, then $\forall\varepsilon \in N$, the farmer can and will pay investors the minimum level of $B(\pi)$ consistent with $\varepsilon \in N$, namely, $B_N \equiv \min_{\varepsilon \in N} B(\pi(A, \varepsilon))$. Thus, for incentive compatibility, $B(\pi(A, \varepsilon)) = B_N \, \forall\varepsilon \in N$. In addition, if $B(\pi(A, \varepsilon))$ were greater than B_N for some $\varepsilon_0 \notin N$, then the farmer would never report ε_0; therefore, for incentive compatibility, $B(\pi(A, \varepsilon)) \leq B_N \, \forall\varepsilon \notin N$. Given the farmer's limited liability, these incentive compatibility requirements imply that the investors must observe profits in some states of nature in order to ever obtain a positive payoff. For a given I, an optimal financial contract will minimize the expected costs of investor observation subject to the incentive compatibility, limited liability, and investor return requirement constraints. A debt contract achieves this minimum by setting $N = \{\varepsilon : \varepsilon \geq \varepsilon^*, \text{some } \varepsilon^* > 0\}$ and $B(\pi(A, \varepsilon)) = \pi(A, \varepsilon) \, \forall\varepsilon < \varepsilon^*$, thereby maximizing the payments in observation states and minimizing the probability of observation. Thus, we have:

PROPOSITION 1. *In model 1, equilibrium contracts take a standard debt form.*

Proof: See Gale and Hellwig, Proposition 4.

Note that, with debt contracts, investor observation implies farmer bankruptcy so that $c(\ )$ can now be interpreted as a bankruptcy cost.

Given proposition 1, the farmer's investment choice problem is as follows:

$$(2) \qquad \max_{I, \varepsilon^*} \int_{\varepsilon^*}^{\bar{\varepsilon}} (\pi(W_0 + I, \varepsilon) - \pi(W_0 + I, \varepsilon^*))h(\varepsilon)d\varepsilon,$$

$$(3) \qquad \text{s.t. } G(I, \varepsilon^*) \equiv \int_0^{\varepsilon^*} (\pi(W_0 + I, \varepsilon) - c(I, \varepsilon))h(\varepsilon)d\varepsilon + \pi(W_0 + I, \varepsilon^*)(1 - H(\varepsilon^*)) - (1 + \rho)I \geq 0.$$

Substituting from (3), problem (2) can be rewritten as

$$(2') \qquad \max_{I, \varepsilon^*} J(I, \varepsilon^*) \equiv \{E(\pi; I) - (1 + \rho)I\} - \int_0^{\varepsilon^*} c(I, \varepsilon)h(\varepsilon)d\varepsilon,$$

subject to (3). The solution to problem (2′) will be denoted by $(\hat{I}, \hat{\varepsilon}^*)$.

Because problem (2′) is constructed as a constrained optimization of one agent's utility subject to another agent's achievement of a given expected payoff, its solution is constrained Pareto optimal (i.e., a criterion 2 welfare improvement is not possible). However, so long as the farm does not always go bankrupt (i.e., $\hat{\varepsilon}^* < \bar{\varepsilon}$), this solution is not first best, setting $\hat{I}$ less than I^*. The reason is that, at the optimum, a marginal increase in I requires an increase in ε^* (i.e., an increase in the probability of bankruptcy) in order to preserve the investors' expected return. (If a marginal increase in I above $\hat{I}$ did not require ε^* to rise, this increase in I would unambiguously raise the value of the farmer's objective function in (2) and $\hat{I}$ could not be optimal.) Therefore, with the *ex-post* informational asymmetry posited here, marginal investment has an additional cost (*vis-à-vis* the first-best case) of raising expected investor observation costs, $\int_0^{\varepsilon^*} c(I, \varepsilon)h(\varepsilon)d\varepsilon$.

The deviation of $\hat{I}$ from I^* admits the possibility that government policy can increase total net expected payoffs in the credit market. For example, if the government simply gave the farmer I^* dollars today, the farmer would choose the first-best investment level, finance it entirely with his own funds, and thereby save the economy the investor observation/bankruptcy costs.[1] However, lump sum transfers to farmers may be very costly to achieve for a variety of reasons, including the incentives that they create for nonfarmers to invest resources in seeking the transfer rents. Therefore, it is of interest to examine the scope for another policy instrument, interest subsidies, to yield gains in total expected payoffs.

Letting ρ_0 denote the unsubsidized cost of funds, we now consider a marginal subsidy on ρ, $s > 0$, which implies a subsidized cost of funds equal to $\rho_0 - s$. Since $J(I, \varepsilon^*; \rho_0)$ represents the total (economy-wide) net expected payoff from farm investment, this marginal subsidy will be welfare improving (in the sense of criterion 1 above) if $J(\hat{I}(\rho_0 - s), \hat{\varepsilon}^*(\rho - s); \rho_0)$ is larger than $J(\hat{I}(\rho_0), \hat{\varepsilon}^*(\rho_0); \rho_0)$, where the dependence of J, $\hat{I}$, and $\hat{\varepsilon}^*$ on ρ is now made explicit. The following propositions can now be derived (see Innes 1989b for proofs):

[1] Leathers and Chavas make a similar point. However, in their model rational farmers and investors would not choose the contract forms that are assumed to prevail.

PROPOSITION 2. *Define $I^\dagger(\varepsilon^*; \rho) \equiv \text{argmax}\ J(I, \varepsilon^*; \rho)$. Then $\hat{I}(\rho_0) < I^\dagger(\hat{\varepsilon}^*(\rho_0); \rho_0) \leq I^*$ if $\hat{\varepsilon}^*(\rho_0) < \bar{\varepsilon}$.*

PROPOSITION 3. *Suppose that $\hat{\varepsilon}^*(\rho_0 - s) \leq \hat{\varepsilon}^*(\rho_0) < \bar{\varepsilon}$ so that a marginal subsidy does not lead to an increase in the probability of farm bankruptcy and, in the absence of subsidies, the farm does not always go bankrupt. Then some subsidy on ρ, $s > 0$, will yield a criterion 1 welfare improvement (i.e., it will increase the total economy-wide net expected payoff from farm investment).*

PROPOSITION 4. *Suppose $\hat{\varepsilon}^*(\rho_0) < \bar{\varepsilon}$, and let $I_G(\varepsilon^*, \rho)$ solve $G(I, \varepsilon^*; \rho) = 0$. Then a credit subsidy policy, $s > 0$, which limits subsidies to investment levels less than or equal to $\bar{I} \equiv \min(I^\dagger(\hat{\varepsilon}^*(\rho_0); \rho_0), I_G(\hat{\varepsilon}^*(\rho_0); \rho_0 - s))$ will yield a criterion 1 welfare improvement.*

A subsidy on ρ will affect the levels of both investment and ε^* (i.e., the probability of bankruptcy). By reducing the investor's required return, the subsidy has the direct effect of reducing ε^*. However, the subsidy is also likely to elicit an increase in I, which raises ε^*. If the first direct effect dominates the second investment effect (as assumed in proposition 3), then the subsidy has two beneficial consequences: (*a*) it leads to a level of I, which is closer to that which maximizes economy-wide net expected payoffs, $I^\dagger(\ )$, and (*b*) it reduces the probability of bankruptcy, thereby saving the economy some bankruptcy costs. However, even if the investment effect dominates the direct effect, benefits from a subsidy policy can be insured by limiting the subsidy to investment levels that do not increase the probability of bankruptcy. Proposition 4 defines such a policy.

Model 2: Moral Hazard

Now suppose that there are no informational asymmetries about profit realizations (as in model 1) or farmer attributes (as in model 3), but that the farmer makes an effort choice that affects the farm profit distribution and is unobservable to external investors. Because the effort level, e, is hidden, the farmer/investor financial contract cannot specify e and, in setting financial contract parameters, investors must infer effort choices from the farmer's underlying choice problem. Thus, a standard principal agent problem emerges.

To analyze this problem formally, let $x = e$

and assume the following ($\forall \pi \in [0, K(\ \ )]$ and $\forall(I, x) \in R_+^2$):

$$(4)\quad \frac{\partial}{\partial \pi}\left(\frac{f_x(\pi; I, x)}{f(\pi; I, x)}\right) > 0, F_I(\ \ ) < 0,$$

and $B(\pi)$ is nondecreasing

Equation (4) implies that higher levels of x (i.e., e) and I elicit better profit distributions in the sense of the monotone likelihood ratio property, MLRP (see Milgrom), and first-order stochastic dominance, FOSD, respectively. (Note that the MLRP implies FOSD, but not vice versa.) Assuming $B(\ \ )$ to be monotone provides a weak restriction on contract forms that can be motivated by a prospective ability of investors to sabotage the farm *ex-post.*

For expositional convenience, the following implication of (4) is now stated, deferring its explanation until later:

PROPOSITION 5. *In model 2, equilibrium contracts take a standard debt form, $B(\pi) = min(\pi, z)$.*

Proof: See Innes (1990).

Proposition 5 implies that the financial contract is fully characterized by the pair (I, z). Given (I, z), the farmer is considered to choose effort to solve the following problem:

$$(5)\quad \max_e \int_z^{K(I,e)} (\pi - z)f(\pi; I, e)d\pi - v(e),$$

where $v(e)$ is the disutility of effort, with $v_e > 0$ and $v_{ee} > 0$. Denoting the solution to (5) by $e(I, z)$ (a function which the investors are assumed to know), the following investor return requirement implicitly defines $z(I)$, the promised payment demanded by investors when they invest I dollars in the farm:

$$(6)\quad E(\min(\pi, z)|I, e(I, z)) = (1 + \rho)I.$$

Abusing notation somewhat, a given investment level I elicits the effort choice $e(I) \equiv e(I, z(I))$. With a substitution from (6), the complete choice problem can now be stated as follows:

$$(7)\quad \max_{I,e} E(\pi|I, e) - (1 + \rho)I - v(e) \quad \text{s.t} \quad e = e(I).$$

The solutions to (7) will be denoted by $(\hat{I}, \hat{e})$. As in model 1, these equilibrium outcomes are the solutions to a constrained optimization problem and, hence, are constrained Pareto optimal (Brander and Spencer). However, they are not first best.

In order to relate $(\hat{I}, \hat{e})$ to their first-best counterparts, it is useful to define a quasi-first-best effort choice function, $e^*(I)$, as the solution to the following problem:

$$(8)\quad \max_e E(\pi|I, e) - (1 + \rho)I - v(e).$$

The following relationship can now be derived (see Innes 1989b for proof):

PROPOSITION 6. *$e(I) < e^*(I)$ when $I > 0$.*

For a given investment level, the farmer employs less effort than he would in a first-best world for the following reason. Being unable to commit to a given e, the farmer must share some of the benefits from marginal effort (i.e., the resulting increase in expected profits) with the external investor, while bearing the full disutility cost of marginal effort, $v_e(e)$. Of course, the farmer would like to commit to an effort level that is as close to $e^*(I)$ as possible. This desire motivates debt contracting. To be specific, marginal effort shifts probability weight from low profit levels to high profit levels. By choosing a contract form that maximizes his own payoffs in high profit states, the farmer will maximize his incentives to exert effort and thereby permit himself to implicitly commit to a higher level of e. Among all possible monotonic contract forms, debt contracts maximize the farmer's payoff in high-profit states of nature, thereby minimizing the disparity between $e(I)$ and $e^*(I)$.

The deviation from a first best suggests scope for policy interventions to yield criterion 1 welfare benefits. To explore this possibility, note that, because of proposition 6, the constraint in problem (7) can be replaced by the inequality restriction, $e \leq e(I)$, without loss in generality. This restatement of problem (7) is convenient because it implies the following proposition:

PROPOSITION 7. *The following conditions are sufficient for a policy measure to elicit a criterion 1 welfare improvement in model 2: The policy (a) raises $e(I)$ for all $I > 0$, and (b) preserves the farmer's objective function in (7).*

Proof: From (*a*), the policy enlarges the opportunity set for the modified problem (7) [i.e., (7) s.t. $e \leq e(I)$]. Therefore, from condition (*b*), proposition 6, and by revealed preference, the policy elicits a higher value of the objective function in (7). Q.E.D.

Now consider the following two policies: (*a*) A government grant to the farmer of G, where G is (*i*) given at the time that profits are realized and (*ii*) not large enough to fully cover the farm-

er's loan obligations at the post-grant equilibrium. (*b*) An interest subsidy, $s > 0$, on investment levels no greater than $\bar{I}$, where $\bar{I}$ is less than the (post-subsidy) equilibrium level of I. When $s\bar{I} = G$, these two policies are equivalent, each yielding the following augmented investor return requirement:

$$(6') \quad E(\min(\pi, z)|I, e(I, z)) = (1 + \rho)I - G,$$

(6′) implicitly defines $z(I, G)$, with $z_G(\ ) < 0$. Substituting from (6′), the farmer's choice problem is identical to problem (7) except that the constraint becomes $e \leq e(I, z(I, G)) \equiv e(I, G)$, where

$$(9) \quad e_G(I, G) = e_z(I, z(\ )) \cdot z_G(\ ) > 0.$$

Therefore, these policies satisfy the requirements of proposition 7 and elicit criterion 1 welfare gains.

Model 3: *Ex-Ante* Asymmetric Information

Finally, following Innes (1988), consider a setting in which there are no moral hazard problems or profit observation costs but there is asymmetric information about the quality, q, of a farmer's profit distribution. Each farmer is either high ($q = H$) or low ($q = L$) quality and is assumed to know his own quality type. However, external investors cannot directly observe a farmer's q and, in the absence of farmer signaling, can only infer that a given agricultural borrower is high quality with probability θ, where θ is the proportion of high quality borrowers in the population of farm loan applicants. Farmer signaling/self-selection can occur if two financial contracts emerge in equilibrium, one of which is preferred by high-quality farmers and the other of which is preferred by low-quality farmers.

In this model, the variable x corresponds to q, the farmer's quality type, and the conditions in (4) are assumed to hold. Thus, high-quality farmers have better profit distributions in the sense of the MLRP. It is also assumed that high-quality farmers have better marginal investment returns in a sense to be made precise momentarily.

Following Wilson, equilibrium in this model is a set of contracts $(B_q(\pi), I_q)$, $q = L, H$, which maximizes the net expected payoff of the high quality entrepreneur subject to three constraints:

(*E*1) investor return requirement: investors earn at least their required expected return, ρ, on each distinct contract;

(*E*2) incentive compatibility: low-quality farmers weakly prefer their own contract; and

(*E*3) low-quality payoff: low-quality farmers earn an expected payoff at least as high as on their perfect information contract.

(*E*1)–(*E*3) represent feasibility constraints on the equilibrium. Moreover, since investors are competitive, any contracts which satisfy (*E*1)–(*E*3) but do not solve the posited high-quality farmer maximization problem will be supplanted by investor offers of the contracts that do solve this problem; the latter solutions will attract the business of at least the high-quality farmers, thereby earning the investors that offer them no less than (and possibly greater than) their required expected return.[2]

For this specification, the following result is proven in Innes (1989a):

PROPOSITION 9. *In model 3, any equilibrium contract either takes a standard debt form or is equivalent to one which does.*

In essence, debt contracts maximize investor payoffs in low entrepreneurial profit states of nature. Since low-quality types have probability weight concentrated in these states, high-quality agents, by taking a debt contract, can minimize the low-quality types' incentive to masquerade. The incentive compatibility constraint (*E*2) is thereby relaxed, permitting higher net expected profits for the high-quality entrepreneur. Thus, proposition 9 emerges and, as before, a contract can be completely described by a pair, (I, z).

Two graphical constructs now permit a simple characterization of the equilibrium (see fig. 1): (1) Farmer indifference curves (IC_q), which give the (I, z) contracts that yield a quality q farmer a given (constant) net expected payoff,

$$IC_q: \int_z^{K(\ )} (\pi - z) f(\pi; I, q) d\pi = \text{constant}.$$

(2) Investor offer curves, which give the (I, z) contracts that yield investors exactly their required expected return when (*a*) the contracts are taken by a quality q farmer (OC_q) and (*b*) the contracts are taken by both types of farmer (OC_p, where p is for "pooling"),

$$OC_q: E(\min(\pi, z)|I, q) = (1 + \rho)I.$$

$$OC_p: \theta E(\min(\pi, z)|I, H) + (1 - \theta)E(\min(\pi, z)|I, L) = (1 + \rho)I.$$

[2] See DeMeza and Webb (1989) and Innes (1988) for a more complete motivation of the Wilson equilibrium.

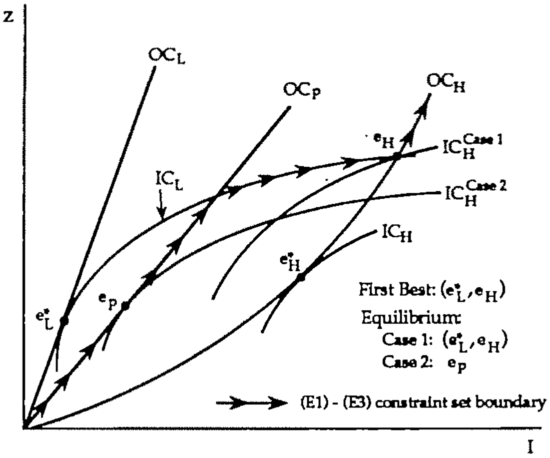

Figure 1. Model 3 equilibrium

Because farmers "like" investment, I, and "dislike" payments to investors, z, indifference curves are upward-sloping and lower curves (in fig. 1) correspond to higher farmer payoffs. In addition, it is assumed that high-quality indifference curves are steeper than low-quality indifference curves due to superior high-quality marginal investment returns.[3] Since investors like z and dislike I, offer curves are also upward-sloping. Further, OC_H is below OC_L due to "better" high-quality profit distributions.

The first-best in this model is the set of tangencies between IC_q and OC_q for $q = L, H$. To make the analysis interesting, it is assumed that these contracts violate incentive compatibility in that the low-quality farmer prefers the high-quality type's first-best contract to his own (see fig. 1). Two types of equilibria are then possible.

Case 1: As shown in figure 1, the equilibrium high-quality contract corresponds to the point on the $(E1)$–$(E3)$ constraint set (as indicated by arrows) that is on the lowest IC_H; in case 1, this contract is e_H, which exactly deters adverse selection by low-quality farmers.

Case 2: When the high-quality farmer prefers his favorite pooling contract, e_p, to e_H, e_p emerges in equilibrium.

The following proposition is now graphically evident (see Innes 1988 for a proof):

PROPOSITION 10. *(i) In a model 3 pooling equilibrium (case 2), $I_L < I_L^*$ and $I_H > I_H^*$, where I_q^* is the first-best investment level for a quality q farmer. (ii) In a model 3 separating equilibrium (case 1), $I_L = I_L^*$ and $I_H > I_H^*$ (i.e., the high-quality farmer overinvests in order to signal his type).*

Given the equilibrium's deviation from a first-best, it is of interest to evaluate the prospective welfare benefits of typical policy interventions. For space reasons, only one type of intervention is considered here, namely, the government's direct offer of a subsidized credit contract that is designed for low-quality farmers. In figure 2, a subsidized contract, e_L^s, is constructed so that low-quality farmers invest at their first-best level and are indifferent between e_L^s and the first-best high-quality contract, e_H^*. It is assumed that either (*a*) e_L^s is above OC_H so that high-quality farmers would not choose to take e_L^s and obtain supplemental private financing, or (*b*) the government offer of e_L^s is combined with a requirement that any takers of this contract obtain no supplemental financing. Then the government offer of e_L^s will elicit a first-best equilibrium by reducing the low-quality farmer's incentive to masquerade as high quality, thereby relaxing the incentive compatibility constraint which is driving the free-market inefficiency. A criterion 1 welfare benefit will thereby result from the intervention.[4,5]

A Few Extensions and Limitations

(*a*) *Entry by inefficient farmers*. DeMeza and Webb (1987) study an analog to model 3 with fixed investment levels (per farm) and the presence of many different farmer quality types. This model yields a pooling (all-debt) equilibrium wherein the lowest quality farmer that operates (i.e., borrows and invests) has a sufficiently poor profit distribution that he would not farm in a "first-best" setting. The reason for the presence of these inefficient farmers is that, in equilibrium, they face a high-quality-farmer-subsidized interest rate which is lower that they would face with perfect information. The resulting ov-

[3] Milde and Riley construct a model in which low-quality indifference curves are steeper due to identical high- and low-quality marginal investment returns. Implications of the latter specification are discussed in Innes (1988).

[4] Model 3 competitive equilibria can often be improved upon in the criterion 2 sense as well (see Innes 1988).

[5] A similar policy result can also be derived in fixed investment models wherein costly collateral provision serves as a signaling mechanism (e.g., see Besanko and Thakor, and Chan and Kanatas).

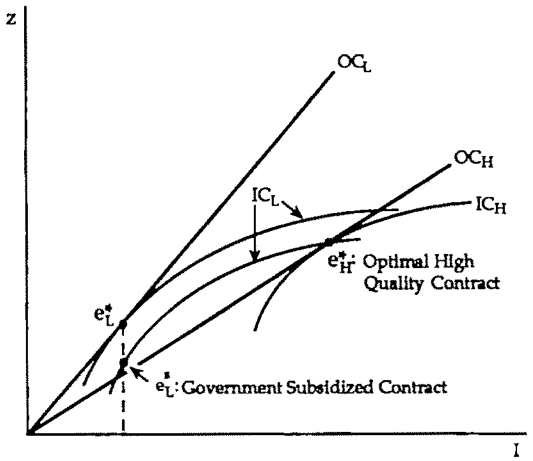

Figure 2. Proposed government debt subsidy policy

erinvestment can be deterred by taxing the loan contract rather than providing subsidies. If farmer investment choices are permitted, as in model 3 above, the possibility of entry by inefficient farmers (i.e., "lemons") may or may not alter the policy conclusions described here [see Innes (1988, pp. 28–29)]. However, the tradeoffs created by a joint policy objective of curtailing both signaling costs and inefficient production by "lemons" deserves more rigorous analysis.

(*b*) *Alternative market and information structures*. This paper has assumed that investors are competitive. However, in many cases, farmers may face a small number of possible lenders, yielding investor market power that can have important implications for the positive and normative properties of equilibrium.[6] In addition, banks (investors) may conceivably be in a position to obtain an informational advantage over farmers concerning both the farmer's own "quality" type and the attributes of his profit distribution. The latter possibility contrasts sharply with the construction of model 3 and merits further thought.

(*c*) *A final caveat*. For obvious reasons, the paper abstracts from several issues that are likely to be important in gaining a fuller understanding of farm credit markets. Foremost among these abstractions is the role of government as a frictionless and benevolent intervenor. In fact, government is subject to political economic forces as well as costly frictions in the processes of both raising revenue and allocating subsidies. Of equal importance are the neglect of equilibrium effects in output and input (e.g., land) markets, and of dynamics.

[6] See the interesting papers by Chambers and Lee, and Besanko and Thakor for some discussion of monopoly lender behavior in financial markets with asymmetric information.

The Effects of Federal Credit Programs on Farm Output

Michael T. Belongia and R. Alton Gilbert

Institutions with the direct or implied support of the federal government have supplied on average in the 1980s 45% of total credit received by the agricultural sector of the U.S. economy. The Farm Credit System (FCS), a borrower-owned cooperative whose bonds carry an implied federal guarantee, held about 27% of total outstanding farm debt in 1987. The Farmers Home Administration (FmHA), a federal agency that makes loans to farmers who are attempting to cope with emergency situations, held an additional 17%.

A primary objective of these public credit programs is to facilitate agricultural production by providing credit that, presumably, would be unavailable to farmers from other sources (Meekhof; Barry and Boehlje, pp. 129–30).[1] This justification for federal support in the supply of credit to farmers raises at least two issues. First, because it seems unlikely that private sector lenders would forego profitable lending opportunities, both a rationale for this discrimination against farm borrowers and evidence that it exists are needed. Second, even if there were some discrimination against farmers as borrowers, the fungibility of credit suggests that at least some publicly supplied credit targeted for agriculture would be diverted to higher-yielding investments, thus reducing its effect on agricultural production. The issue in this case is not whether credit is diverted but, rather, the extent to which it occurs.

In this paper we use a model of credit rationing to evaluate whether farmers receive more of their credit from federal agencies when the aggregate supply of credit declines. We then examine the relationship between credit originating from the FCS and FmHA and changes in farm output.

Credit Rationing

Credit rationing typically is defined as an instance in which borrowers do not receive all of the credit they desire at the prevailing interest rate. Stiglitz and Weiss argue that banks may prefer to ration credit to borrowers on nonprice terms rather than raising interest rates in response to excess demand for bank credit because higher interest rates on loans may attract relatively high-risk borrowers or induce their existing loan customers to pursue riskier projects. To avoid this adverse selection problem, which may cause expected bank profits to decline, the credit-rationing hypothesis posits that banks attempt to make distinctions among borrowers on the basis of characteristics associated with relatively low risk. Thus, if farmers represent a relatively large share of those borrowers who are perceived as a high-risk group, they may receive less credit from the private sector when the aggregate supply of credit declines.

The credit-rationing hypothesis applied to agricultural credit markets implies several testable hypotheses. First, the share of government-supported lending to farmers should increase as a share of total lending to farmers when the aggregate supply of credit declines. This relationship is modeled formally in equation (1), where G is credit extended to farmers by the FCS and FmHA, TF is total farm credit, and TC is total aggregate credit.

$$(1)\quad \Delta \ln\left(\frac{G}{TF}\right) = a + \sum_{i=0}^{P} b_i\, \Delta\Delta \ln TC_{t-i} + e_t.$$

As written, (1) relates percentage changes in the share of total farm credit originating from the FCS or FmHA to changes in the growth rate of total credit. If farmers face credit rationing, the sum of coefficients on changes in the growth

---

The views expressed do not necessarily represent those of the Federal Reserve Bank of St. Louis or the Board of Governors of the Federal Reserve System.

Richard A. King, Marc Johnson, Ewen Wilson and staff at the Economic Research Service provided comments on an earlier draft. Laura Prives provided research assistance.

[1] More background on the justifications for farm credit programs is provided in Bosworth, Carron, and Rhyne, pp. 6–10 and chapter 5.

rate of total credit (*TC*) should be negative: the share of farm credit from government agencies will tend to rise when the growth rate of total credit declines.

An increase in the quantity of credit supplied to farmers by government-sponsored programs, however, may offset reductions (if any) in farm credit from the private sector. In this case, the total supply of credit to the farm sector would be insulated from the effects of changes in aggregate credit supply. To examine how changes in the aggregate supply of credit affect the share of total credit extended to farmers, equation (2) also was estimated:

$$(2)\quad \Delta \ln\left(\frac{TF}{TC}\right) = a + \sum_{i=0}^{p} b_i\, \Delta\Delta \ln AMB_{t-i} + u_t\,,$$

where the change in the growth rate of the supply of credit is measured using the adjusted monetary base (*AMB*). Growth of the *AMB* reflects Federal Reserve actions that affect the ability of banks to extend new credit. If credit rationing exists, the sum of coefficients for changes in the growth rate of the monetary base should be significantly greater than zero. That is, farmers would receive a smaller share of total credit when growth in the aggregate supply of credit slows. The relationships in equations (1) and (2) are similar to those reported by Blinder and Stiglitz.

The results of these estimations, using annual data over 1947–86, are reported in table 1. The models were estimated for lags on right-hand-side variables up to three years, but only the results for the best overall regressions are reported. The results from equation (1) offer some evidence that farmers face nonprice credit rationing. As growth in total credit slows, the share of farm credit from government sources is observed to rise significantly. Although equation (2) does not show a significant relationship between Federal Reserve actions that affect the total supply of credit and the share of total credit to farmers, these results nonetheless provide some evidence on credit rationing. A story consistent with these two results is that farmers are subject to credit rationing in the private sector [equation (1)] but, because of the federal credit programs, are able to maintain a fixed share of total credit during a contraction of credit supply [equation (2)]. Therefore, if the FCS and FmHA are justified on the assertion of a credit-rationing process, these results support that assertion.

Table 1. Results of Tests for Credit Rationing

$$(1)\quad \Delta\ln\left(\frac{G}{TF}\right) = \underset{(1.89)}{1.857} - \underset{(2.07)}{1.438}\Delta\Delta\ln TC_t$$

$\bar{R}^2 = 0.09$ $\quad F = 4.296 \quad$ D-W = 2.04

$$(2)\quad \Delta\ln\left(\frac{TF}{TC}\right) = \underset{(1.10)}{-1.330} - \underset{(0.16)}{0.155}\Delta\Delta\ln AMB_t$$

$\bar{R}^2 = -0.03$ $\quad F = 0.024 \quad$ D-W = 0.47

Note: Absolute values of *t*-statistics are in parentheses.

Credit in a Model of Agricultural Output

Even in the presence of credit rationing, an additional issue is relevant to the existence of federal agencies that direct credit to farmers. In this case the question is whether credit from public institutions will stimulate agricultural production. Because the FCS and FmHA typically lend to farmers at interest rates below those charged by private sector institutions, the public credit programs would tend to function more as a pure subsidy.[2] Variations in the subsidies, therefore, would induce variations in the amount of credit demanded from the public agencies. But borrowers, subject to the restrictions and monitoring of the public credit programs, could very well use the credit for purposes other than agricultural production. Moreover, restrictions on the nonagricultural use of farm credit from public agencies can be circumvented in a variety of ways.[3] Thus, if credit is diverted to its highest-valued opportunities and these are not in farm production, the existence of the federal credit agencies may have little impact on farm output.

Specification of the Model

The role of credit as a determinant of agricultural output can be analyzed within a theoretical model of the demand for and supply of agri-

[2] Bosworth, Carron, and Rhyne estimate the FCS is able to lend at rates 0.1 to 0.5 percentage points less than comparable private sector lenders. See their chapter 5 for more discussion of this subsidy and its effects.

[3] Suppose, for example, that a farmer receives subsidized credit from a public agency for the first time in the current year. If the farmer uses the funds from the public agency to buy his usual amount of farm inputs, his equity, which in prior years had been used to buy farm inputs, could be invested in nonagricultural concerns.

cultural output. Credit is incorporated into the supply function under the assumption that farmers must borrow in order to increase the quantity of inputs they employ.

Demand for agricultural output is specified as a function of contemporaneous real gross national product (GNP) and the difference between the rates of change in agricultural prices and prices of nonfarm commodities:

$$(3) \quad \Delta\ln Q_t^D = a_0 + a_1\,\Delta\ln RGNP_t + a_2\,(\Delta\ln P_t^F - \Delta\ln P_t^{NF}) + e_t\,,$$

where Q^D is demand for agricultural output, *RGNP* is real GNP, P^F is the price level for farm output, P^{NF} is the price level for nonfarm output, and e_i is a random error term $\sim N(0,\sigma^2)$. We expect $a_1 > 0$ and $a_2 < 0$. In general, this assumes that demand for farm output will move with changes in aggregate demand and will vary inversely with changes in the farm/nonfarm relative price ratio.

The supply function, equation (4), can be written as

$$(4) \quad \Delta\ln Q_t^S = b_0 + b_1\,\Delta\ln INPUT_{t-1} + b_2\,\Delta\ln PROD_t + b_3\,(\Delta\ln P_t^F - \Delta\ln P_t^{NF}) + \mu_t\,,$$

where Q^S is supply of agricultural output, *INPUT* is the real value of farm inputs, *PROD* is the productivity of farm inputs, and μ_t is an error term with classical properties. We expect b_1, b_2, and $b_3 > 0$. This specification incorporates a lag in production by making output in the current calendar year a function of the real value of inputs purchased in the prior year. The index of input productivity is derived by dividing an index of farm output by an index of mechanical power and machinery inputs.[4] Constructed in this way, the productivity measure reflects both transitory influences, such as weather, and more permanent influences, such as new types of machinery.[5] The relative price variable captures the responsiveness of the supply of agricultural production to changes in the relative price of agricultural commodities in the current year, given the investment of inputs made in the prior year.

Credit is incorporated into the supply function through a third equation that specifies agricultural inputs as a function of the real value of agricultural credit. That is, by writing

$$(5) \quad \Delta\ln INPUT_t = c_0 + c_1\,\Delta\ln CREDIT_t + v_t\,,$$

where $c_1 > 0$, it is possible to substitute the terms on the right side of equation (5) for the variable $\Delta\ln INPUT_{t-1}$ in equation (4). The reduced-form equation for agricultural output then is derived by treating the supply and demand functions as a system of equations and solving for $\Delta\ln Q_t$:

$$(6) \quad \Delta\ln Q_t = d_0 + d_1\,\Delta\ln RGNP_t + d_2\,\Delta\ln PROD_t + d_3\Delta\ln CREDIT_{t-1} + z_t\,,$$

where d_1, d_2, and $d_3 > 0$. In this reduced form, the relative price variable ($\Delta\ln P_t^F - \Delta\ln P_t^{NF}$), which appears in both the supply and demand functions, is eliminated and the coefficients d_0 and d_1 through d_3 are combinations of the coefficients on the variables in equations (3) through (5).

To use equation (6) to test hypotheses about the effect of public sector credit on farm output, the aggregate credit variable must be disaggregated. A first refinement separates total credit into real estate and non-real estate debt. The presumption is that real estate debt (*REDEBT*) should have little impact on output because it would be used primarily to finance transfers of ownership of farmland already in production. Thus, if credit has any effect on output, it should be associated with non-real estate credit (*NREDEBT*) used to purchase the variable inputs of production. A second division of total credit segments non-real estate credit into that provided by private sector lenders (commercial banks) and public sector lenders [FmHA and the Production Credit Associations (PCAs) of the FCS]. If public sector lending to agriculture increases farm output, either the FmHA or PCA variables should have significant and positive coefficients.[6]

Estimation

Farm output, the dependent variable in regressions reported in table 2, is the real value of U.S. gross domestic product in the farm sector as reported in the GNP accounts. Annual data are used; the number of annual observations is

[4] The choice of which input to use as a benchmark for a productivity series is somewhat arbitrary. The machinery series was chosen under the assumption that it is the type of capital expenditure most likely to be related to an extension of credit. See Ball for an analysis of measures of productivity in U.S. agriculture.

[5] Although the *PROD* measure reflects both transitory and permanent influences on the productivity of farm inputs, distinguishing between them is not crucial to the hypothesis under investigation, and no attempt is made to separate these influences.

[6] The coefficients on credit from public sector sources need not be as large as those on private credit, however, because credit from the public institutions may finance the operations of the least efficient farmers. Barry and Boehlje, pp. 137–41.

constrained by the availability of data on total farm debt, divided into the real estate and non-real estate components, which are available only since 1940. These data are used in regression (1) of the table. Data for selected categories of lenders are available from 1934 and are the basis of regressions (2) and (3).

The results in regression (1) indicate that neither the non-real estate nor real estate measure has a significant effect on farm output; contemporaneous values for the credit variables also failed to produce significant coefficients for any measure of farm credit. Regression (2), which distinguishes between credit originating from public and private sector lenders finds that none of the coefficients associated with non-real estate credit, either from the FmHA and PCAs or from commercial banks (*BANK*), is statistically significant at the 5% level. These results reject a link between public sector lending for the purchase of variable inputs and increased farm output. Of the real estate credit measures, neither that from the Federal Land Banks nor that from other sources has a significant influence on farm output. These results similarly refute the notion that farm output would be adversely affected by a deficiency in privately supplied credit for farmland purchases and question one of the primary rationales for the existence of the Federal Land Banks.

It should be recalled, however, that the observations on farm output and farm credit for about the first ten years of data used in equation (6) reflect unusual circumstances. The years include part of the Great Depression, when the banking system was weakened by widespread failures, and World War II, which had substantial effects on resource allocation. Assuming that the weakness of the banking system and poor returns in agriculture discouraged farm lending during this period, credit from government agencies may have been more important in facilitating agricultural production than during later periods. To account for the possibly unique influences for the years 1936–45, regression (3) adds variables that are the components of non-real estate debt in regression (2) multiplied by a dummy variable (D); this dummy takes a value of unity in the first years through 1945 and zero for subsequent years. Including the additional variables has little effect on the results: none of the credit variables is significant and the prewar–postwar distinction apparently is unimportant.

Conclusions

Federal involvement in the supply of farm credit is justified by arguing that there are imperfections in the supply of credit to farmers by the private sector. Tests for credit rationing provide evidence consistent with the idea of discrimination against farmers as a class of borrowers: when growth in total credit slows, the share of farm credit originating from federal agencies rises. Regression results for the influence of farm credit on farm output, however, reject the hypothesis that non-real estate credit either from public or private sources has positive and statistically significant effects on farm output. Thus, the results fail to indicate an important role for subsidized credit in facilitating agricultural production and, in doing so, suggest that this credit is fungible and diverted to higher-valued opportunities.

Moral Hazard in Federal Farm Lending

Eddy L. LaDue

In financial markets, moral hazard occurs at both the institutional and borrower level.[1] It is currently an issue relative to commercial banks and, particularly, savings and loans, where the insurance provided by FDIC and FSLIC has resulted in high-risk activities by institutions under financial stress (Barth, Bartholomew, and Labich). Moral hazard at the individual level results whenever the borrower's economic environment contains incentives which encourage actions that reduce the probability of repaying a loan.

In its role as the lender of last resort to agriculture and as a social program to encourage entry or continuation in agriculture, the Farmers Home Administration (FmHA) operates a number of loan programs that the private sector would not provide. One of the problems that these programs face is that they provide economic incentives for the farmer to make decisions which reduce the likelihood of repayment and increase government costs. In the discussion that follows, I will (*a*) identify some of the more important situations where moral hazard may be important, (*b*) review the data available that indicate the presence or severity of the problem, and (*c*) discuss some of the possible procedures for minimizing costs.

Moral Hazard Situations

At a very basic level, the mere existence of a safety net program such as that provided by FmHA programs, particularly emergency loan programs, provides incentives for farmers and lenders to take higher-risk positions (Barry, Kaufman). Some farmers may undertake higher-risk activities, using private funds, knowing that if the venture is not successful, they will become "eligible" for FmHA programs. Lenders may encourage this strategy knowing that they have a good chance of shifting the borrower to FmHA should a financially distressed situation result (Herr and LaDue).

At the individual program level, FmHA's periodic reassessment provisions for their limited resource and low-income housing programs create strong incentives. Under these programs, borrowers are charged below market (subsidized) interest rates, and at periodic intervals, usually every two years, FmHA reviews the financial position and cash flows of the borrower to determine whether the borrower can afford to pay a higher interest rate. If cash flows will support greater interest payments than are currently being made, the interest rate being charged is raised to the lower of (*a*) the level the cash flow can support or (*b*) the unsubsidized regular (contract) rate in effect at the time the loan was made.

Within this environment, except for the lumpiness caused by the length of the reassessment interval, any increase in income is paid to FmHA in the form of higher interest payments until the rate of payments equals the contact interest rate. The borrower has little incentive to increase income unless the increase would push cash flow above the level necessary to allow payment of interest at the contract rate. In effect, the borrower receives zero marginal product for efforts required to get cash flows up to the contract rate and 100% of efforts above that level. Given the lumpiness of real-world activities, many activities with substantial marginal products that might push income over the contract rate level will not be undertaken because the marginal products received by the borrowers will be small. Farmers, and rural homeowners whose income comes from operation of small businesses, are encouraged to

Eddy L. LaDue is a professor of agricultural finance, Cornell University.

Helpful comments on an earlier draft were received from William Herr, John Brake, George Casler, and Bernard Stanton.

[1] Moral hazard is defined as actions of economic agents who maximize their own utility to the detriment of others in situations where the agents do not bear the full consequence (costs) of their actions because of uncertainty or the inability of the contracts used to assign full damages to the agent responsible (Eatwell, Milgate, and Newman). Moral hazard differs from adverse selection in that moral hazard refers to actions taken by managers which influence the performance, including risk, of the business, while adverse selection refers to situations where managers of higher risk or lower performing businesses are more likely to select (participate in) a program.

make investments in the business that will reduce current income (i.e., land and building improvements) but result in higher incomes in later years when subsidies are no longer being received. The program also provides incentives to underreport income whenever income is not clearly documented.

FmHA requires farmers to "graduate" to commercial credit whenever their income and financial position have sufficiently improved to obtain credit from other lenders. The contract rates charged by FmHA are generally the rate paid by the U.S. Treasury for funds of similar term plus up to 1%. Although such rates do not involve a subsidy payment by the government, they are normally considerably below competitive market rates for financing farm businesses. Some FmHA rates are fixed at even lower rates. Graduation, then, means giving up a favorable interest rate. Farmers nearing a financial position which would allow (require) graduation have little incentive to maximize income or reduce expenses, including family living expenses, when all, or a major part, of the income improvement would be paid to the commercial lender to cover the higher interest payment.

The loan guarantee program provides moral hazard incentives to the commercial lender. Because only 10% of any loss (90% guarantee) is borne by the lender, the economically rational level of attention to detail in loan documentation, servicing, and mitigation of losses on problem loans is much below the level that could be expected on the lender's nonguaranteed loans. Under these conditions, loan losses would be higher and lenders would have a tendency to follow the legal requirements "by the book" rather than the spirit within which they were developed.

The foreclosure moratorium which FmHA was effectively under for a number of years, as a result of *Coleman* v. *Block*, provided strong disincentives to repay FmHA loans. It was clear to farmers that no severe penalty could be assessed by FmHA for delinquency. The cost to the borrower for not paying local merchants and other lenders could be loss of services and of the ability to farm. The cost of not paying FmHA was minimal because they could not foreclose and do not compound late interest charges (do not charge interest on interest). Farmers who could not make all debt payments received a clear signal as to who not to pay. Farmers with (perceived) investment opportunities with higher rates of return than the rates charged by FmHA (zero on unpaid interest) had incentive to allow FmHA delinquencies to occur or mount.

The loan-servicing program, developed as a result of the Farm Credit Act of 1987, allowed farmers with insufficient cash flow to repay debts to pay off their debt by paying the recovery value to FmHA. The FmHA recovery value was the market value minus all costs FmHA would incur in foreclosing and selling the assets. In many cases this was a very favorable price for the assets. In most cases farmers in this financial condition could not obtain the financial backing necessary to pay the FmHA recovery value. However, because most of these farmers were headed out of business anyway, there was incentive for them to find a purchaser of the assets, for a price between fair market value and recovery value, who would provide the funds for the farmer to purchase the assets back at the recovery value. The assets would then be immediately sold to the funds provider (frequently in the parking lot outside the FmHA office) at a price favorable to both.

The most important set of moral hazard incentives created by FmHA programs likely results from their role as a last resort lender. Within that role, low-equity loans are extended. The borrowers frequently have promise but are not proven managers (Farm Ownership and Farm Operating Loans). They may also have been placed in a weak financial position by natural or economic disasters (Disaster Emergency and Economic Emergency Loan Programs).

Under this set of conditions, a significant proportion of borrowers will find themselves in a zero or negative equity position where the value of the business is less than the outstanding principal and interest on the loan (L). The value of the business that is relevant here is the recoverable value to the farmer (R). Although most farm assets are saleable, there are normally selling costs and, in some cases, contingent tax liability that will reduce the recoverable value. For many businesses, these costs may range from 10% to 25% of the market value of the assets.

Whenever $L \geq R$, the economic loss associated with failure is zero. The disutility associated with higher risk levels becomes small. High-risk strategies with a higher expected payoff and higher probability of failure become optimal. Given that an average farm business cannot generate the cash flow to make the payments on a very low-equity business (LaDue 1979), operators may, in fact, be economically forced to adopt such strategies.

The actual actions of a farmer will be modified to some degree by his or her expectations

relative to the probability that the business will be able to achieve a position where $R > L$. At the time most initial FmHA Operating and Ownership Loans are made, the expected probability is high. This is also true for some Emergency Loans. However, many Emergency Loans are made in situations where this is the last hope for survival, and the expected probability of survival is quite low.

Borrowers who have farmed with FmHA loans for a number of years and who still find that $R \leq L$ may be subject to a different set of expectations. As the expected probability of success declines, the perceived benefit from making payments to FmHA and maintaining assets used as collateral moves toward zero. Any income earned and not consumed becomes the property of FmHA with no benefit to the operator. This could lead to a lower level of input by the operator, nonmaintenance or nonreplacement of assets and increased consumption expenditures, particularly of luxury items.

The Emergency Loan programs are particularly susceptible to providing the financing that moves farmers into the position where the recovery value is less than the loan value and establishing cash flow requirements that do not allow recovery from that position. A farmer who obtains a loan for crop losses is effectively being allowed to spread much of one year's expenses over a number of years for a modest additional annual cost. This means that returns must be above average in the coming few years in order to pay for the annual installment on the crop loss. Unless the farm has above-average profitability, it is unlikely that income will be sufficiently high to allow the higher payment level and provide funds for any financial progress of the business. In these cases, the Emergency Loan programs tend to delay rather than forestall default and bankruptcy. Farmers tend to accept such situations because future bankruptcy is generally preferred to current bankruptcy.

Empirical Observations

The amount of data available to document the severity of the moral hazard problem for the Farmers Home Administration is small. For some cases, the observed results are the joint product of moral hazard and other factors, such as adverse selection and the normally lower success rate of highly leveraged farm businesses. This makes isolation of the moral hazard effects difficult. In other cases, FmHA does not collect and/or summarize the data that would be required.

The incentives generated by the interest subsidy reviews could be expected to result in most borrowers paying either the initial limited resource or subsidized housing rate (as long as potential income is less than that necessary to pay the contract rate) or the contract rate, with few paying any rate in between. Unfortunately, FmHA does not collect data at either the state or national level on the results of the subsidy reviews. The distribution of interest rates paid or the average rates paid by loan program could also provide evidence of the magnitude of this problem. However, the data are not summarized in this manner.

A national study of FmHA borrowers using data collected during 1977–78 (LaDue 1984) found that 17% of the existing Emergency Loan borrowers and 14% of the Farm Ownership Loan borrowers likely had the resources to graduate to other sources of credit but continued with FmHA in order to continue receiving low interest rates.

Unpublished data on a random sample of New York Emergency Loan borrowers interviewed in 1979 and 1986 found that of those still farming in 1986, 6% admitted that they could have obtained credit elsewhere. An additional 12% had over 70% equity in their business and three-fourths of these also had estimated net incomes above $25,000.

National FmHA data on the number of borrowers refinanced through other credit sources is also illustrative. The number refinanced during the year as a percentage of the number of borrowers at beginning of year declined precipitously in 1983, when the foreclosure moratorium eliminated FmHA's ability to force graduation.[2] The percentage of Operating Loan borrowers who refinanced declined from 2.6% in 1981 to 0.4% in 1983. Similarly, refinancing by Ownership Loan borrowers declined from 1.2% to 0.3%. Unfortunately, the deteriorating financial condition of agriculture contributed to this decline, making it difficult to determine the proportion of the decline that resulted from a voluntary reduction in graduation. Clearly, a significant number of farmers are finding ways to avoid graduation.

The USDA Office of the Inspector General (OIG) and the General Accounting Office (GAO)

[2] Number of borrowers refinancing from FmHA Report Code 813; number of borrowers from FmHA Report Code 616.

have reported the types of problems with FmHA guaranteed loans that moral hazard would be expected to generate. On the loan-making side, they found incomplete assessment of repayment ability, inadequate verification of income and debt, and imperfect documentation of collateral. Documented loan-servicing deficiencies include not obtaining periodic financial statements, not performing required collateral inspections, and making unauthorized loan advances under the guarantee. Although these studies did not compare their results to normal lender practice, the apparent degree of inadequate servicing appears significant. For example, of a sample of over 15,000 loans, OIG found that periodic financial statements were not obtained for 23% and collateral inspections were not conducted for 10%.

The loan-servicing program initiated in 1988 to handle delinquent loans marked the end of the foreclosure moratorium that had effectively been imposed for the preceding five years. Of the 66,426 borrowers who received foreclosure or servicing notices, many were already out of business or prepared for foreclosure (FmHA). However, more than 4,000 of the 35,146 who did respond, brought their loan to "current" status, or paid it in full at that time. These people clearly had the ability to keep current on their payments but had not done so. This underestimates the number of delinquent borrowers who had the resources to stay current because many county supervisors contacted borrowers who they thought could make their delinquent payments and indicated that receipt of these loan-servicing (foreclosure) notices could be avoided by bringing their accounts current. Original estimates of the number to receive notices ranged from 70,000 to 80,000. Many other farmers who did request one or more of the many options FmHA was offering undoubtedly allowed their delinquencies to FmHA to rise under the protection of the moratorium. These higher delinquencies are likely contributing to the high write-down and write-off costs currently being borne by FmHA.

Evidence on the degree of risk undertaken by low-equity borrowers compared to others is limited. Anecdotal evidence that low-equity borrowers have a higher tendency not to carry fire insurance on buildings (as well as other types of insurance) has been observed by many familiar with agricultural lending.

Expansion of a highly leveraged business involves higher risk than operation at the status quo. In the New York study of Emergency Loan borrowers, 15% of the borrowers with 25% or less equity expanded their businesses during 1979–86 through purchase of real estate. Sixteen percent of those with higher equity expanded. In the same study, 30% of the dairy farms with 25% or less equity expanded their businesses through purchases of animals. Only 16% of those with higher equity expanded similarly. This appears to provide some evidence of moral hazard. In some cases, however, increasing the livestock investment may sufficiently improve the input mix to result in lower business risk.

If low-equity farmers adopt higher risk strategies, higher variance in income levels could be expected. The standard deviation of 1986 net cash farm income in the New York study was $13,915 for low equity (≤25%) farms and $34,303 for higher equity farms. The coefficients of variation were 106% and 123%, respectively. Coefficients of variation estimated for a larger national sample of FmHA borrowers (LaDue 1984) were higher for Operating Loan, Farm Ownership, and Emergency Loan borrowers with less than $25,000 of equity than for higher equity borrowers.[3] Hence, the evidence is contradictory.

Farmers can use outside information sources to reduce the risk when considering expansion or large investments. In a 1987 survey, a random sample of all commercial farmers in New York State (LaDue and Kwiatkowski) were asked to identify the sources of assistance they used in making investment decisions. For expansion investments, cooperative extension or consultants were used by 20% of low-equity farmers and by 22% of other farmers.

FmHA personnel indicate that borrowers who perceive their probability of success as low do not maintain their collateral. Quality is allowed to deteriorate, and animals or machines are frequently not replaced. It is unclear whether this reflects explicit operator recognition that the returns to such maintenance are low or zero or an inability to purchase replacements because of cash flow limitations.

Minimizing the Costs

A particular problem that FmHA and other government lenders must bear is the low "moral cost"

[3] Midpoints of tabled values and number of borrowers for each range were used to estimate the coefficient of variation. Relationships were unchanged when more extreme values were used for the midpoint of the open ended high and low ranges of the tabled values.

(Jaffee and Russell) of default on government loans. Many borrowers convince themselves that defaulting on the government is not a serious transgression, rationalizing that the government got them into the problem, either through inappropriate price support policies or by lending the money (for examples, see GAO, Sep. 1989). Neighbors and friends frequently view not paying the government as less sinful than not paying local individuals or local businesses owned and operated by people they know. U.S. lenders rely on the moral cost of default to encourage effort to repay loans. This has historically been quite important for the farm population. However, the government gains less from this than do other lenders.

Government programs also operate under the handicap that they be "responsive" to the people. Thus, FmHA is less apt to take actions that are viewed as politically unpopular, and borrowers are provided many more avenues for leniency than a private lender could provide. For example, borrowers can use multiple levels of appeal, bring political pressure to bear, and make extensive use of legal recourse.

FmHA application forms and Farm and Home Plans typically list assets at their market value without adjustment for selling costs or contingent tax liabilities. To the degree that the borrower believes the net worth value calculated by such a procedure, he or she will tend to act as if the recovery value exceeds the principal plus interest, when in fact it is only the market value that exceeds the loan value. This equity illusion will increase the proportion of borrowers who believe the value of their business exceeds the value of their loans.

One of the commonly suggested methods of combating moral hazard in lending programs is to require collateral (Chan and Thakor). However, this usually involves additional collateral to that used in the business (i.e., a home or other nonfarm asset). Because FmHA is the lender of last resort, most borrowers do not have significant additional assets to pledge.

The method of minimizing moral hazard risk that likely has the greatest potential, particularly in a government setting, is use of complex financial contracts (Barnea, Haugen, and Senbet). This approach is already in use for some FmHA situations. To limit the "parking lot" sales of assets sold to the borrower at FmHA's recovery value, a recapture provision has been developed.

Similarly FmHA has written detailed procedures for correct making and servicing of guaranteed loans. The limitation of this approach, however, is that the procedure has become so complex that lenders may reduce their use of the program because of the complexity itself. This has led to further contracts in the form of preferred lender status for loan making where, once a lender's procedures are accepted by FmHA, loans put forth by that lender are guaranteed with modest further review.

Improved contracts in the form of completely documented annual financial statements, including a statement of cash flows and reconciliation of income statement and balance sheet, could be required. Such statements would allow more accurate business evaluations for adjusting subsidized interest rates and assessing graduation potential. This practice would be particularly useful where the problem is caused by inaccurate reporting. Given the positive relationship between maintenance of such records and success (LaDue and Christensen), such a requirement could have other benefits. FmHA's attempt to require coordinated financial statements was "shouted down" because of their complexity, but such statements may reflect the type of effort required to reduce moral hazard. Contracting can also be used for situations where a high-risk investment or income shifting to future years is clearly identifiable and appropriate penalties for conducting such activities can be identified. For example, maintenance of fire insurance could be monitored.

Conclusions

Moral hazard incentives exist for a number of FmHA's programs. Data are not available to allow a clear measurement of the risk involved for most programs. In cases where some documentation is available, the risk is apparent but relatively modest. Taken together, however, it is clear that moral hazard is a problem for FmHA. Improved contracts appear to be the most likely method of controlling the risk for continuing programs. Risks could be significantly reduced by not allowing foreclosure moratoriums, eliminating Emergency Loan programs or making such loans only when commercial lenders accept a substantial part of the risk, and returning to true supervised credit.

Imperfect Information and Intervention in Farm Credit: Discussion

Daniel A. Sumner

In beginning a discussion of "imperfections" in farm capital markets, it is tempting to encourage the reader to study Stigler and just to stop there. However, given a couple of pages of *Journal* space, I cannot resist adding a few additional words that correspond more directly to Innes's paper.

Innes deals with three cases of costly and asymmetric information and for each finds that, in the simple and pure world in which his models reside, there is an opportunity to improve economic output by giving farmers money or credit subsidies. Let me stress two points at the outset. First, the basic results are not surprising: in the Innes world, we should expect "market" failure and "government" success. Second, Innes does not do the easy case in which the government is somehow immune from the costs of information that afflict the other agents in the model. In that sense, Innes is operating squarely within the realm of the famous Stigler observation that, "information costs are the costs of transportation from ignorance to omniscience, and seldom can a trader afford to take the entire trip" (p. 290). In Innes's models, not only is information costly, it is more costly for some than for others. The government differs from the other agents in these models, not in information costs but in that the objective of each other agent is to improve her own wealth, whereas the government acts to improve the total pie with no regard for who gets how much. Innes shows that in his "imperfect" world there are conceivable improvements to unfettered market forces. His final paragraph indicates, however, that even Innes may not take these results seriously as an indication that a real government could improve economic welfare but only as an indication that the market is not perfect.

A traditional debate among economists has been for a free market theorist to show that unfettered markets lead to some optimal allocations, and then for the response to be that in the real world the stringent conditions that lead to the optimality result do not hold. In part, the current exchange is just a reversal of the roles. The Innes paper shows theoretically that, in some rarified models, government subsidies lead to improved economic allocation. I argue that no one should expect these results to hold in practice, and that the practical problems in actual markets are overwhelming.

It is useful to list briefly the three cases that Innes studies and indicate the essence of his subsidy results. In model one, each farmer observes his own farm's output, but the banker does not without incurring significant costs. As a result, it is in the interest of the bankers to hold back on loans and to allow some excess farm failures. Innes shows that in such a world, an economy with more wealth in the hands of farmers or with subsidized credit on farm loans would produce more. If taxes did not distort and if the funds were distributed costlessly without themselves distorting behavior, then taking from taxpayers and giving to farmers would be profitable for the economy. The key here is that the asymmetric information costs and the chance that farmers will not reveal accurate data about their farm earnings cause bankers to loan less than might be socially optimal in a nicer world. The government, not worried about the cost to taxpayers or anything else, could improve economic efficiency.

The second case that Innes considers is the standard share contract problem applied to credit markets. About one hundred years ago, Alfred Marshall argued that because the share renter got only a portion of the returns for his effort, he would expend less effort than if he owned the land outright. Innes provides the same argument for farmers in the credit market. And the argument is clearly sound as far as it goes. The

Daniel A. Sumner is a professor, Department of Economics and Business, North Carolina State University.

problem with the argument, as shown by the extensive literature of the last four decades, is that it does not go very far.

The incentive problem is solved in the credit market by the government giving farmers money, so that they have less interest in borrowing, or by subsidizing their borrowing itself. Forty years ago D. Gale Johnson emphasized, in the sharecropping case, that there are lots of ways to provide incentives. Contracts can be arranged to minimize incentives to shirk by including multiyear agreements and monitoring, among other things. In practice, the one clear applicable case of reduced incentives in farm credit concerns the lack of incentive of farmers to show enough progress to graduate from subsidized government loans of the Farmers Home Administration to private lenders.

The final case that Innes develops concerns good and bad farmers, each applying for credit. The farmers know which they are, but each farmer has an incentive to spend resources trying to convince the bankers that he is "good." Once again, waste and misallocation can be avoided if the government will distribute money to farmers. In this particular case, the information demands of the government in order to do the right thing are severe, but they do not include knowing a priori which farmers are of which type. The trick is that, if it knows enough technical information, the government can provide subsidies to bad farmers that cause them to reveal themselves.

It is also informative to note that the Innes models may prove too much. The same arguments that he applies to costly information about farmers by bankers applies to the costs of information about bankers by farmers and others. The result of applying the Innes model to banking would be that the government should subsidize banks, especially the incompetent ones.

As with any theoretical argument, the results of the Innes models would be different under alternative assumptions. For example, Innes assumes that farmers put all the eggs in their one "farming" basket. But, Belongia and Gilbert argue that one reason that farm output is unaffected by subsidized credit is that farmers divert part of their total resources to risk-reducing or returns-enhancing nonfarm investments. If this option were allowed in the Innes models, the major results might evaporate.

The bottom line is that it may be interesting to have had these models set out in the context of farm credit, but no one should think that they help justify the real government participation in real farm capital markets.

Effect of Federal Credit Programs on Farm Output: Discussion

Howard D. Leathers

Five reasons have been advanced for government intervention in farm credit markets: (*a*) to mitigate effects of credit rationing, (*b*) to correct underinvestment in agriculture, (*c*) to subsidize some group, (*d*) to counteract effects of lender monopoly power, and (*e*) to reduce default costs. Belongia and Gilbert (BG) focus on the first of these and address two important questions: (*a*) Do commercial lenders ration credit to agriculture? (*b*) Would addition of government-supplied farm credit stimulate production?

It is difficult to define credit rationing in a real-world context. Credit rationing is distinct from underinvestment or discrimination. In making a loan, a lender first collects information about each potential borrower and divides the total pool of borrowers into groups (e.g., good and bad risk borrowers). All members of a group are indistinguishable to the lender but are not necessarily identical (information is imperfect). Second, the lender designs a contract to offer to each group. Credit rationing occurs when some member of a group cannot receive credit on the terms offered to the group (Stiglitz and Weiss). Underinvestment occurs when the terms offered result in a loan size which is less than the social optimum (Innes). Discrimination occurs when the contract offered to one group differs from the contract offered to another.

The existence of credit rationing means that some borrower could earn enough profits to repay the loan but cannot get the loan; thus, there is an obvious role for government. But is credit rationed to farmers? BG says yes because government share of farm credit increases as the growth rate of total credit declines. I am sympathetic to the answer but not entirely convinced by the reasoning. First, I know of no basis in theory for thinking that the incidence of credit rationing increases as the credit supply shrinks; if government perfectly corrects for credit rationing, its share of credit will not necessarily rise as credit declines. Second, theoretical models (in which borrowers have limited liability) predict that credit is rationed to the least risky borrowers (Stiglitz and Weiss). This is at odds with my intuition about what kind of borrowers patronize government lenders. Third, the relation estimated by BG relates government share of farm lending not to total credit but to change in total credit. The former would seem to be a more appropriate representation of BG's argument, as I understand it.

The BG evidence seems to imply that FCS and FmHA act to smooth out the supply of credit to agriculture. This may be attributable in part to the fact that FCS must estimate future demands for its credit before deciding how many bonds to sell. (One hears anecdotal evidence that in certain periods, FCS has excess funds and local PCAs and FLBAs try to "drum up business.") This mechanistic explanation seems consistent with BG's evidence [equations (1) and (2)] but imputes no policy objective to the FCS decisions. The desire of FmHA to provide credit to certain farmers who are unable to obtain credit from other sources would also explain why government share of farm credit increases when credit tightens. FmHA's goal here is redistribution (to help a certain groups of farmers) rather than efficiency (to counteract credit rationing). As LaDue discusses, failure on the part of FmHA to discriminate among groups of borrowers may exacerbate a moral hazard problem, leading to efficiency losses.

In their second section, BG examine whether farm credit programs have increased farm output or whether the credit provided by these programs has been diverted to nonfarm uses. They conclude that subsidized credit has not increased production, which seems to imply that government programs have been largely ineffective. I am uncomfortable with this conclusion for two reasons. First, if the FCS and FmHA programs are acting to smooth out the supply of farm credit, as suggested above, then total (production) credit should be positively related to output, but gov-

Howard D. Leathers is an assistant professor, Department of Agricultural and Resource Economics, University of Maryland.

ernment credit should not be related to output. Second, there may be some econometric explanations for the BG results. BG find that coefficient d_3 in equation (6) is not significantly positive. But $d_3 = [b_1c_1/b_3]/[1/b_3 - 1/a_2]$. For b_3 (supply elasticity) sufficiently high, d_3 will be close to zero even when b_1 and c_1 are positive. In addition, growth in productivity is probably not independent of past borrowing, so part of the effect of credit could be captured by the productivity variable.

While theoretical work has advanced in terms of explaining actions and interactions in credit markets, empirical work has lagged behind. The BG paper is a useful first step. Their paper raises important issues and suggests some interesting lines of research. If the government credit programs act to smooth out the supply of credit, is that an unintended consequence of the programs? Does it result from a desire to subsidize certain groups? Is it an effective way of counteracting the effects of credit rationing, or is there some other rationale? Are changes to these programs or new programs needed to deal with the effects of credit rationing?

Moral Hazard in Federal Farm Lending: Discussion

Marc A. Johnson

LaDue presents (*a*) situations identifying moral hazard in FmHA programs, (*b*) empirical observations supporting the existence of moral hazard, and (*c*) suggestions for minimizing the cost of moral hazard.

A more precise definition of moral hazard is required than LaDue implies. Moral hazard is the hazard that an individual will succumb to the temptations (incentives) not to try to fulfill the objective an agency is helping him or her achieve. Thus, moral hazard is, in part, defined by the policy objective of the agency. LaDue assumes that the policy objective of FmHA is to serve as a lender of last resort and to encourage entry and continuation of families in farm enterprises. Stated differently, the farm credit policy objective is to save family farms or to extend the margin of opportunity to stay in farming below the line of performance acceptable to commercial credit markets.

FmHA borrowers are observed using cheaper credit to undertake riskier farming strategies in order to stay in farming. They are observed to pay local merchants first, to maintain a flow of inputs onto the farm, and repay FmHA last. They are observed to invest in nonfarm ventures with higher returns than farming to generate cash for the farm family. They are observed investing in land and animals to gain farm size efficiencies. However, these actions could be consistent with the policy objective of FmHA and do not necessarily represent moral hazard. Moreover, underreporting income is not moral hazard; it is fraud, similar to underreporting income on tax returns.

LaDue's remaining situations represent moral hazard. The agency's two-year loan reviews that search for the ability to pay higher interest rates may provide an incentive not to try to raise income because the marginal income goes back to the government. However, the individual farm family would have to exhibit a despairing lack of hope for success, not to try to break past the ability to pay commercial interest rates. Another moral hazard situation is where commercial lenders with only a 10% risk share put a low priority on loan service on FmHA guaranteed loans. When defined in a narrower sense, the cost of moral hazard to taxpayers is less than LaDue implies.

Empirical measurement of moral hazard suffers from a lack of precise modeling and a lack of data. None of LaDue's empirical observations can be explained only by moral hazard. The fact that a small percentage of farm firms could have obtained commercial credit, or could have graduated to commercial interest rates, or did bring their loans current after the moratorium could be explained by the borrower's quest for greater security and liquidity before deciding to stay in farming. Businesses on the edge of failure often will drop their insurance and adopt risky strategies in a last effort to survive, regardless of who supplies credit. Inadequate documentation and loan servicing on agricultural loans were widespread in the mid-1980s, not just for FmHA guaranteed loans. Empirical verification of moral hazard in federal farm lending will require sufficient modeling and data to pinpoint taxpayer losses resulting directly from intentional lack of effort by borrowers and participating bankers.

LaDue's recommendations to reduce loan losses resulting from moral hazard represent good business practice, i.e., require strict borrower record keeping with annual financial statements, more collateral, complex financial contracts, and strict lender servicing procedures. These remedies have been tried. FmHA was phasing in consolidated financial statements for borrowers in the early 1980s, but political action was used to stop the practice. A principal borrower complaint in the early 1980s was that FmHA required assignment of virtually all assets of the farm family to get an FmHA loan, leaving nothing to offer as security on additional commercial credit. Moreover, attempts by FmHA to achieve

Marc A. Johnson is a professor and Head, Department of Agricultural Economics, Kansas State University.

compliance on their loan contracts resulted in a five-year moratorium on foreclosure. Strict paperwork and lender servicing guidelines nearly scuttled the FmHA loan guarantee program; procedures were eased to attract bank interest in the program.

LaDue summarizes by saying, "It is clear that moral hazard is a problem for FmHA." However, based on the results of his paper, the conclusion is too strong.

A related question is whether the FmHA is a cost-effective way to save family farms. When policy makers observe that the credit market is less lenient with farmers than taxpayers would desire, it is questionable whether a government program can improve on conditions at a reasonable cost. Three considerations are important. First, is moral hazard likely at the agency, whereby efforts to maintain the agency's budget and clients would reduce the incentive to try to graduate all farm families? Second, can a program be designed to help farm families survive without trapping them in a cycle of low performance, with high implied tax rates on marginal income? Third, how can a program be cost effective under a cloud of policy uncertainty; for a while FmHA is a social agency dispersing cheap credit, and then it becomes a sharp penciled lending agency foreclosing on loans. When better management techniques are attempted, political forces intervene. When lender functions are attempted, a foreclosure moratorium is called. Are federal farm credit programs really the best way to save the family farm?

A Price Forecasting Competition (Arnold Zellner, University of Chicago, presiding)

A Price Forecasting Competition: Introduction

Christopher S. McIntosh and Jeffrey H. Dorfman

Accurate forecasts are important to professional agricultural economists. Forecasts are used not only for predicting random variables but as proxies for unobservable expectations in many analytical settings. When using forecasts, the analyst strives to obtain the most accurate forecast possible, where "accuracy" is determined by the specific objective of the forecasting exercise. Forecasts can be obtained by (*a*) purely judgmental approaches, (*b*) structural econometric models, (*c*) univariate time-series models, (*d*) multivariate time-series models, or (*e*) any combination of the above. The problem becomes one of choosing the most appropriate method (or combination of methods) for a given application.

Professional agricultural economists need to understand various forecasting approaches and how they differ from one another. Such information would aid forecast users in making rational choices regarding which forecasting methods to employ for a given application. A "best" forecasting method may not exist in all situations. Any one of the methods (or combination of the methods) mentioned above may provide the best forecasts in a given situation according to a particular loss function. Makridakas et al. summarize the conclusions from several previous studies by saying (*a*) judgmental approaches are not necessarily more accurate than objective methods, (*b*) causal (structural) econometric methods are not necessarily more accurate than time series methods, and (*c*) more complex or statistically sophisticated methods are not necessarily more accurate than simple methods.

The purpose of this paper is to present a forecasting competition, where three different techniques are applied to the identical information set of seven variables in an attempt to forecast two of the seven variables out of sample. All the forecasts will be judged by the same criteria to determine the relative success of the various methods. First, we will describe the data in the information set and the delineation between in-sample and out-of-sample data. Then the criteria for judging the forecasts will be discussed. After the three papers which present the attempts to forecast the series, a final paper discussing and comparing the results completes the competition.

The Data

The information set consists of seven series, each 100 observations in length. The seven variables were price and quantity series for two hypothetical, related agricultural products (to be referred to as feed and livestock), a price index for other goods, an income series, and a population series. The series were identified to the participants simply as price of good one (p_1), price of good two (p_2), quantity of good one (q_1), quantity of good two (q_2), price of other goods (p), income (y), and population (pop); the designations as feed and livestock were not provided to the participants.

The data generation process involved 150 observations. The price index of other goods and the income series were comprised of actual monthly data for the period from 1970:1 to 1982:6. The price index of other goods was the U.S. consumer price index (CPI) for food, and the income series was the index of industrial production. The population series was artificially generated using an exponential growth formula,

$$pop_t = 200e^{t/720} + N(0, .01) \qquad t = 1, \ldots, 150, \tag{1}$$

where $N(0, .01)$ represents a normal random variable with zero mean and variance equal to 0.01. This creates a population series with an

The authors are assistant professors in the Department of Agricultural Economics, University of Georgia.

average growth rate of approximately 1.7% per year to match the recent U.S. population growth rate. These three series were then used as exogenous variables in a four-equation structural stochastic model of supply and demand for "feed" and "livestock."

Referring to the "feed" series as series 1 and the livestock series as series 2, the two supply equations were specified as

$$(2)\quad \ln(q_{1t}) = 0.46 + 0.02\ln(p_{1t-1}) + 0.005\ln(p_{1t-2}) + 0.05\ln(p_{2t-1}) + 0.9\ln(q_{1t-1}) + N(0, .0064),$$

$$(3)\quad \ln(q_{2t}) = 4.6 - 0.1\ln(p_{1t-1}) - 0.05\ln(p_{1t-2}) + 0.3\ln(p_{2t-1}) + 0.1\ln(p_{2t-2}) + 0.05\ln(p_{2t-6}) - 0.003(q_{2t-4} - \bar{q}_2) + N(0, .0049).$$

The variable $\bar{q}_2$ represents the mean of q_{2t} and was set to 115 to represent the true mean; the sample mean was, in fact, quite close to 115. The demand equations were specified in inverse form as

$$(4)\quad \ln(p_{1t}) = 13.2 - 2.5\ln(q_{1t}) + 0.1\ln(q_{2t}) + 0.000001pop_t + 0.000002y_t + 0.0000015p_t + N(0, .0004),$$

$$(5)\quad \ln(p_{2t}) = 8.3 - 0.2\ln(q_{1t}) - 1.4\ln(q_{2t}) + 0.0000015pop_t\, 0.00001y_t + 0.000002p_t - 0.0000001t + N(0, .0016).$$

The series p_1, p_2, q_1, q_2, were initialized to 5, 2, 100, and 100, respectively, for the first six observations. The variable t is a linear time trend which began at 1. Beginning with observation 7, each period's quantities were generated using the supply equations. The prices were then generated by the demand equations. The process was continued until the data set consisted of 150 observations. The first 50 observations were then discarded to avoid excessive dependence on initial conditions.[1]

The participants received the first 90 of the remaining 100 observations. They were instructed to produce one-step-ahead, out-of-sample forecasts for observations 71 through 90 for the two price series. No other specific rules or guidelines for constructing the forecasts were provided. As many models as desired could be tried, and updating of coefficients was allowed. After each team selected a final forecasting model based on observations 1–90, out-of-sample forecasts for the final 10 observations (91–100) were constructed according to instructions and final coefficient estimates provided by each of the participants. Thus, the last 10 forecasts are truly out of sample because the participants could not change their models if the performance on the final 10 observations was poor.

The Criteria for Forecast Evaluation

The participants were told in advance that the forecasts would be evaluated by measures including mean-squared forecast error and ability in predicting turning points. The measures that were decided upon a priori were mean-squared forecast error, a Henriksson-Merton test that measures ability to predict the direction of revision, and the mean absolute percentage error. These three criteria captured attributes of many decision makers' loss functions.

Forecasting Multiple Time Series with Little Prior Information

David A. Bessler

It is difficult to do much in the way of prior specification when you have been handed seven series of data with a few-word description on each: series 1 is a price series, series 2 is a price series, series 3 is a quantity series corresponding to series 1, etc. Perhaps the data were generated as the outcome of a laboratory experiment, where a high degree of control on omitted variables was present, or maybe the data were generated as the outcome of a real-world economy where no control was present; finally, perhaps the data are from the real world but the person recording the data made mistakes entering series 3.

The amount of prior information which our competition group brings to this task, while meager, is perhaps no less than that brought to many econometric exercises (the experimental group excepted). As the list of possible explanatory variables which have been omitted from studies with secondary data is long, procedures built for summarizing regularities and forecasting are perhaps useful in both settings. Arguably, in both modeling environments "true" structure is unobtainable [as randomization is present in neither case (Rubin)]; demonstration of success (relative success) is obtained by comparing out-of-sample forecasts from alternative models.

The paper is presented in four sections. First the univariate properties of each series are studied. Simple measures on the autoregressive behavior of each series are presented. The product of this first section is a univariate model on each series. The second section considers the multivariate representation of these data. Three approaches to multivariate specification are taken. The third section of the paper considers the forecasting results from the alternative models. The final section of the paper offers a short discussion on forecasting with multiple economic time series.

David Bessler is a professor of agricultural economics at Texas A&M University.

John L. Kling wrote the time-varying parameter, Bayesian vector autoregression program used in this paper. Cameshia Sims and Liisa Menzel provided word processing assistance.

Univariate Specifications

The univariate properties of these data are viewed from four vantage points: plots of the data; stationarity tests (Dickey and Fuller-type); autocorrelation and partial autocorrelation functions; and final prediction error (FPE) statistics. Because limitations were placed on our overall page offerings, no plots are presented here. Series referred to as one through seven are given as: price 1, price 2, quantity 1, quantity 2, price 3, income, and population, respectively. The first fifty data points are used for specification (model identification and initial estimation), data points fifty-one through seventy are used for out-of-sample forecasting. One-step-ahead forecasts of points seventy-one through ninety are then the twenty data points to be provided to the session organizers.

Plots (not shown here) of the series suggest that series 5, 6, and 7 are mean nonstationary; while series 1, 2, 3, and 4 do not show strong trends. These visual results are consistent with formal tests of nonstationarity, as given in unit root tests. Table 1 gives t-statistics on Dickey-Fuller and augmented Dickey-Fuller tests of nonstationarity. These are conducted on both levels and first differences. The null hypothesis in each case is that the original series is a random walk (nonstationary); a negative and significant t-statistic is required to reject nonstationarity in favor of stationarity. To our knowledge, critical values on these statistics have been explored by Monte Carlo methods for explicit models; we do not apply particular critical values but offer the tests as evidence supporting the general impression from the plots. Some may argue that all series need at least one difference, as the t-statistics on the augmented tests with levels exceed -3.0 in all cases. We are reluctant to pursue this strategy on series 2 and 4 and are close to indifferent with respect to series 1

Table 1. *t*-statistics on Tests for Stationarity

	$(1-B)^1$		$(1-B)^2$	
Series	DF[a]	ADF[b]	DF[c]	ADF[d]
1	−2.30	−1.73	−8.63	−5.56
2	−7.61	−1.58	−13.66	−6.17
3	−2.44	−1.76	−9.10	−6.17
4	−7.42	−2.07	−13.23	−5.43
5	+1.95	+1.21	−3.59	−3.03
6	+1.12	−0.13	−2.85	−2.50
7	+0.03	+0.81	−10.52	−7.58

[a] Dickey-Fuller (DF) test is on the coefficient $\hat{A}_1$, from regression $(1-B)X_t = \hat{A}_0 + \hat{A}_1 X_{t-1}$; where B is the lag operator. Failure to reject the null hypothesis ($A_1 = 0$) is consistent with the process X_t being generated as a random walk.
[b] The augmented Dickey-Fuller (ADF) test is of the same form as that given in the DF test except lags of the dependent variable as are specified using FPE on the right-hand side of each equation.
[c] Dickey-Fuller test on second differences is defined analogous to the test on first differences.
[d] Augmented test is defined similarly to that given in note.[b]

and 3. Tests on first differences (null hypothesis is that first differences have a unit root) show no sign of nonstationarity. Our preference is to model series 1, 2, 3, and 4 as stationary in levels and series 5, 6, and 7 as stationary in first differences.

Table 2 gives estimated autocorrelation and partial autocorrelations on each stationary-transformed variable. Using the Box and Jenkins' suggestion to study the tailing-off and cutting-off patterns in these functions, series 1, 3, 5, and 6 appear to be generated as autoregressions of low orders (one or two lags). Series 7 appears to be generated as a first-order moving-average process (its estimated partial autocorrelation function tails-off). Series 2 and 4 appear to have some higher-order lag characteristics (perhaps seasonality).

Table 3 gives estimated *FPE*-statistics on lags 1 through 8 on each series. Eight lags permits us to capture most of the large partial autocorrelations in series 2 and 4 and gives more than forty observations for subsequent fit.

The minimum *FPE*-statistics generally agree with the autoregressive orders suggested by the partial autocorrelation functions. Series 1 and 3 show minimum *FPE*-statistics at lags of two, which are the same orders suggested by the partial autocorrelations (table 2). *FPE*-statistics for series 2 and 4 are minimum at lags of 5, which again are consistent with the rather large partial autocorrelations on these series at these lags. Differences in series 5, 6, and 7 are generated by autoregressions of orders 1, 1, and 2, respectively.

Multivariate Representations

Three different approaches to building multivariate representations of these data are considered. First an unrestricted vector autoregression using (at most) five lags on each variable is built. This model is expected to perform rather badly. Our past experience with unrestricted VARs suggests their poor forecasting performance (Bessler and Kling).

Note: Estimated standard errors at low lags are approximately $(50)^{-1/2} = .14$. Series 5, 6, and 7 are differenced.

Table 3. FPE-Statistics on Stationarity-Transformed Data

	Series						
Lag	1	2	3	4	5	6	7
0	2.200	.069	351.8	87.1	1.24	1.16	.024
1	0.927	.070	161.4	88.7	1.04*[a]	0.56*	.019
2	0.926*	.071	157.3*	91.4	1.08	0.59	.017*
3	0.972	.065	162.4	87.0	1.07	0.60	.018
4	1.021	.067	170.0	85.4	1.12	0.63	.019
5	1.071	.063*	168.5	85.3*	1.17	0.66	.018
6	1.112	.067	176.1	89.5	1.22	0.70	.019
7	1.167	.069	182.1	92.6	1.28	0.71	.019
8	1.210	.068	190.9	91.6	1.34	0.75	.020

[a] Asterisk indicates minimum value of FPE-loss. FPE loss is estimated over the first 50 observations on each series. Series 5, 6, and 7 are differenced.

Two types of restrictions on the multivariate representation are considered. First are explicit zero restrictions (variable i enters the autoregressive representation of variable j at lag k with a zero value). These are determined using the multivariate search procedure introduced by Hsiao. This approach has shown some promise in previous out-of-sample forecasting competitions (Kling and Bessler). Our second method for building a restricted VAR is to put a Litterman-type prior on an unrestricted model, allowing a small degree of parameter variation.

An unrestricted VAR is specified with the help of likelihood ratio statistics on the order of lags. These results are not reported in tabular form because of space limitations. We start at lag zero and test (upward) successive orders, $k = 1, 2, 3, 4$, and 5. The test is on the restriction that the parameter matrix at lag $k + 1$ is zero. The results suggest a first-order model, using a 1% significance level.

Table 4 gives a summary of lags selected using the Hsiao search procedure. No subset models are entertained. Interestingly, lags of both quantities (series 3 and 4) do not enter their corresponding price equations, equations (1) and (2). Equally puzzling is that lagged price of the first commodity does not enter the autoregressive representation of quantity of commodity 1 (series 1 does not enter the third equation, with lags). Finally, another puzzling result is that price of commodity 1 (series 1) enters the autoregressive representation of population.

Our final multivariate representation is an application of Litterman's Bayesian vector autoregression. It has been described in Litterman, and Doan and Litterman and applied in several settings, including Bessler and Kling. Our prior on each nondifferenced variable (series 1 through 4) is centered on a random walk—all coefficients in an unrestricted VAR have a prior mean of zero except those on the first lag of own series in each equation. Priors on each differenced variable (series 5, 6, and 7) are centered on zero.

Dispersion on each prior distribution is determined empirically by studying the logarithms of the determinant of the error covariance matrix on out-of-sample forecasts of points fifty-one through seventy for series 1 and 2 only. Settings on overall tightness, cross-equation tightness, and lag decay are specified and used to generate one-step-ahead forecast errors from a four-lag vector autoregression over this out-of-sample

Table 4. Lags on Each Variable in the Autoregressive Representation of Each Variable as Determined Using Hsiao's Search Procedure

	Equation						
Lags on Series	1	2	3	4 (lags)	5	6	7
1	1	5	0	5	0	0	3
2	0	4	0	4	0	1	0
3	0	0	1	0	0	0	0
4	0	0	0	5	0	0	0
5	3	0	3	0	1	4	0
6	1	2	0	5	0	1	0
7	0	0	0	3	1	1	2

Note: Autoregressions were selected applying the multiple search procedure described in Hsiao. This procedure was applied recursively to each series on data points 7–50.

Table 5. Forecast Results (Log Determinant) from Alternative Settings on Overall Tightness (λ), Cross-Equation Tightness (γ_2), Harmonic Decay (Decay), and Time Variation (T.V.)

T.V. = .00; decay = .00

	λ		
γ_2	.00	.50	1.00
.00	−2.41	−3.43	−3.44
.50	−2.42	−3.37	−3.22
1.00	−2.45	−3.13	−3.09

T.V. = .01; decay = .00

	λ		
γ_2	.00	.50	1.00
.00	−2.44	−3.43	−3.44
.50	−2.45	−3.37	−3.21
1.00	−2.49	−3.14	−3.10

T.V. = .00; decay = 1.0

	λ		
γ_2	.00	.50	1.00
.00	−2.39	−3.35	−3.41
.00	−2.40	−3.50	−3.49
1.00	−2.41	−3.37	−3.35

T.V. = .01; decay = 1.0

	λ		
γ_2	.00	.50	1.00
.00	−2.42	−3.35	−3.41
.50	−2.43	−3.52	−3.51
1.00	−2.45	−3.39	−3.36

Note: The reader should consult Wolff and Litterman for details on the general form of the model specified here. Briefly, we study estimates of parameters using Theil's mixed estimator, where the parameter, β, is specified to depend on λ, an overall tightness parameter; γ_1, a decay parameter; γ_2, a parameter on cross-equation influence; and T.V., a parameter governing the degree of time variation permitted.

period. Values of these parameters which give lowest log determinant measures are then used as our priors for forecasting over data points seventy-one through ninety. Included in this search is a small degree of parameter variation following the procedure introduced by Wolff.

Table 5 gives the log determinant values from out-of-sample forecasts associated with various settings on the priors and degree of parameter variation. Note that some parameter variation appears to be beneficial. The log determinant measures on the two no-time variation panels lie above panels with a small degree of time variation (our setting on time variation (.00 and .01) were selected following the recommendations in Wolff. So too, some decay appears beneficial; as the lowest log determinant measure is achieved under a decay parameter of 1.0. Of course, more extensive searches over the four-dimension space may sculpt a more interesting figure. The Bayesian parameter settings used for our forecasting competition are as follows: overall tightness = .6; cross-equation tightness = .4; decay = 1.0; and time variation = .01.

Results

Table 6 gives root-mean-squared error measures on forecasts over periods fifty-one through seventy and seventy-one through ninety. The most striking result in the table is that the univariate models appear to do quite well.

Discussion

Our results agree with those found in earlier forecasting competitions, where forecasts of prices from vector autoregressions do not show much improvement over forecasts from univariate representations of prices. Kling and Bessler write (with respect to hog prices): "the price series do not seem amenable to better forecasts through the additional information which the VARs incorporate." Perhaps this is a funda-

Table 6. Root-Mean-Squared Error (RMSE) Out-of-Sample Forecast Performance Metrics on BVAR, RVAR, UVAR, and Univariate Autoregressions, Observations 51–70 and 71–90

	Series 1	Series 2
Model	*(RMSE)*[b]	
UNIV	.710/.752	.257/.353
UVAR	.818/.796	.222/.496
RVAR	.877/.757	.238/.417
BVAR	.745/.767	.238/.441

[a] BVAR is a four-leg Bayesian vector autoregression with time variation; RVAR is a restricted vector autoregression with zero restrictions determined using Hsiao's search procedure; UVAR is an unrestricted vector autoregression (no zero restrictions); and UNIV is a univariate autoregression with lags determined by applying FPE to each series. In all cases series 5, 6, and 7 were first differenced.
[b] The numerator gives RMSE's on forecasts of observation 51 through 70; while the denominator gives RMSE's on forecasts of observations 71 through 90.

mental regularity of market-generated secondary data.

Forecasts from a State Space Multivariate Time-Series Model

Keith R. Criddle and Arthur M. Havenner

Several recent papers have presented theoretical extensions and applications of the multivariate time-series modeling technique described in Aoki. Examples include some of the papers with which we have been personally involved. Aoki and Havenner (1989a) develop the relationship between system-theoretic time series (STTS) and two kindred techniques. Aoki and Havenner (1989b) is a comprehensive review of STTS with extensions. Havenner and Aoki (1988a) present an instrumental variables interpretation of STTS. Havenner and Aoki (1988c) develop the connection between STTS and traditional econometrics. Havenner and Aoki (1988b) extend STTS to nonstationary time series. Havenner and Criddle recast STTS in an autocorrelation rather than autocovariance framework, contrast this autocorrelation version of STTS with a multivariate time series model developed by Akaike, and present an application to California cattle inventories and beef prices. Cerchi and Havenner apply STTS to stock prices. Criddle and Havenner (1989a, b) present applications of STTS to forecasting changes in fish populations. Havenner and Tracy compare the performance of STTS and hydrological models of the Eel River watershed. Dorfman and Havenner develop a Bayesian approach to STTS.

This paper will present a detailed discussion of model specification at an applied rather than conceptual level. Section one gives a brief overview of STTS. The second section specifies, develops, and evaluates STTS forecasts of the two price series explained in McIntosh and Dorfman. We discuss the performance of STTS in this competition in the final section.

System-Theoretic Time Series

Exploiting a unique arrangement of autocovariances, the system theory approach is able to specify the lag structure of the model based on the rank of an estimated Hankel correlation matrix. This Hankel matrix of autocorrelations is obtained as the expectation of the outer product of the observed series with itself lagged. The usual carriers of past information, lagged observations, and moving-average errors are combined in a set of state variables, which are minimum sufficient statistics for the past history of the series. Robustness with regard to model specification is obtained by forming these states as specific linear combinations of the observed series. Because of the way in which the states are formed, a largely nonsubjective search can be conducted over possible models while assuring consistency of included coefficients even if model order is misspecified. [For a development of these attributes, see Aoki and Havenner (1989b), Havenner & Aoki (1988b, c), as well as the original Aoki reference.]

The state space model consists of two matrix equations:

$$z_{t+1/t} = Az_{t/t-1} + Be_t \tag{1}$$

$$y_t = Cz_{t/t-1} + e_t. \tag{2}$$

There are T observations on each of m stochastic series in y. Equation (1) relates the vector of scaled centered observations, y_t, to the n-element vector of unobservable states, $z_{t/t-1}$ through the $m \times n$ matrix C. The number of states n depends on the degree to which the component series follow common processes and on the complexity of the underlying dynamics, with higher-order dynamics resulting in increased states. Motion of the state variables is described by equation (2). Because the number of states is to be determined, and because it is always possible to define new elements equal to the lag of other elements in the state vector to reach any lag desired, there is no loss of generality in assuming that the state equation is first order (Aoki or Aoki and Havenner 1989b).

The $n \times n$ matrix A relates the state variables to each other through time, while B is an $n \times$

Keith R. Criddle is an assistant professor of economics at the University of Alaska, Fairbanks; Arthur M. Havenner is a professor of agricultural economics at the University of California, Davis.

m matrix of Kalman filter updates included to incorporate current innovations into the forecasts of the states. Given stationarity, the model can always be formulated so that the m element error vector e_t is serially uncorrelated and centered on zero, with a constant contemporaneous covariance matrix denoted by Ψ. Aoki demonstrates that the optimal states are linear combinations of the observed residuals so that equations (1) and (2) can be written with the same error. When the data are centered and scaled by their standard deviations, the autocovariances of the transformed data are also autocorrelations of the original data; see Havenner and Criddle for an analysis of the effect of this scaling on the properties of the procedure.

The sample Hankel autocorrelation matrix is

$$(3)\quad H = \begin{vmatrix} \Gamma_1 & \Gamma_2 & \Gamma_3 & \dots & \Gamma_N \\ \Gamma_2 & \Gamma_3 & & & \\ \Gamma_3 & & & & \\ \cdot & & & & \\ \cdot & & & & \\ \Gamma_N & & \dots & & \Gamma_{2N-1} \end{vmatrix},$$

where the Γ_i are the $m \times m$ sample autocorrelation matrices

$$(4)\quad \Gamma_i = Ey_{t+i}y_t^T \qquad i = 0, 1, 2, \dots, 2N-1,$$

and $2N - 1$ is the maximally distant autocorrelation to be modeled. In practice, selection of the lag parameter N involves trading off errors in the estimated sample autocorrelations at long lags against the risk of not capturing all of the important lags. All modeling procedures require specification of such a parameter, whether explicitly, as in this case and structural modeling, or implicitly, as when inspecting the autocorrelation functions in a more traditional time-series setting. One of the difficulties in specifying multivariate time-series models is that the order of the determinantal polynomial in the lag operator for any individual series has a maximum equal to the product of the system lag and the number of series, so that N may be relatively small but with complex interactions between series.

By the Kronecker theorem, the rank of the population counterpart of the sample Hankel matrix is the number of states necessary to characterize the system (see Havenner & Aoki 1988a for an intuitive justification of this result). The singular value decomposition is a computationally accurate method of determining the rank of the sample Hankel matrix

$$(5)\quad H = U\Sigma V^T = U\Sigma^{1/2}\Sigma^{1/2}V^T,$$

where Σ is a diagonal matrix of estimated singular values, pre- and postmultiplied by the orthonormal singular vectors U and V, $U^T U = I$, $V^T V = I$. If the autocorrelations were observed exactly, the redundant singular values would be zero. Because the autocorrelations are determined from the data, there is sampling error in the estimated Hankel matrix and in the singular values derived from it. Aoki and Havenner (1989a) list several criteria which can be used to estimate consistently the cutoff point when the estimated singular values are ordered from largest to smallest. Selection of the estimated rank of H and the required number of states, n^*, so that σ_{n^*+1}/σ_1 of order $T^{-1/2}$, is analogous to a criterion based on condition number.

Estimates of the dynamic coefficient matrix A, and the observation-state mapping matrix C, can be obtained from equations (1) and (2), conditional on n^*.

The first block row of the sample Hankel matrix, denoted H_{1*} is used to estimate C

$$(6)\quad C = H_{1*}V\Sigma^{-1/2},$$

(see Aoki). Define $\mathcal{H}$ as the matrix formed by shifting the blocks of the original sample Hankel matrix left one block column and filling in on the right. Then an estimate of A is

$$(7)\quad A = \Sigma^{-1/2}U^T\mathcal{H}V\Sigma^{-1/2}.$$

The first block column of the sample Hankel matrix, denoted H_{*1} is used to estimate Ω,

$$(8)\quad \Omega = \Sigma^{-1/2}U^T H_{*1},$$

a covariance matrix necessary for estimation of B. An estimate of B can be obtained from the joint solution of three matrix equations which minimizes Ξ, the contemporaneous covariance of the states:

$$(9)\quad \Xi = A\,\Xi A^T + B\,\Psi B^T,$$

$$(10)\quad \Gamma_0 = C\,\Xi C^T + \Psi,$$

$$(11)\quad \Omega = A\,\Xi C^T + B\Psi.$$

Equations (9), (10), and (11) can be solved for estimates of Ξ, Ψ, and B conditional on estimates of A, Γ_0, Ω, and C both by iterative and noniterative methods (see Aoki).

With estimates of A, B, C, Ω, and an estimate of the initial state vector z_0, equations (1) and (2) can be solved for in and out of sample forecasts.

Models

In the context of this competition, and in many applications, the single most important requirement of a model is that it produce accurate forecasts. Although economic theory suggests that income, price of other goods, population, and own quantity may contribute to an understanding of price, it is by no means assured that they will contribute to improved forecasts of P_1 and P_2.

Plots of the data show trends in income, price of other goods, and population, but not in Q_1 or Q_2, and not in either price series to be forecast. If we were to include income, price of other goods, or population, any effects of these other variables would have to offset each other's trend. Further, the price forecasts would then be conditional on forecasts of the exogenous variables. Accordingly, we decided to ignore these other variables in specification of our model.

Simple structural models of price, given quantity, were very successful at explaining the observed data but were not used because of our interest in unconditional forecasts of price. Adoption of the simple structural model merely changes focus from forecasting the price series to obtaining forecasts of the quantity series to be used to generate forecasts of the price series via the estimated structural relationship.

On the basis of these considerations, three models were selected for further analysis:

(*i*) Univariate P_1
Univariate P_2,
(*ii*) Bivariate P_1, P_2,
(*iii*) Multivariate P_1, P_2, Q_1, Q_2.

The number of state variables required to characterize the system depends on the complexity of the processes and on the presence of common dynamics. The univariate models are simple and often very successful, especially if dynamics are low order or the time series are independent. By exploiting common factors, multivariate models may produce better forecasts when the time series are not independent.

Determination of the number of states required to represent the processes entails a conditionally one-dimensional search when there is reasonable prior information on the lag parameter N. When the lag length is unknown, as is typical, the specification search is two dimensional in N and n^*. Given a choice of N (perhaps as an element of a grid search), there typically are no more than two or three choices of n^* which satisfy the condition number criterion. The preferred model specification is determined on the basis of in-sample mean-squared error. In-sample mean-squared errors for all of the models that we considered are reported in table 1.

Univariate models of P_1 with $N = 1, 2, 3, 4$, 5, and 6 performed similarly in-sample. We selected the simplest model: $N = 1$, $n^* = 1$. For the univariate P_2 model, $N = 3$, $n^* = 3$ was the preferred specification, although models with $N = 4$, 6, and 12 were nearly as successful.

Bivariate models of P_1 and P_2 for $N = 2$, 3, 4, and 6 were fairly similar, as would be anticipated from the results of the univariate models. On the basis of minimum mean-squared error, the preferred specifications for the bivariate P_1, P_2 model are $N = 6$, $n^* = 3$, and $N = 6$, $n^* = 4$. Because the number of states required to model the bivariate series was less than or equal to the number of states required to model the series individually, P_1 and P_2 may share common dynamics. The bivariate models were characterized by smaller in-sample mean-squared errors for both price series than the corresponding univariate models.

Multivariate P_1, P_2, Q_1, Q_2 models performed poorly except for $N = 3$, $n^* = 3$, which produced a very slight (0.01) reduction in mean-squared errors for the P_1 series while matching the bivariate P_2 series mean-squared errors. While the total number of state variables was not increased by adding Q_1 and Q_2 to the model, their inclusion doubled the number of coefficients to be estimated, and, given the performance of all multivariate P_1, P_2, Q_1, Q_2 models except the one, we preferred the bivariate specification over this model.

On the basis of in-sample mean-squared error, the two bivariate models (P_1, P_2 with $N = 6$ and $n^* = 3$, and $n^* = 4$) appeared marginally more promising than the univariate models. While the additional state in the second model does not

Table 1. Model Specification: Mean-Squared Error

	Univariate		Bivariate		Tetravariate
N	1	3	6	6	3
n^*	1	3	3	4	3
Coefficients	4	10	18	23	37
P_1	.67		.63	.62	.61
P_2		.05	.04	.04	.04
Q_1					130.42
Q_2					53.58

seem important, both models were estimated and their out-of-sample performance examined. Because the model with three states is strictly nested in the four-state model, common coefficients are identical. The 3×3 upper left-hand block of the state dynamics matrix, A, for the model with four states is the A matrix for the three-state model,

$$A$$

$$\begin{array}{rrrr}
0.857 & -0.021 & 0.007 & 0.050 \\
0.027 & -0.801 & 0.583 & -0.056 \\
-0.009 & -0.344 & -0.543 & -0.117 \\
 & & & \\
0.028 & 0.313 & 0.259 & 0.505
\end{array}$$

Similarly, the 2×3 left-hand submatrix of the four-state mapping matrix, C, is the three-state C matrix,

$$C$$

$$\begin{array}{rrrr}
-1.120 & -0.111 & -0.081 & 0.186 \\
-0.109 & 0.100 & 0.144 & 0.002
\end{array}$$

While the 3×2 upper submatrix of the four-state covariance of the states and observations, Ω, is the three-state Ω,

$$\Omega$$

$$\begin{array}{rr}
-1.131 & -0.082 \\
0.070 & 0.025 \\
0.049 & -0.184 \\
 & \\
0.188 & -0.030
\end{array}$$

The unconditional covariance matrix Γ_0 is shared by all of the bivariate models,

$$\Gamma_0$$

$$\begin{array}{rr}
1.694 & 0.093 \\
0.093 & 0.069
\end{array}$$

Although the remaining coefficient and covariance matrices are not nested, they are closely related

0.012 & 0.912 & -0.083 \\
0.006 & -0.083 & 0.582
\end{array}$$

$$\Xi$$

$$\begin{array}{rrrr}
0.786 & 0.025 & 0.005 & -0.109 \\
0.025 & 0.874 & -0.098 & -0.137 \\
0.005 & -0.098 & 0.580 & 0.057 \\
-0.109 & -0.137 & 0.057 & 0.349
\end{array}$$

The out of sample performance of the three-state model was slightly better than that of the four-state model (table 2). Although the model was not exceptionally successful at forecasting P_1 or P_2, the model was accurate at predicting direction. The Henrikson-Merton test statistic indicates that our model achieved a 99.4% confidence level in matching actual turning points in our joint forecasts of the two price series. Accordingly, given the information available, we choose the bivariate model with $N = 6$ and $n^* = 3$ as our best model.

In Retrospect

It is perhaps fair to summarize our performance in the competition (see Dorfman and McIntosh)

Table 2. Model Validation: Summary Statistics

	$n^* = 3$	$n^* = 4$
In sample		
MSE	0.633	0.622
	0.036	0.037
Percent error	19.2	19.0
	9.2	9.3
R^2	0.626	0.633
	0.479	0.466
D-W	1.946	2.174
	2.072	2.028
Out of sample		
MSE	0.735	0.821
	0.141	0.142
Percent error	22.8	24.1
	17.7	17.8
R^2	0.222	0.131
	0.411	0.410
D-W	2.031	2.359
	1.825	1.847

as having produced clearly the best P_2 forecasts and equally clearly the worst P_1 forecasts, and from a joint model no less. It would be useful to understand how this situation could occur. We do not, but three sources of error present themselves: errors in the modeling procedure, incorrect use of prior information, and as always, sampling error.

Procedural Errors

The first thing to consider is flaws in the state space modeling procedure employed, either inherent or as we applied it. In the latter category, after learning the nature of the true model, we realized that we had not even considered two separate bivariate models, each with one price and quantity. Running such a pair of models, as occurred after the fact, results in mean-squared errors very similar to those of the selected model in sample, but much lower on the twenty observations from seventy-one to ninety. While our selected model deteriorated out of sample, this formulation improves. (We do not have the last ten observations, and so cannot evaluate any of the models over this interval.) Similarly, there may be other potentially valid models that simply did not occur to us.

Selection of a particular model from the set of plausible models is a common problem in time-series analysis.[1] While the states in the procedure described above have been chosen to provide a measure of robustness with respect to models within a particular set, e.g., of given series and lag parameter, it is not possible to make the choice robust over models as different as two univariate (price) specifications versus a single tetravariate (two prices, two quantities) specification. Econometricians naturally wish to formalize this decision in a statistical test, but the pattern recognition used informally in assessing graphical output and summary statistics is difficult to capture in a single test statistic. In addition, there is probably a natural indeterminacy that is removed only by arbitrary choice. For example, we use out-of-sample mean-squared error to validate the model choice from in-sample information, while others formally or informally optimize in the out-of-sample periods. We are not aware of definitive arguments favoring one procedure over the other. In this case, our out-of-sample mean-squared errors for the selected model increased to 0.736 from 0.632 for the first series and to 0.141 from 0.036 for the second series, over the twenty observations from seventy-one to ninety. The mean-squared errors of the univariate models decreased out of sample, as did those of the two bivariate price-quantity models.

Prior Information

While time-series analysis is relatively free of specific prior information, nevertheless it is typical to know the names and characteristics of the series being modeled. In this case, triangularity would probably have been imposed by all modelers had the names of the price series been disclosed. In addition, clues regarding seasonality would have been available given the frequency and nature of the data.

We were surprised that the errors in the data-generating process were uncorrelated across equations. While uncorrelated errors are convenient for ordinary least squares estimation, they are probably not typical for data of this type and would be expected to importantly influence the outcome.

Sampling Error

This experiment is but one realization, providing just one set of outcomes. Apart from attempting to average over the true model characteristics, one can imagine running the experiment repeatedly, with different error draws and possibly very different results. Of course, it would be so much work that no one would participate. Sampling error may well be an important consideration in a contest of this sort when the models are all so close in terms of in-sample summary statistics.[2] This is particularly apparent when we examine our univariate model forecasts for observations seventy-one to ninety: the mean-squared errors are 0.5535 and 0.1296 for the two price series (better than any of the contest models for these observations), when the specifications cannot possibly be consistent with what we know to be the true model without major cancellation of factors.

Finally, lest this postmortem sound like an

[1] Combining model forecasts in a logically consistent manner is more easily accomplished under Bayesian assumptions than with the classical assumptions underlying our estimates.

[2] While this sort of sampling error is typical of actual data, it does complicate the evaluation of methods.

apology or a criticism of the experiment, let us note that these exercises are in our opinion invaluable. We have always made it a point to include applications with out-of-sample forecasts, being devout believers in the importance of falsifiability. While one draw is all the information that you get, over time the evidence builds up, and a general conclusion regarding modeling procedures emerges along with mandated refinements in method.

Forecasts from a Nonparametric Approach: ACE

Peter Berck and James A. Chalfant

Optimal forecasting requires both a choice of variables to include and determination of the appropriate functional form. The alternating conditional expectations (ACE) method (Breiman and Friedman) is a general functional form. It is not a philosophy of model testing and revision like Box-Jenkins. It does not include a model selection algorithm like the state space models do. ACE does internally make use of the idea of cross validation, which is closely related to prediction error. We have carried that empirical philosophy over to the area of model selection and combined strongly held economic priors with a search for models with low values of the final prediction error criterion. Our model selection strategy was to consider only those models with homogeneity and per capita quantities. Because our interest is in prediction, we considered only those models in which the regressors would be predetermined.

The ACE Algorithm

Consider the model

$$\phi(y) = \sum_{i=1}^{K} \theta_i(X_i) + e,$$

where y is the dependent variable, each of the K variables X_i is an explanatory variable, and e is the residual. With ordinary least squares, the transformations ϕ and θ_i are linear; logarithms or Box-Cox transformations are often substituted in an attempt to strengthen the empirical relationship between y and the X_i vectors. ACE generalizes this process by substituting data-smooths for a parametric transformation and finds the optimal transformations to minimize unexplained variation in $\phi(y)$.

Breiman and Friedman introduced ACE and provided the proofs for the algorithm's convergence to the optimal transformations. They also showed that the algorithm produces the maximal correlation between y and x in the bivariate case. The output from the procedure is a series of plots of $\phi(y)$ against y and of each $\theta_i(X_i)$ against X_i. As long as additivity on the right-hand side is acceptable, ACE provides a general approach to discovering the functional form with which a regressor should enter an equation. After inspection of the plots, one is free to specify a parametric functional form that mimics the observed plots, although this is not necessary.

Friedman and Stuetzle defined a smoother as a procedure applied to two series $(X_1, y_1), \ldots, (X_n, y_n)$ that decomposes observations y_t according to

$$y_t = s(X_t) + e_t \quad t = 1, \ldots, n,$$

where $s(\cdot)$ is any smooth function. Friedman describes a smoother as a procedure for estimating the condition expectation of Y given $X = x$. Regression models are examples, as are regression models that use a subset of the data (e.g., Tibshirani), called a window, around each observation. ACE makes use of the Super Smoother of Friedman and Stuetzle, where the smooth is based on a local linear regression and a window size chosen by cross validation.

Predictions from ACE are made using ACEPRED. It estimates ϕ^{-1} by smoothing y on the sum of the transformed x's.

An Example

To illustrate the use of ACE,[1] suppose one has available observations on a random variable $X \sim N(0, 1)$ and $Y = X^2$. Even though there is a perfect relationship between these two random variables, a linear regression of Y on X would suggest no relationship, i.e., a horizontal regression line.

Peter Berck and James A. Chalfant are associate professors of agricultural and resource economics, University of California, Berkeley.

The authors wish to thank Angie Erickson and Richard Gray.

[1] The authors thank Richard Carson for suggesting this example.

By examining the relationship between Y and X in only a neighborhood of each observation and thereby allowing for nonlinear and nonmonotonic transformations, ACE is able to detect that the optimal transformations are $\phi(y) = Y$ and $\theta(X) = X^2$, as shown in the top portion of figure 1. These plots are based on 200 data points generated as described above.

ACE also detects regime shifts. Suppose

$$Y = \begin{cases} X^2 & |X| \leq 1 \\ 1 & \text{otherwise.} \end{cases}$$

Given 200 observations for Y and, again, $X \sim N(0, 1)$, ACE obtains the plots in the lower part of figure 1.

Data Transformations

We used observations one through seventy and the seven variables provided, denoted by $P1$, $P2$, $Q1$, $Q2$, P, Y, and POP. We were not informed as to the true model or even that the true model concerned an agricultural market. Nevertheless, we assumed the data were from a sensible economic model and imposed the usual restrictions on the models. To begin with, we assumed that P was an appropriate deflator for this model and that the true relationship would be in real terms. Similarly, we assumed that the true demand relationship would involve quantities per capita. To implement these reasonable restrictions from economic theory, we produced per capita quantities $q_1 = Q1/POP$ and $q_2 = Q2/POP$. We then obtained a real per capita income measure $y = Y/(POP \cdot P)$ and real prices $p1 = P1/P$ and $p2 = P2/P$. These restrictions left us with five variables entering our model with unknown numbers of lags.

With our five-variable data set, we took an empirical approach—we considered all possible linear regressions of $p1$ and $p2$ on up to four lags of $p1$, $p2$, $q1$, $q2$, and y, giving us twenty

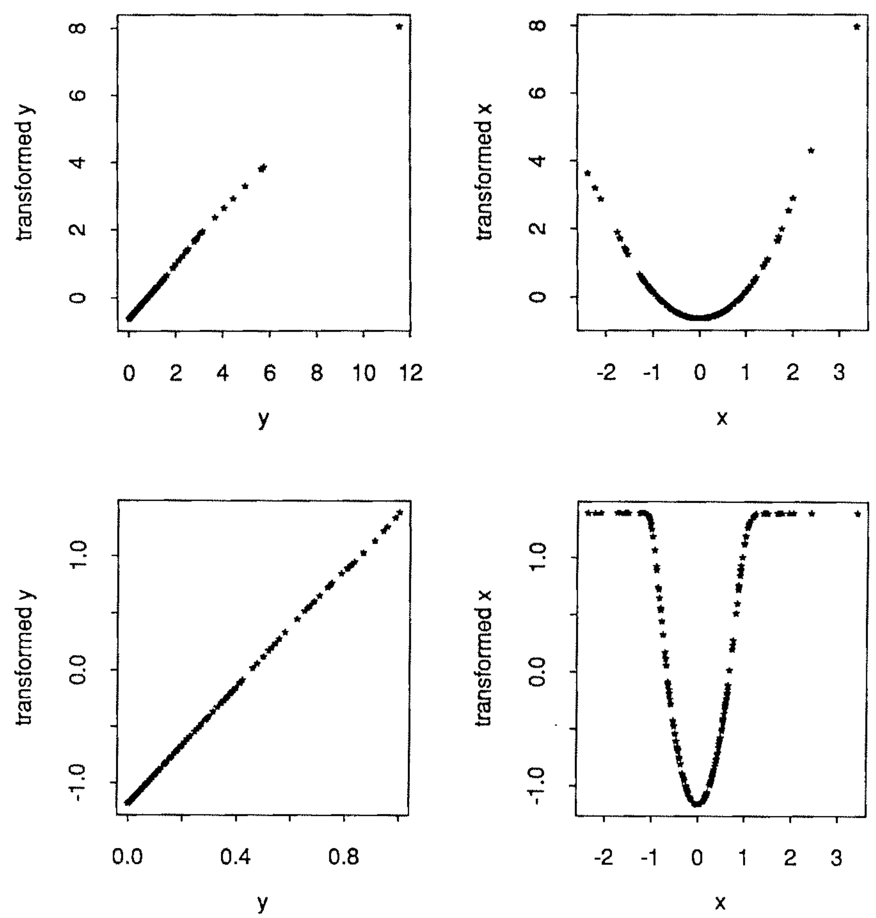

Figure 1. Example transformations using ACE—y and x

potential regressors. Four was, of course, an arbitrary choice made without knowledge of the periodicity of the problem (monthly, quarterly, etc.). We then found the collection of regressors that minimized the final prediction error (FPE) criterion.

For $p1$, the regressors were

$$p1(t-1), p2(t-4), y(t-2), y(t-3), y(t-4).$$

For $p2$, the regressors were

$$p1(t-1), p1(t-4), q1(t-1), y(t-1), p2(t-1), p2(t-2), p2(t-3), q2(t-2), q2(t-3), q2(t-4).$$

The parentheses indicate the length of the lags. We fit these two models using ACE and calculated the root mean-squared errors (*RMSE*) of our predictions for observations seventy-one through ninety. To compensate for possible overfitting, we then searched for models with smaller numbers of regressors that predicted out of sample equally well. For both models, we found that it was possible to reduce the RMSE for observations seventy-one through ninety by deleting some regressors. For instance, we examined the best four variable model for $p1$, using the FPE results, and so on, seeking a "smaller" model with better out-of-sample predictions.

For $p1$, we settled on three regressors—$p1(t-1)$, $p1(t-2)$, and $y(t-3)$. Six were optimal for $p2$—$p1(t-1)$, $y(t-1)$, $q2(t-1)$, $q2(t-4)$, $p1(t-4)$, and $q2(t-3)$. Each regressor is believed to use up about four degrees of freedom with ACE, so trimming the number of regressors can have a dramatic impact on the precision of the estimates. Breiman and Friedman use R^2, the only statistic calculated by ACE, for this purpose.

The rules of the competition specified prediction of the nominal prices as the goal. We tried two different approaches: (*a*) nominal ACE—ACEing the nominal price on the chosen regressors and the price index and (*b*) real ACE—predicting the price index in an autoregressive model and multiplying the real ACE predictions by the price index predictions. We chose among these methods based upon *RMSE* prediction error. As a (depressing) check on our work, we also estimated an autoregressive model for $P1$ and $P2$.

Our second prediction method required an estimate of the price level, which we made with a simple autoregressive model. No alternate models were considered, and none of the standard tests were run. The price level, P, was predicted by

$$P_t = \underset{(.69)}{-1.29} + \underset{(106)}{1.013}\, P_{t-1} + \underset{(4.22)}{.46}\, E_{t-1}$$

with an R^2 of .9982. The numbers in parenthesis are t-statistics. The prediction error from this equation was on the order of 1%—more than good enough for our purposes.

For $P1$, the nominal ACE method had an *RMSE* of 1.34; using real ACE and multiplying by the price index prediction gave .745 as did the simple autoregressive method. We chose the real ACE method for $P1$.

For $P2$, the *RMSE*s were .392 for nominal ACE, .436 for the autoregressive model, and .572 for real ACE. We selected the method of using the nominal $P2$ in ACE directly, adding the lagged price level as a seventh right-hand-side variable.

The Transformations

Since the detailed numerical results are documented in Dorfman and McIntosh, we will focus on the plotted transformations found by ACE. Figure 2 contains the results for the variable $p1$ with the three right-hand-side variables $p1(t-1)$, $p1(t-2)$, and $y(t-3)$.

In the upper left of the figure, values of $\phi(y)$ are plotted on the vertical axis against those of y on the horizontal axis. For the most part, something like a logarithmic transformation is suggested, as the points appear to lie along a curve which is concave. The more horizontal portion is harder to interpret; for this region, the best fit is obtained by mapping all values of y to essentially the same $\phi(y)$, around -0.9.

The plots for the three right-hand-side variables should be interpreted similarly. The relationship between $\theta(p1(t-1))$ and $p1(t-1)$ is essentially linear, although the smallest values are not too informative, in the sense that a range of lagged values of $p1$ yields nearly the same value of $\theta(p1(t-1))$. To aid in interpreting the results, note that an increase in lagged price, from 0.03 to 0.04, appears to increase $\theta(p1(t-1))$, which is added to the dependent variable $\phi(y)$, by around 0.5. When so desired, this could be transformed into a corresponding change in y using the first plot.

A plot of the optimal transformation of $p1(t-2)$ shows a highly nonlinear relationship.

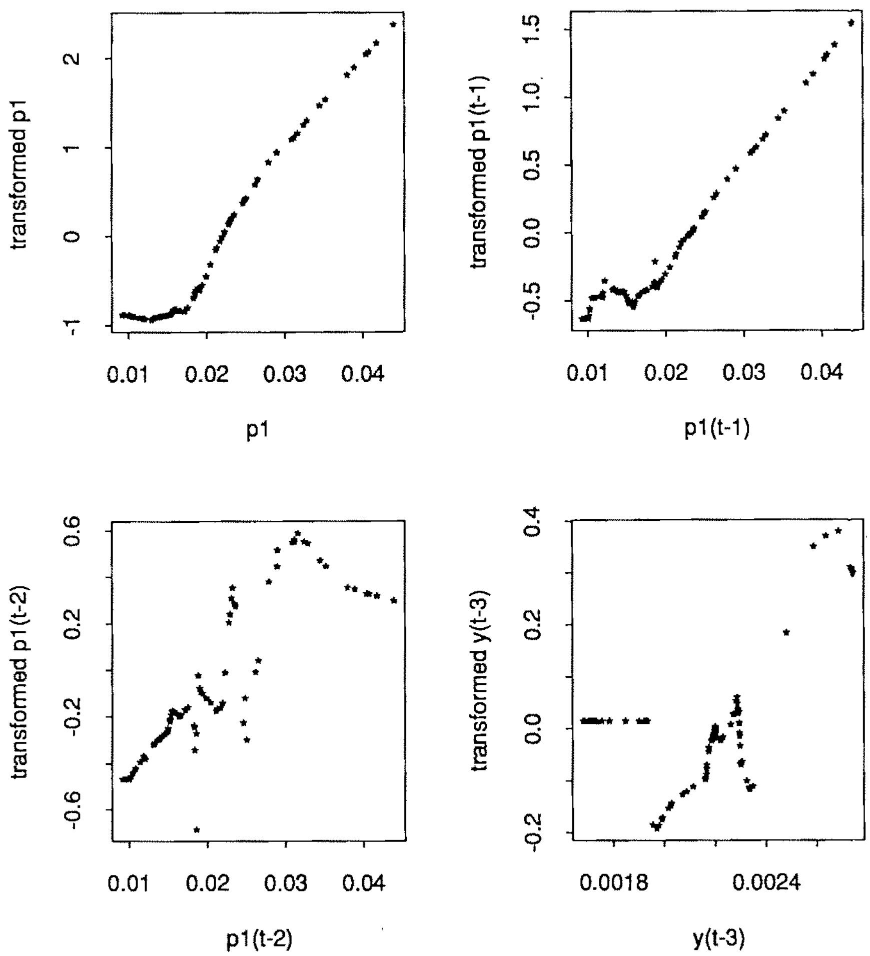

Figure 2. Optimal transformation using ACE—$p1$

Values of this variable below around 0.03 are characterized by a positive association with $\phi(y)$—the transformation $\theta(p1(t-2))$ is increasing, for the most part; values above 0.03 are characterized by a decreasing transformation.

As noted by Breiman and Friedman, ACE can find very nonlinear relationships where the association between two variables is actually rather weak. In situations where the correct variables to include are in doubt, therefore, there is some danger of overfitting. When this is not the problem, plots such as this one illustrate a gain that ACE affords over regression methods based on an arbitrarily chosen parametric transformation—nonmonotonic transformations are permitted with ACE, while these are almost always ruled out with parametric approaches, for instance, with a Box-Cox transformation.

Summary and Conclusions

We used a nonparametric regression technique, ACE, to estimate the optimal transformations of the prices for which forecasts were desired and the variables on which they were based. Our artificial example illustrates the power of the technique, as do the examples of Breiman and Friedman. For the present case, the optimal transformations appear to be both nonlinear and, in some cases, nonmonotonic. The common practice of double-log or Box-Cox regressions, while often good approximations, do not admit the latter possibility.

Two applications for ACE are suggested any time the functional form is in doubt. First, plots such as those we obtained could be used to suggest the appropriate parametric transformation. For instance, the monotonicity assumption could

be examined. Second, models such as the double-log model can be tested. ACE provides a diagnostic check in the following manner. Suppose that the true model is believed to be $\ln y_t = \beta \ln X_t + \varepsilon_t$. Applying ACE to $\ln y_t$ and $\ln X_t$ should reveal that the optimal transformation of each variable is linear if the hypothesis is true. If an alternative model were true, ACE would transform the logged data to better mimic that relationship.

With regard to the competition, we were at first impressed with the performance of heuristic, ad hoc, model selection, combined with the ACE method. Havenner and Criddle's state space methods are appealing because they avoid the ad hoc model selection, so it was impressive to see a series of (incorrect, it turned out) economic assumptions and blatant empiricism outpredict the state space model for $P1$. On further reflection, we note that even a very simple autoregressive model predicts quite well and wonder what kind of *RMSE*s would have been turned in by an experienced user of the Box-Jenkins techniques.

Results of a Price Forecasting Competition

Jeffrey H. Dorfman and Christopher S. McIntosh

This paper evaluates the results of the price-forecasting competition in which three teams of econometricians attempted to forecast two time series of unidentified prices. The price series were presented as part of an artificial data set containing a total of seven variables and 100 observations. The seven variables were identified as price of good one, price of good two, quantity of good one, price of other goods, income, and population. The participants were sent the first 90 of the 100 observations and asked to construct one-step-ahead forecasts for the final twenty observations in the data sets they received. Forecasts for the final ten observations were then generated according to an *ex ante* rule so that the last ten forecasts would truly be out of sample. As in the introduction, the two price series will be referred to as the prices of "feed" ($p1$) and "livestock" ($p2$).

The Forecasts

The three teams of forecasters were Peter Berck and James Chalfant, David Bessler, and Keith Criddle and Arthur Havenner. The methods employed by each are described in detail in preceding papers and are only briefly described here.

Berck and Chalfant employed a statistical package shown as ACE which, when given a dependent variable, y, and a set of independent variables, X, searches for the $\phi = g(y)$ and $\theta = h(X)$ that maximizes the correlation coefficient between θ and ϕ. It then uses these transformations of the variables to forecast ϕ and recover a forecast of y by applying the inverse transformation $\hat{y} = g^{-1}(\hat{\phi})$. To forecast the price of feed, Berck and Chalfant included one-period and two-period lagged values of the price of feed deflated by the price of other goods and real per capita income lagged three times as independent variables. They used the deflated price of feed as the dependent variable, then recovered it with an AR(1) prediction of the price of other goods. For the forecasts of the price of livestock, Berck and Chalfant used seven independent variables: the deflated price of feed lagged once and four periods, per capita consumption of livestock lagged one, two, and four periods, lagged real per capita income, and the lagged price of other goods. They did not deflate the price of livestock.

Bessler used a Bayesian vector autoregression (BVAR) which included all seven series in the data set. The series for price of other goods, income, and population were included in differenced form. The BVAR was determined by Bessler to be a fourth-order model with some time variation to the parameters. The coefficients all had prior means of zero; the nondifferenced series had priors of random walks, while the differenced series had priors of zero. The parameters that control the strength of the priors were set as follows: overall tightness = .6, cross-equation tightness = .4, decay = 1.0, and time variation = .01.

Criddle and Havenner used a bivariate state space model of the two price series for their forecasts. The best model was characterized by three states and a lag parameter of six periods. Their state space model constructs the conditional state vector of the bivariate series from lagged values of the two price series and lagged errors in a form that is a minimal sufficient statistic for the two series. This state vector is then multiplied by a parameter matrix to obtain forecasts of the two series. For more details on all three of the methods, see the papers immediately preceding this one (Berck and Chalfant, Bessler, Criddle and Havenner).

The forecasts for the three models, along with the actual values of the two price series are shown in table 1. The actual values were constructed

by the authors using the methods and equations described in McIntosh and Dorfman.

Evaluation of the Forecasts

As discussed in McIntosh and Dorfman's introductory paper, the participants were told in advance that their forecasts would be evaluated on the basis of mean-squared forecast error and on ability to predict turning points. Given this information, the participants are likely to have based their loss functions for the selection of their final models on these two criteria. As pointed out by Zellner, one must be careful to evaluate forecasts with a norm consistent with the loss function used to construct them. Therefore, the main statistics used for evaluating the performance of the forecasts will be the mean-squared forecast errors of the models and the values of the Henriksson-Merton test for value of information in a forecast series.

The Henriksson-Merton test has a null hypothesis that a forecast series contains no information. The test is based on the direction of revision of the series (i.e., whether the differences are positive or negative) and how often the forecasts correctly predict those revisions. The ability to predict the direction of revision of a series is considered by this test to be the definition of a forecast containing information. This makes sense for many financial series where the ability to predict the direction of change of a series is enough to make money (or decide on hedges, etc.). The result of the test is an exact, finite sample, confidence level for the rejection of the null hypothesis. For example, a given series of forecasts might lead the test to declare a 95% confidence level for that series' containing information. The higher the level of confidence, the more revisions the model correctly identified with its forecasts. For more details, see Henriksson and Merton.

Along with the mean-squared forecast errors (*MSFEs*) and the Henriksson-Merton confidence levels, the mean absolute percentage errors (*MAPEs*) were also calculated because they are a commonly reported statistic (table 2). The subtable for each statistic has three rows: the first for all thirty observations (71–100); the second

[a] ACE1 is the ACE model for $p1$, the price of feed, ACE2 is the model for $p2$, the price of livestock. Similarly BVAR1 and BVAR2 are the forecasts of $p1$ and $p2$ from the BVAR model, SS1 and SS2 are the forecasts of the state space model, and MOD1 and MOD2 are the forecasts from the OLS estimation of the true model.
[b] This row is for observations 71–100.
[c] This row is for observations 71–90.
[d] This row is for observations 91–100.

for the first twenty (71–90), which the participants could see; and the third row for the last ten observations (91–100), which were truly out of sample. For comparison, the statistics for the "true model" used to generate the data are included in the table. This true model is the OLS estimation of the correct functional forms for the demand and supply models shown in McIntosh and Dorfman. The only current period right-hand-side variables in the price-dependent demand functions are the current period quantities. For these variables, the predicted values from the quantity-dependent supply equations were used (the supply equations had only lagged right-hand-side variables).[1] OLS estimates are consistent and efficient because the system of equations is recursive and because the errors used in generating the data set were independently distributed normal random variables.

Several general conclusions can be drawn from table 2. For the price of feed, the BVAR model seems generally to have outperformed the other models in terms of accuracy (*MSFE* and *MAPE*). For ability to predict turning points, the ACE model had the highest confidence levels for the price of feed. For the price of livestock, the state space model performed the best in terms of the accuracy-measuring norms (*MSFE* and *MAPE*). The results of the Henriksson-Merton tests showed that the BVAR and state space models had identical confidence levels for the ability to predict turning points. In a number of instances, the forecasts from the three models beat the performance of the true model in terms of accuracy. The ACE and BVAR models each had a smaller *MSFE* for the price of feed than did the true model over the first twenty observations (71–90), and the state space model had a smaller *MSFE* than the true model over the last ten observations (91–100) for the price of "livestock." The state space and BVAR models also beat the true model once each in terms of *MAPE* and tied it twice each in the Henriksson-Merton test results. The ACE model also tied the true model once in the Henriksson-Merton test.

To draw a clearer picture of the relative performances of the different models, a loss function combining qualitative and quantitative measures was developed. Assume that a decision maker must select a single model for use in forecasting each of the series. Further, assume that the decision maker desires a small *MSFE* and the ability to predict the direction of revision. A particular loss function that such a decision maker could use is

$$(1) \qquad L = \alpha MSFE + (1 - \alpha)(1 - c),$$

[1] While it might be possible to construct a better instrument for the quantities than the predictions from the supply equations, these instruments were used so that the true model's forecasts were completely based on structural equations. Although a better instrument for the quantities likely would have improved the true model's performance, the construction of the true model's forecasts was for comparison purposes only and not an attempt to produce the best forecasts possible.

where c is the confidence level from the Henriksson-Merton test. This loss function simply takes a convex combination of the *MSFE* and the significance level from the Henriksson-Merton test of the forecasts. The significance level is used in place of the confidence level so that a low value is a "good" instead of a "bad" result. The loss function in (1) was evaluated for each participant's forecasts of each price series for three subsets of the data: all thirty observations (71–100), the first twenty (71–90), and the last ten (91–100), and for values of α ranging from 0 to 1 (the loss was computed at intervals of 0.01 over this range).

The results of the loss computations for each model allow the models to be compared by a single scalar-valued norm. For the price of feed, the ACE model dominated completely over the first twenty observations (71–90), having the smallest loss for all values of α. Similarly, the BVAR model had the smallest loss over the last ten observations (91–100) for all values of α. Over all thirty observations (71–100), the ACE model had the smallest loss for $\alpha \in [0, .78]$, while the BVAR model had the smallest loss over the remaining range, $\alpha \in [.79, 1]$. The state space model never had the smallest loss for the price of feed. However, for the price of livestock, the state space model completely dominated in terms of minimum loss. The state space model had the smallest loss for all values of α over all three subsets of the data. Because of equal values for the Henriksson-Merton test confidence levels, the ACE model tied the loss function value of the state space model at $\alpha = 0$ over the first twenty observations and the BVAR model tied with the state space model at $\alpha = 0$ over both the entire thirty observations and the final ten observations. Other than these ties at an extreme point of the range, the state space model had the smallest loss for all values of α because of smaller *MSFE*s than the other two models over all three subsets of the data and equal or greater confidence levels for the ability to predict direction of revision. This dominance was interesting in light of the fact that the state space model failed to have the smallest loss for any value of α for the price of feed.

Another point to be made about the loss function concerns the loss connected with a pair of models not included in the competition. A pair of univariate ARMA models for the two prices were estimated. The univariate model for the price of feed, an ARMA(2, 0), proved to have the smallest loss for all values of α for the last ten observations and for all thirty observations. For the first twenty observations, the ACE model still had the smallest loss for all values of α. For the price of livestock, the univariate model, an ARMA(5, 0), also had the smallest loss everywhere except for the subset of the last ten observations and values of α from 0.51 to 1.0. The state space model still had the smallest loss for this subset over this range of loss functions. This performance by the univariate models suggests that the techniques used by the participants failed to noticeably improve the performance of their forecasts beyond forecasts from standard Box-Jenkins methods.

Diagnostics

For further insight into the performance of the various forecasts, several additional diagnostic tests were run. First, a test for unbiasedness of the forecasts was conducted; then, a Granger-Newbold test for significant differences in *MSFE*s was performed. The unbiasedness tests will be discussed first.

To test the hypothesis that the forecasts of a given model are unbiased a simple F-test from a least squares linear regression was used. The regression

$$p_t = \beta_o + \beta_1 f_t + e_t \tag{2}$$

was estimated for each price (p) and corresponding set of forecasts (f). The null hypothesis for the F-test was simply the joint restriction that $\beta_o = 0$ and $\beta_1 = 1$. The ACE model for the price of livestock proved to be biased when tested for all thirty observations—the test statistic was $F = 9.351$ compared to a critical value of 4.155 for a 5% significance level; but none of the other models had test statistics greater than 2.0. Thus, except for the ACE model's forecasts for the price of livestock, the forecasts all are statistically unbiased.

The results of the Granger-Newbold tests for significant differences in the *MSFE*s between a pair of models were more interesting. This asymptotic test utilizes only the forecast errors from each of the two models being tested. It creates two variables, $ep_t = e1_t + e2_t$ and $em_t = e1_t - e2_t$, where $e1$ and $e2$ are the forecast errors from the two models being tested. If the correlation coefficient between ep and em is significantly different from zero, then the model with the smaller *MSFE* has a significantly smaller *MSFE* at whatever significance level is used. The asymptotic variance of the correlation coeffi-

cient under the null hypothesis of equal *MSFE*s is $(1/T)$, where T is the sample size and a simple one-tailed t-test is appropriate (one-tailed because it is the absolute value of the correlation coefficient that is important; which *MSFE* is smaller is obvious).

The test was performed on all possible pairs of forecasts including the forecasts from the true model. Using a 5% significance level, ten of the pairs of *MSFE*s proved to be statistically different in size. For the price of feed, only two pairs of *MSFE*s were significant: both the BVAR and true model had significantly smaller *MSFE*s than the state space model over the last ten observations. For the price of livestock, however, many pairs of *MSFE*s proved to be significantly different in size.

Over all thirty observations the ACE model had a significantly larger *MSFE* than all three other models, and the BVAR model had a significantly larger *MSFE* than both the state space and true models. Over the first twenty observations, the BVAR model again had a significantly larger *MSFE* for the price of livestock than either the state space or the true model. Over the final ten observations of the price of livestock the ACE model's *MSFE* was significantly larger than the true model. The state space model was the only model to have a significantly larger *MSFE* for the price of feed (in two cases) and the only model not to have a significantly larger *MSFE* for the price of livestock. The estimated correlation coefficients for the tests and the critical values are shown in table 3.

Table 3. Results of *MSFE* Difference Tests

	Price of Feed			Price of Livestock		
	BVAR	SS	MOD	BVAR	SS	MOD

[a] Asterisk indicates significant at the .05 level.

Conclusions and Overview

The results of this forecasting competition cannot be generalized in order to make sweeping claims about which methods work better than others given a criterion to evaluate forecast performance. The participants forecast only one set of data from one model. Even to make strong conclusions for one model would necessitate multiple draws from the data-generating process. However, while caution is in order, several conclusions can be drawn from this competition. First, no single method dominated the others; each proved superior for a series and a given set of loss functions. More important, the three models were not dominated by the true model. All three forecasting methods produced results that were relatively comparable to the known, true model. This suggests that structural econometrics may not be superior to time-series techniques even when the structural modelers are given the elusive true model. This, in turn, calls into question the use of large structural models for forecasting purposes when the true models are clearly unknown. Ultimately, the choice of the "best" forecasting model will remain problem specific and tailored to the particular loss function of the decision maker employing the forecasts.

Policy Reform and Economic Development (Ann Krueger, Duke University, presiding)

Policies for Economic Development

Stanley Fischer and Vinod Thomas

At the end of a decade in which many developing countries have seen economic regress rather than progress and in which the formerly socialist economies for the most part turned away from central planning toward a market-oriented approach, there appears to be more agreement on the policies needed to produce growth and economic development than at any time in the post-World War II period. It remains to be seen whether the moment is more than fleeting. But it is certainty a good time to attempt to set out a mainstream, pragmatic view of what those policies are and of the uncertainties that surround the basic market- and outward-oriented approach to development.

In this paper we summarize the consensus views of the major economic policies needed to generate economic growth and development, consider issues that cut across these policy areas, and then provide brief concluding comments.

Consensus Views in Major Policy Areas

Policies conducive to economic development in three broad areas are an appropriate macroeconomic framework, the right set of sectoral policies and investments, and integration of the domestic economy into the world economy.

Getting the Macroeconomic Framework Right

Economic development is unlikely to occur unless policies produce a stable macroeconomic environment in which inflation remains reasonably low, the real exchange rate is competitive and stable, and foreign exchange and debt crises are avoided.

Fiscal policy. Tax rate and expenditure policies of government, including the composition of government spending, are the government's major microeconomic tools for affecting the allocation of resources. Beyond these microeconomic effects, fiscal policy is increasingly seen as the key to successful macroeconomic policy because, in its macro impacts, it has direct effects on the current allocation of resources, and because all methods of financing budget deficits have potentially adverse macroeconomic consequences when used to excess.

Given private saving, fiscal deficits displace private domestic investment or cause current account deficits. Thus, unless private saving responds fully to public sector deficits—and there is little reason to think it does—reduction of the fiscal deficit is likely to improve the current account and, perhaps after a period of adjustment, increase investment.

Fiscal deficits can be financed by printing money, by running down foreign exchange reserves, and by borrowing, at home or abroad. Each of these methods of financing can be used on a small scale (and in the case of running down foreign exchange reserves, on a transitory basis), but each is likely to have seriously adverse consequences if used on a major scale. Printing (high-powered) money is inflationary; running down foreign exchange reserves leads to a foreign exchange crisis; domestic borrowing can lead to higher real interest rates and an unstable domestic fiscal situation; and excessive foreign borrowing can lead to an external debt crisis.

While the conclusion is that fiscal moderation is the key to macroeconomic stability, this does not mean a zero deficit is optimal: a country that is growing fast can afford to run a larger deficit than one that is growing slowly; a country with a higher saving rate can run a given deficit for longer than a country with a lower saving rate. Fiscal moderation must be judged by the projected path of the debt (the sum of internal and external debt) to GNP ratio, and of the inflation rate and external balance. On the whole, inadequate fiscal policies remain a central factor be-

Stanley Fischer is chief economist, and Vinod Thomas is chief, Trade Policy Division, the World Bank.

The views expressed in this paper are those of the authors and are not official views of the World Bank.

hind the macroeconomic instability and poor performance of many developing countries.

The exchange rate. The second key to a sound macro framework is the exchange rate; it plays two roles in economic policy. First, the level of the real exchange rate is crucial to the development of the domestic economy: it establishes market incentives to export and the level of protection for domestic industries. Second, stability of the nominal exchange rate is one potential monetary anchor and a powerful anti-inflationary factor. When an economy operates with a fixed nominal exchange rate, the quantity of money becomes endogenous. This simplifies the job of the monetary authority; but, as experience shows, it frequently leads to a host of foreign exchange controls.

The two roles of the exchange rate sometimes clash: governments afraid of inflation hold the nominal exchange rate constant or devalue it too slowly, with the result that the domestic currency appreciates, and—with a lag—the current account goes into crisis. When the monetary anchor and trade incentive roles of the exchange rate conflict, the monetary anchor should be pulled up first and attention turned to the underlying source of inflationary pressure, typically the budget. Intermediate steps, such as a crawling peg, in conjunction with appropriate fiscal policy can provide some monetary stability without tending to produce an overvalued currency.

Investment, saving, and growth. Investment and saving ratios in rapidly growing economies are typically higher than those in stagnating economies. It is further clear that sustained growth will not resume in Sub-Saharan Africa and Latin America until investment ratios there rise significantly. The rise in the real interest rate in the 1980s reduces the possibilities of financing investment from abroad; economic growth in the 1990s will have to be largely domestically financed. The surest way to increase domestic saving is to increase government saving, i.e., to reduce the government budget deficit. The emphasis in the 1980s was on the importance of positive real interest rates for development. The emphasis is appropriate when the real interest rate is significantly negative, as it frequently is in high inflation economies: negative real interest rates appear to reduce saving and impair the efficiency of the financial system by reducing the share of saving that is intermediated through financial institutions. But once the real interest rate is positive, or nearly so, there is little empirical or theoretical reason to believe that further increases will increase saving.

Responding to shocks. Emphasis on the stability of the macroeconomic framework should not obscure the importance of the ability of the government to adjust macroeconomic policy quickly to external and internal shocks. Fiscal and monetary policy, and the exchange rate, may have to change rapidly when external conditions change; the more successful governments recognize change and respond to it. The need for flexibility is especially great for economies whose external earnings fluctuate a great deal, typically because they are dependent on earnings from one or a few primary commodities.

Sectoral Policies: Projects and Beyond

Macroeconomic policies for stability and growth usually need to be underpinned by appropriate sectoral policies to obtain a satisfactory supply response. Sectoral policies include investment decisions, pricing and regulatory policies, and institutional development.

Investments in agriculture, industry, infrastructure, and human resources have long formed the core of development efforts. The traditional approach was to pursue development projects in these sectors with the aid of project analysis of benefits and costs. The effectiveness of the investments, however, depends on the policy environment affecting the sector and the degree of institutional development.

Sectoral priorities and investments. Although there is no universal prescription for sectoral priorities for development, development usually requires increases in agricultural productivity permitting an increasing share of the labor force to contribute to industrial production. Accordingly, development is usually accompanied by an increasing share of industry in output. Human resource development is both an independent goal of development and an essential in-

strument of economic progress.

Unprecedented rates of population growth in the post-World War II period have contributed to low or negative per capita income growth in much of Africa, Asia, and for some time in China and India. Despite significant political opposition within the United States, international agencies have sought to assist governments to reduce population growth. Success to date has been limited, but there have recently been encouraging signs from some African countries, where population growth rates appear to be turning down as a result of government educational programs and the provision of contraceptives. Reducing the rate of population growth remains a priority of development policy in many developing countries.

Sectoral policies and strategy. The emphasis on the centrality of sectoral and macroeconomic policies to the success of projects has strengthened in recent years, along with the recognition that policies are of independent importance to sectoral performance. Measures to bring domestic relative prices closer to international levels and to establish a relatively neutral macroeconomic framework are often essential to enhancing sectoral performance. In agriculture, for example, incentives were historically suppressed by agricultural taxes. Perhaps more important, macroeconomic policies resulting in overvalued exchange rates have translated into heavy (often unintended) taxation of that sector. Adjustment programs in the 1980s have therefore focussed on both macroeconomic policies (exchange rate, import protection) and sectoral pricing policies (eliminating price controls on agricultural output, for example). Concurrently, many programs have also attempted to reduce the rather ineffective input subsidies in agriculture while improving the delivery of inputs and services.

The consensus is converging to the view that macroeconomic and sectoral pricing and regulatory policies should be relatively neutral, that governments should move away from interventions designed to favor particular industries, regions, or factors of production. However, moving toward neutrality may require active transitional government policies, for instance in restructuring public enterprises or the financial system (see also the next section). It also remains true that an active government investment program in the sectors, especially, physical infrastructure and human resource development and technology, is essential to development.

Integrating with the World Economy

The most successful performers of recent decades have been the newly industrializing economies, characterized by their relative openness and links with the world economy. To maintain these links, they have had to remain competitive in a rapidly changing world environment. Common to successful competition strategies is the reduction or elimination of discrimination against tradables—permitting exports and efficient import substitutes to be produced on a similar footing with nontradables.

However, such neutrality in the trade regime has been approached through different routes. Some successful reformers have substantially liberalized their trade restrictions (Chile, Mexico), others have intervened to offset existing biases against exports (Korea, Taiwan), and still others have done both (Indonesia, Turkey). Government controls have been especially prevalent in the area of capital flows in many countries. Interventions to encourage new technologies and to industrialize have also paid off on occasion.

Commercial policy reform. Developing countries are more open, and their trade regimes are more efficient than a decade ago. They have substantially reformed their exchange rate and export policies. They also have increased the efficiency of their import regimes by switching from quantitative restrictions to tariffs. But reductions in the levels of nominal and effective protection have been more limited than is generally believed.

Most countries that have implemented trade policy reforms have won long-term economic gains. The policy changes and additional financing under adjustment programs have both been associated with moderate improvements in output and export growth. However, supply response to changes in relative prices associated with the trade reforms has been limited in many countries. The main constraints on the supply response have been restrictive domestic regulations and inefficient public enterprise policies; growing protectionism in industrial countries; doubts about the permanence of the reforms; and inadequate institutions, infrastructure, entrepre-

neurial, and managerial capacity in the reforming country.

Issues Spanning Policy Areas

There are several issues that span policy areas. These include sustainable development, both country-specific and global environmental sustainability, and social, political, and economic sustainability of adjustment programs. Other issues include poverty alleviation, the balance between both public and private sectors, the World Bank's role, and adjustment lending.

Sustainable Development

Two issues fall under this heading. The first is environmental sustainability, which has both a country-specific and global aspects. One fear is that in many countries development is taking place by exploiting and destroying much of the resource base, and that such development is accordingly not sustainable. The presumption is that two-way links exist between growth and the environment: certain growth policies are consistent with environmental protection, and environmental care in turn contributes to sustained growth. But knowledge of the tradeoffs between measured growth and environmental protection must increase. At the same time, simple steps to prevent environmental damage, such as environmental assessments for all projects, are already being implemented.

Global environmental issues pose more difficult problems. If global warming is taking place, it is largely the result of current and past economic activities of the now-industrialized countries. If measures are put in place to reduce global environmental damage, the issue of burden sharing between developing and industrialized countries—as well as among all countries—will pose major political difficulties.

A second sustainability issue is whether the adjustment programs of many countries are socially, politically, and economically sustainable. Adjustment is more likely to be socially sustainable if the poor are protected during the process of adjustment. Political sustainability may depend on how adjustment affects the segment of population with political clout. In general, adjustment is more likely to be sustainable the sooner it shows economic results. One reason to provide external financing during the adjustment process is temporarily to reduce the extent of cuts in expenditures and in imports that would otherwise have been necessary.

Poverty Alleviation

Although the purpose of economic development is to reduce poverty, poverty alleviation is a separate goal of policy in developing as well as industrialized economies. Specific policies, such as targeted food subsidy and health programs, can be used to protect the poor and reduce poverty, even during adjustment. Bolivia's experiment with the Emergency Social Fund and Ghana's Program of Actions to Mitigate the Social Cost of Adjustment are examples. These are temporary measures (three years in Bolivia and two in Ghana). More fundamentally, education and other social programs can be designed to reduce poverty, even though in many countries social spending helps mainly the middle and upper classes. More effective and better targeted public expenditures are needed. Sometimes it would help to correct mis-targeting of existing public social expenditures, for example, by reducing public funding of education and curative health care expenditures.

The Balance between Public and Private Sectors

The new consensus on development policy places greater stress than before on the central role of markets, and on the private sector (in some countries, the informal private sector) as the engine of growth. The role of the public sector is seen as the creation of a favorable enabling environment for economic activity. The enabling environment consists of the legal, institutional, and policy framework within which economic agents operate.

A government that creates a favorable enabling environment has a large role to play, for instance in ensuring the provision of infrastructure, including social services, such as poverty alleviation, basic education, and access to health care; public security; a stable macroeconomic framework; and an efficient fiscal and regulatory system.

The most difficult question about the role of the government is whether it should take an active part in promoting particular industries, that is, whether it should pursue an industrial policy. Some successful elements of an active policy are clear: export development and assistance in

marketing, information, technology, and know-how. Expanding manufactured exports requires sustained efforts on both macroeconomic and microeconomic levels. Japan, Korea, and Taiwan have paid attention to the many nonprice requirements of export development. For a period of time, they also pursued export development while maintaining a certain degree of import protection.

The World Bank's Role

Since the start of its operations in 1946, the World Bank has moved from assisting in the reconstruction of post-World War II Europe to the development of basic physical infrastructure in the developing world, to financing developmental projects, and to the support of structural reform through adjustment lending. This evolution largely reflects a shift in the economics of development. A professional view that focussed on "critical mass" and the role of the economic planner has shifted, under the weight of four decades of experience, to a view that centers on establishing an enabling policy environment, the efficient decentralization of information, operation of incentives, and integration with the world economy.

This view also has become more realistic with respect to the goals and operations of governments. It has moved away from the simple notion of government as an altruistic entity and at the same time has accepted that significant changes cannot be instituted if they are not owned by the policy makers and administrators.

For the three decades from 1950 to 1980, the World Bank's almost exclusive role was to provide financing and technical assistance in the development of investments. Even since the advent of adjustment lending in 1980, about 75% of World Bank lending has continued to be for projects.

Adjustment Lending

The shift of World Bank operations toward adjustment lending in the 1980s has been associated with the debt crisis and its associated external shocks, the decline in general balance-of-payments lending to developing countries by the commercial banks. As the debt crisis developed, it became clear that the adjustments many of the indebted countries would have to make to the sharp reduction in external financing could be smoothed by the provision of rapidly disbursing loans by the World Bank. But to ensure that such loans were used to make economic adjustments to changed circumstances, the loan conditionality was tied to policy changes in the borrowing country.

Adjustment lending, as it has taken place in the 1980s, can be characterized as rapidly disbursing and policy based. However, these characteristics are separable, and slowly disbursing policy lending is possible.

Analytically, the shift to adjustment lending coincided with the recognition that the overall quality of economic policy management is key to economic development, and with the realization that a good economic environment is essential to project development. While early structural adjustment loans focussed on general macroeconomic reforms, the adjustment experience of the last decade has led to greater emphasis on sector-oriented programs, and thus to sectoral adjustment loans. These adjustment loans typically support significant policy changes in a particular sector or sectors, with disbursement depending on both the sectoral policy measures and the maintenance of an appropriate macroeconomic framework. The design of policy lending programs has been a subject of controversy for borrowing members, international organizations, and World Bank staff and management alike. Borrowers under the pressure of debt service requirements and domestic resistance protested at the hardships coincident with undertaking such programs. Some observers in donor countries also objected to the social burdens associated with the implementation on program conditionality, while others argued that adjustment loans enabled borrowers to avoid implementing required policy changes.

This controversy has tended to die down as some countries have shown success in pursuing adjustment policies, as nonadjusting countries have descended into economic disorder, and as the lack of alternatives to adjustment has become clearer.

Outstanding Issues

General agreement on the policies needed to produce growth and economic development will remain only if the currently agreed upon policies produce growth and development. Seen in that light, the challenges, particularly from Africa and Latin America, and most recently from the reforming socialist economies, are formi-

dable. In many cases, the problems are analytic, for instance, how to sequence the adjustment of a heavily distorted economy with macroeconomic and external imbalances to the market-oriented structure that its policy makers seek. In other cases, the problems are political: countries with infrastructure and analytic capacity lack the political ability to implement changes that are generally recognized to be desirable. This is not a problem only for developing countries. In other countries, inadequate human capital and institutional framework constrain development. It is essential to recognize that the problems of development differ from country to country, and that each country's policies have to fit its own structure while still recognizing the realities of the world economy in which it operates.

There are also deep questions about the role of external funding and the international development agencies. It is often argued that countries would have done better if left to their own devices and forced to confront their budget constraints earlier and harder. One can agree with this judgment for some countries, but not for most. Nonetheless, it is essential to recognize that an important goal of development is for countries to reach the stage at which they manage their own affairs.

Adjustment Policies and Economic Development

Jacob A. Frenkel and Mohsin S. Khan

The principal objective of the International Monetary Fund (IMF), as defined by its articles of agreement, is the correction of balance of payments disequilibrium in member countries. The policies the IMF recommends to reduce the degree and duration of external and internal imbalances that give rise to balance-of-payments difficulties must, however, be set within the context of achieving and maintaining price stability and satisfactory rates of economic growth.

In analyzing IMF policies designed to achieve these multiple objectives, it is useful first to consider the circumstances in which the IMF is called upon to assist in designing an adjustment program and in providing temporary financial support for it. The need for a stabilization program, whether supported by the IMF or otherwise, arises when a country experiences a persisting imbalance between aggregate domestic demand (absorption) and aggregate supply, which is reflected in a worsening of its external payments position. As long as foreign financing is available, the relative expansion of domestic demand can be sustained for an extended period, although at the cost of a widening deficit in the current account of the balance of payments, a loss of international reserves, rising inflation, worsening international competitiveness, and a heavier foreign debt burden. However, this situation cannot last indefinitely. Eventually, the country would lose international creditworthiness, and the cessation of foreign credits would necessitate adjustment. This forced adjustment may be very disruptive for the economy. The aim of the IMF under these circumstances is to provide for an orderly adjustment, and the first task is to stabilize the economy—lower the rate of inflation, restore international competitiveness, reduce the current account deficit, and check the loss of international reserves—by correcting the macroeconomic imbalances that led to these problems. Once macroeconomic stability is assured, then policies to expand the productive capacity of the economy and improve the efficiency with which resources are utilized are more likely to be successful. Experience and theory both suggest that, to achieve adjustment with growth, such a pattern of sequencing of macroeconomic and structural policies is warranted.

Although growth is a central element in the IMF's objectives, it should be stressed that the IMF is not a development agency. Its mandate is to provide temporary financial support and not development aid. Consequently, the IMF does not possess a "development paradigm" as such. Nevertheless, by establishing macroeconomic equilibrium in the economy, the IMF sets the necessary foundation on which development is based. Furthermore, the IMF has increasingly emphasized structural reforms in its policy advice. While this change stems from the recognition that economic stability cannot be regained without basic institutional and economic change, such reforms have a direct bearing on long-term growth and the structural transformations that make up the development process.

This paper outlines in broad terms the policy content of IMF-supported adjustment programs designed to achieve macroeconomic stability and higher growth. The description of policies, including aggregate demand policies (principally monetary and fiscal), structural policies, exchange rate policies, and external debt policies, is taken up in the next section. The empirical relationship between macroeconomic stability and long-run growth in a sample of 101 developing countries over the period 1973–88 is then examined. The concluding section draws some lessons on the role of IMF policies in economic development.

IMF Economic Policies

To achieve balance-of-payments viability, price stability, and a sustained satisfactory rate of economic growth, the IMF helps countries de-

The authors are with the International Monetary Fund.
The views expressed are the sole responsibility of the authors.

sign a fairly comprehensive package of economic policies (IMF 1987). The specific policy measures differ across countries, but each package has certain common features. The most important characteristic of the IMF policy package is perhaps the emphasis placed on the role of the market and relative prices in the expansion and allocation of resources. For this reason, measures to reduce distortions created by price rigidities, monopolies, and imperfect competition, taxes, subsidies, trade restrictions, and other direct controls over different facets of economic activity are generally given prominence in IMF-supported adjustment programs. Experience has shown that the decentralization of economic decisions and the use of realistic prices to guide such decisions can improve the efficiency of production and investment in a variety of political and institutional settings (including centrally planned economies. See Wolf).

However, this emphasis on "getting prices right" is not to suggest that the IMF sees no role for the government in the economy or that it is opposed to any and all forms of government intervention. The standard economic case for government intervention, i.e., when there is evidence of obvious market failure, is well appreciated, as are the arguments that developing-country governments need to provide the basic infrastructure for development to take place. The general market orientation has implications for the type of development strategy that is adopted, but this is not why the IMF advocates the policies it does. Indeed, the IMF is neutral on development strategies, and its policies are geared primarily to achieving the best possible macroeconomic outcomes under given circumstances. (For a discussion of alternative development strategies, see Sen.)

What then are the policies that would be considered to achieve balance-of-payments viability in the context of low inflation and improved growth performance? In general, most economists would tend to subscribe to the following set of measures typically included in IMF-supported adjustment programs:

(*a*) *Monetary restraint* aimed at reducing the growth of absorption and the rate of inflation. Generally speaking, a fall in the supply of credit will lower absorption directly through wealth effects and, by pushing up interest rates, cause the interest-sensitive components of aggregate demand to decline. The reduction in aggregate demand would tend to improve the current account of the balance of payments and put downward pressure on inflation (Frenkel and Johnson; Frenkel and Mussa; and IMF 1977, 1987). However, in curtailing monetary and credit expansion, care must be taken to prevent crowding the private sector out of the credit markets, so that government borrowing from the banking system, including the central bank, frequently must be restricted.

(*b*) *Interest rate policies* are employed to set rates at positive real levels, but not so high as to choke off investment and possibly cause the collapse of financial institutions. Thus, in general there is a consensus that real interest rates should be positive but low.

(*c*) *Reduction in the fiscal deficit* through cuts in government expenditures and/or increases in taxes. Theory and substantial empirical evidence can be used to support the proposition that a reduction in the fiscal deficit tends to reduce aggregate demand. *Ceteris paribus,* this improves the balance of payments and reduces inflationary pressures in the economy. Furthermore, because developing-country governments rely heavily on bank financing of fiscal deficits, an improvement in the budgetary position reduces the amount of liquidity being injected into the system. For both these reasons—reducing the claim on resources in the economy and restricting monetary expansion—cutting the fiscal deficit becomes an essential, if not the most critical, element of an adjustment program. However, in choosing the method for reducing the deficit, the relationship between public and private saving and public and private investment also must be considered. For example, under some circumstances, an increase in public saving may lead to a partially offsetting fall in private saving.[1] Also, private and public investment may be complementary to the extent that the public sector provides the necessary infrastructure; thus, reductions in public investment may have adverse effects on private investment and growth (Blejer and Khan).

(*d*) *Exchange-rate action* to ensure a real exchange rate that would improve international competitiveness and create the incentive to expand the production of internationally tradable goods. The main theoretical aspects of devaluation are well known (e.g., Dornbusch), but determining the appropriate change in the nominal exchange rate to achieve a target real exchange rate as well as predicting the effects of

[1] For a theoretical discussion of this issue, see Barro, Frenkel and Razin (1987, 1988). Empirical tests of the relationship between public and private savings in developing countries are contained in Haque and Montiel.

the policy are not easy tasks. Without a comprehensive general equilibrium model to specify relevant relationships among the exchange rate, trade and capital flows, and inflation, short-cut methods based on considerable judgments must be used. For example, it is common in developing countries to employ variants of purchasing power parity (PPP) calculations to assess the extent of the overvaluation of the domestic currency. It is assumed that a particular real exchange rate was "right" at some base period; and, using this as a target, nominal exchange-rate action and supporting policies (monetary, fiscal, incomes) to attain it are employed. This approach is susceptible to error and should be used with appropriate caution. By and large, the limited empirical evidence available supports the hypothesis that devaluation will work in the direction of improving competitiveness and the balance of payments. While it is sometimes argued that devaluation leads to a recession, there are doubts about the generality of this proposition (Lizondo and Montiel).

(*e*) Policies to *reduce external debt* if it is perceived as currently unsustainable or to limit foreign borrowing if it is likely to become unsustainable in the future. To assist countries in a debt crisis situation, the IMF has undertaken a number of steps: providing additional financing from its own resources, facilitating rescheduling of the existing stock of debt, encouraging additional lending to the country from both official and private sources, and participating in market-based debt reduction schemes.[2] All of these efforts are made with the idea that the country eventually will return to normal borrowing relations. In general, external-debt policies in IMF-supported programs are aimed at easing the liquidity problems of countries facing a debt problem and helping them maintain their long-run growth path.

(*f*) Introducing *structural reforms,* i.e., financial sector reforms, producer pricing policies, trade liberalization, tax reforms, etc., to make the economy more flexible and efficient. Such structural reforms can help in the adjustment process by expanding productive capacity of the economy. Nevertheless, structural reforms are not without difficulties. First, by their very nature, distortions tend to be microeconomic, and microeconomic policy measures suffer from certain theoretical weaknesses. Very soon one runs up against the propositions of the theory of the second best, and it is not always clear whether removing only some distortions will produce an increase in efficiency and welfare in the economy overall. Second, the issue of time lags is very relevant to the IMF as a short-term lender.[3] Substantial time may be needed for structural policies to show positive benefits, and adequate foreign financing is usually essential in the interim to ensure that the adjustment is as costless as possible. Finally, there is the sequencing of reforms. Unfortunately, economic theory provides little guidance on the optimal sequence, and it is difficult to generalize from country-specific experiences. What does emerge from experience is that domestic goods and labor markets should be liberalized prior to trade liberalization. Similarly, it has been argued that the liberalization of the trade account of the balance of payments should precede that of the capital account because asset markets adjust more rapidly than goods markets. The opposite sequence could result in large capital movements that could adversely affect the real exchange rate and domestic monetary conditions (Frenkel 1982, 1987; Khan and Zahler). Sound theoretical and empirical reasons also suggest that macroeconomic stabilization should generally precede large-scale domestic financial sector liberalization to prevent interest rates from overshooting (Villanueva and Mirakhor). Other than these broad lessons, little more can be deduced; accordingly, one needs to proceed on a case-by-case basis with the pace and sequencing of structural reforms.

Empirical Aspects of IMF Economic Policies

The next question is the extent to which IMF policies achieve their objectives of an improvement in external and internal balance—that is, macroeconomic stability—and whether macroeconomic stability is associated with higher long-term growth.

Starting with the first part of this question, consider the recent evidence in Khan for a sample of sixty-nine countries that had upper credit tranche arrangements with the IMF during 1973–88. Khan shows that on average the implementation of an IMF-supported program led to (*a*)

[2] The theoretical and empirical aspects of the debt crisis are addressed by the papers in Frenkel, Dooley, and Wickham.

[3] The new Structural Adjustment Facility (SAF) and the Enhanced Structural Adjustment Facility (ESAF) that provide financing to low-income countries have significantly lengthened the maturity period.

an improvement in the overall balance of payments, (*b*) an improvement in the current account balance, and (*c*) a reduction in the rate of inflation. But as is almost always the case with stabilization efforts, this improvement in the external position and in the inflation picture is achieved with some short-term cost, namely a decline in the growth of real gross domestic product (GDP).[4] Over time, however, this cost is reduced, and the positive effects of programs are strengthened. Thus, the empirical evidence confirms the hypothesis that the adoption of an IMF-supported adjustment program generally will lead to a more stable macroeconomic situation.

Establishing that IMF programs are conducive to macroeconomic stability is not the end of the story; the link between macroeconomic stability and long-run growth and development also must be shown. Linking macroeconomic stability to long-run growth is not easy. The economics profession lacks a fully satisfactory theory that directly relates macroeconomic policies and structural reforms to growth, other than through changes in the rate of capital formation. Therefore, macroeconomic policies are judged by their effects on investment, under the argument that policies with a favorable effect on investment are good for growth. But growth involves many factors other than physical investment. In general, growth of output will depend, *inter alia,* on growth of the labor force, changes in the efficiency of investment, changes in human capital (education, skills, and health), and technological developments.[5] It is not known as yet how precisely economic policies of the type contained in IMF programs will affect these other determinants.[6] There is presumption, supported by limited empirical evidence, that policies to achieve macroeconomic stability will affect growth in a positive fashion because they create a climate which is conducive to investment, increased domestic savings, and a larger flow of foreign financing, all of which will tend to raise the growth rate (Fischer, Dornbusch and Reynoso). Beyond these generalities, relatively little is known.

In the absence of a suitable theory to test, we conducted a purely statistical analysis of the relationship between long-run growth and macroeconomic stability. To this end, simple regressions were run relating the growth of real GDP to various indicators of macroeconomic stability using cross-section data for 101 developing countries averaged over the period 1973–88. These indicators were chosen arbitrarily because there is no generally accepted measure of macroeconomic stability. The following alternatives were included: inflation, the variance of inflation, the fiscal balance (as a percentage of GDP), the percentage change in the real exchange rate, and the variance of the real exchange rate.

The results of these alternative regressions are shown in table 1.[7] These equations are not intended to explain growth; they should be interpreted only as simple tests of association. As such, one should not be overly concerned with the general lack of goodness-of-fit one observes in the estimated equations. With regard to the relationships themselves, there is uniform support for the hypothesis that growth and alternative measures of macroeconomic stability are positively related in this large sample of developing countries. The countries with higher average growth rates over the period 1973–88 also tended to have lower average rates of inflation,[8] lower variance of inflation rates, better average fiscal positions, larger average depreciations of the real effective exchange rate, and lower variance of real effective exchange rates.

Taken at face value, the regressions confirm the view that countries that have adopted appropriate policies aimed at keeping the inflation rate low, not allowing overvaluation of the currency, and maintaining fiscal responsibility, and, furthermore, making these policies predictable, have also managed to attain higher long-run growth rates. One could, therefore, argue that to the extent that IMF policies establish macroeconomic equilibrium in the economy, they play a positive role in the growth and development process.

Conclusions

This paper has shown that the IMF recommends a variety of policies to attain balance of viabil-

[4] This result is consistent with other empirical evidence; see the survey by Khan and Knight.

[5] See, for example, Fischer for a recent discussion of the factors that are important in the determination of growth.

[6] Available empirical evidence indicates that these factors could account for more than 50% of the changes in growth rates in developing countries.

[7] The data for these tests are obtained from IMF, *International Financial Statistics*, and the *World Economic Outlook* database.

[8] A similar negative relationship between growth and inflation is obtained by Dornbusch and Reynoso.

[b] As percentage of GDP.
[c] Percentage change in the real effective exchange rate. The exchange rate is defined as units of foreign currency per unit of domestic currency.

ity, price stability, and the development of the productive resources in its member countries. Eliminating internal or external imbalances can in principle be accomplished by a range of policy packages; some of these packages stimulate economic growth, and some do not. The IMF recognizes that strong and long-lasting adjustment is feasible only if the economy is expanding; thus, it is committed to favoring those policies that enhance the growth rate. To the IMF, the establishment of a stable macroeconomic environment is a *sine qua non* for increased savings, investment, and foreign inflows, all of which are central to the growth process. The empirical tests described in this paper provide some support for this view.

The main lesson that emerges from experience, as well as from the analysis in this paper, can be summarized as follows: without macroeconomic stability, economic growth can falter and not be sustained. Furthermore, without broad-based economic growth, the basic structural and social transformations which comprise the process of development will not occur, and the other objectives of development policy (such as a more equitable distribution of resources and income, providing employment, improving living standards and the quality of life, and the alleviation of poverty) are unlikely to be met. This does not mean that adequate growth will automatically follow if countries achieve macroeconomic stability. But the chances are greatly improved. In this sense, IMF policies can be thought of as improving these chances and, thus, the basic conditions for economic development.

A New Paradigm for Policy Reform and Economic Development

Gordon C. Rausser

Throughout much of the world, significant institutional changes are in the air, wind, and water. Evidence is accumulating that democracy has won the political battle and that markets have won the economic battle. Some serious scholars have even argued that the history of thought about first principles, including those governing political and social organizations, has come to an end (Fukuyama). For those who hold this view, Hegel was simply too early in forecasting the end of the evolution of thought about such first principles nearly two centuries ago. The entire Marxian experiment was nothing more than a 150-year detour which corroborated Hegel's view that the "end of history" coincided with the emergence of liberal-democratic states following the French and American revolutions.

Regardless of whether the history of ideology is over, a new consensus on economic, political, and civil freedoms has emerged. This consensus means more than simply adjusting macroeconomic policy, achieving stability, and selling off a few government-owned enterprises in an attempt to set developing countries on a path toward broad-based economic growth. Instead, it means creating a vision of an open economy underpinned by an open polity; identifying and removing the obstacles to economic participation, obstacles that lock the ordinary citizen out of the game; enhancing the availability and utility of information resources by shaping incentives and helping to establish the basic rules of social transactions; encouraging more efficient organization of economic activity whether by market, hierarchy, or hybrid modes (Williamson) in ways that may lead to fundamental restructuring of an economy; and fostering institutional frameworks that expand the role of human choice and promote the full panoply of entrepreneurial energies.

In developing countries, the above consensus emerges from the empirical evidence, not through the tunnel vision of some theoretical constructs. In operationalizing this experience, a number of economic "lessons" must be kept in mind. The lessons are drawn from developing countries which differ not only in the details of their economic policies but also in their whole approach to growth and development. These differences have lasted not just a year or two but, in some cases, for decades. As a result, one of the major crosses our profession must bear, namely, that we cannot conduct controlled experiments, has been largely removed. Although the post-World War II experience is admittedly an imperfect substitute for controlled experiments, it does reveal that in economic development the facts speak loudly about the links between actions and consequences.

Serious inspection of postwar economic development suggests that (*a*) "getting the prices right" or "setting the property rights straight," or both, is not sufficient if an economy is to reach its full potential; (*b*) bad governments and institutions have been a serious, if not the most serious, obstacle to economic development in less-developed countries (LDCs); and (*c*) all public sectors pursue a mix of predatory and productive activities—bad governments emphasizing the former and good governments finding a way of promoting the latter. As Krueger (p. 19) has recently noted, successful developers have governments which "have been active in providing infrastructures—communication, transport, power, education, agricultural research, and extension—in support of economic growth. But, in almost all of the countries in which intervention, controls, and parastatal activities have been far reaching, these infrastructure investments have been sadly neglected." In terms of nuts and bolts, de Soto has shown that government regulations create serious roadblocks to economic participation. In many instances, cleverly disguised

Giannini Foundation Paper No. 946 (reprint identification only).

This paper does not attempt to represent the views of the U.S. Agency for International Development.

The author wishes to thank Scott Thomas for his helpful comments and suggestions on an earlier version of this manuscript. This paper is a severely condensed version of Rausser 1989, which is available from the author upon request.

regulatory roadblocks provided significant deterrence to entry.[1] North has observed that, in much of the developing world, because governments play such an immense role in economic allocations and choices, the integration of political and economic theory is essential.

The Role of AID

In the above setting, what is the role or business of the Agency for International Development (AID)? As suggested in a recent report on the mandate of AID, a long list of concerns has engaged the agency's personnel and resources: humanitarian, political, national security, poverty alleviation, equity, economic growth, etc. (U.S. Agency for International Development). Evidence is provided that, increasingly, the role of the U.S. foreign aid program is limited either to smaller, strategically less significant countries or to playing the part of disbursement agent in strategically important countries. (For an analysis supporting this view, see Rausser 1989.)

In the face of the conflicting objectives for AID, there is some hope that this agency of the U.S. government, in fact, may be able to reduce strategic considerations in its outlay decisions over the next few decades. The signals justify the hope that economic growth-oriented development will no longer take a back seat to other U.S. objectives are fundamental. First, as noted earlier, ideological differences will be far less important over these next few decades than they have been since World War II. Moreover, if Hegel's view is correct, it is only a matter of time before liberal-democratic first principles are accepted by all LDCs. Second, the world itself has changed, both with the United States playing a relatively less dominant role on the world economic stage and with the potential for a new rapproachment with the Soviet Union. With these changes may come less concern about strategic alliances with developing countries.

It is to be hoped that the eideological battle that has existed in many LDCs over much of the post-World War II period is close to an end. However, regardless of how the trade-offs between economic and geopolitical or military goals unfold as the world role of the United States changes, AID should be able to focus more easily on providing support for achieving self-sustaining economic growth and development. In reviewing the potential effectiveness of AID's programs in promoting sustainable economic growth, a few conclusions are inescapable: (*a*) policies that encourage competitive forces are key to attaining sustainable economic growth; (*b*) institutions play a crucial role in creating and maintaining growth-oriented policies, whether defining and improving the security of property rights, lowering the costs of transactions (organization, supervision, coordination, monitoring, metering, etc.), or enhancing enforcement through an improved judicial system; and (*c*) policies and programs supported by international development agencies often place heavy emphasis on prescriptions from macroeconomic paradigms and fail to consider institutional bottlenecks and political constraints to implementing these prescriptions.

Given the expertise and charters of the World Bank and the International Monetary Fund and the comparative advantage of other bilateral donors, the niche where AID can be the most effective may be in the development of new institutions, institutional change, and the political economy of policy reform. These activities are labor intensive and require long-term commitments. The "mission infrastructure" of AID is well suited to perform the needed tasks. At the core of these tasks is a serious investigation of constitutional economics in each country.

The basic questions that pertain to such analysis are of the following types: Is the constitutional order of the country conducive to free inquiry and social experimentation or is it fundamentally repressive? Does the constitutional order provide ease of entry into the economic system, the political system, and ease with which the legal foundations of new institutions can be established? Does the constitutional order provide sufficient self-correcting mechanisms to limit excessive predatory governmental behavior? Does the constitutional order motivate agreement on basic values and processes for conflict resolution—a sense of civil order—to reduce the cost or risk of innovation?

Along with such fundamental constitutional issues, the basic political economic questions that must be analyzed include: What are the constraints and obstacles to economic growth that directly result from the power of interest groups? Who wins and who loses from current or reformed policies? What is the sustainability of

[1] To demonstrate this problem, de Soto tried to open a clothing business in Peru, legally and without paying bribes along the way. It took a lawyer and 3 other people a total of 300 days, or 1,200 man days, to complete all the necessary forms and to obtain all the signatures that were needed to start a business. As a comparison, de Soto performed the same task in Florida. Here, it took only 3 hours to start a new business. Peru is not unique.

the institutions and policies that support the status quo? What are the economic policy reforms that will promote economic efficiency and counter the constraints and obstacles that currently exist? What mechanisms or approaches can be utilized to obtain political consensus for the implementation of the proposed reforms? Does compensation make sense for those groups that are harmed by the adjustments that emerge after the policy reforms are implemented? With the implementation of growth-promoting policy reforms, are there public goods that might be offered to improve social services (e.g., health, population, education, etc.) that would ease the pain of adjustment resulting from the policy reforms? How can the interests of those groups which will benefit from reforms be appropriately articulated and channeled? What institutional changes are required for the reform policies to be sustainable? Do these institutional changes effectively alter the level and distribution of political power within the country?[2]

Alternative Paradigms

Over the years, a number of paradigms have been advanced for economic development (Bardhan). But very few, if any, paradigms exist which structure internally consistent analytical frameworks for policy reform. For the determination of government policy, two extreme perspectives within the economics profession have emerged over the years. The first is the public choice perspective, which focuses on the allocation of public resources in the political market, emphasizing redistribution to powerful interest groups (Downs, Buchanan and Tullock, Olsen, Becker). This literature quite naturally has led to analysis of rent-seeking and directly unproductive activities (Tullock, Bhagwati) which generate predatory behavior or "government failure." In this paradigm, interest groups play the role of the proverbial 800-pound gorilla—they go where they want, they sit where they want, and they take what they want. In essence, this paradigm is limited by its profoundly cynical view of the political process.

The predatory government perspective may, in fact, be an overreaction to the harm done by the paradigm at the other end of the spectrum (namely, the conventional welfare economics framework), where the state is a benign instrument for serving the public interest. As Stiglitz has emphasized, market failures abound in LDCs, and it would indeed be fortuitous if a benign instrument such as government intervention could be found for solving these pervasive failures. The market failures emanate from a number of different sources: unclear and insecure property rights, significant externalities, imperfect competition, informational imperfections, myopia, irreversibilities, sufficient need for and maldistribution of public and mixed goods, etc. Considerable empirical evidence supports a deeply skeptical view about the existence of a benign state to solve such problems anywhere in the world.

The conventional welfare economics paradigm presumes that "first-best outcomes" are achievable. The poor performance of many third world countries argues against the achievability of first-best outcomes. Neoclassical economic theory, on which the conventional welfare economics paradigm is based, cannot account for such performance. Moreover, as North (p. 32) notes, this theory "simply assumes away all the relevant issues."

Throughout the developing world, the public sector is not the perfect benign instrument envisaged by conventional welfare economics. But neither is it the manifestation of powerful interest groups concerned only with their well-being. In the conventional welfare economics paradigm, all political power resides in the hands of a benign government that attempts to correct whatever market failures might exist. In the new political economy paradigm, all political power resides with interest groups, and whatever actions are taken by the public sector can be characterized as predatory. Both of these paradigms represent extremes on a continuum. Either of them will make incorrect inferences of how policy outcomes are generated and thus should not be used in isolation to assess and evaluate reforms.

Governments do more than either engage in the improvement of allocative efficiency through collective action or simply serve rent seekers and the politically powerful. Accordingly, an alter-

[2] In this discussion, the implied dichotomy or separation between institutional change and the political economy of reform is made for convenience only. These two components of the development process are not separable. Bad policies will, over time, fundamentally corrupt and distort institutional performance. As most would agree, by initializing the movement to more innovative and competitive economies, policy reform and structural adjustment are essential to the process of institutional change in economic development. As the work of Ruttan and his associates has shown empirically on numerous occasions, market signals can induce institutional change. To the extent that these signals are severely distorted through predatory government behavior, institutional change can be expected to be misdirected.

native paradigm is needed that recognizes that power is distributed between the various interest groups and government and that maldistribution of power can blunt any and all efforts at economic policy reform. Moreover, this paradigm must recognize that governments can have some separate autonomy and can seek "leadership surplus" (Froelich, Oppenheimer, and Young).[3] What is needed is an internally consistent framework which admits the possibility and necessity of accommodating various interests. An appropriate political economic model is needed to conceptualize the bargains, pacts, compromises, and efforts that are undertaken to shape policies acceptable not only to those that have the greatest capacity to obstruct the process but also to others who stand to benefit from the policies.

Effective governments pursue productive activities while engaging in predatory pursuits for political-economic reasons. Specifically, predatory policies can compensate those groups and individuals that have sufficient political power to limit or obstruct efficient policies which lower transaction costs in the private sector. What is needed is an integrated framework that recognizes the joint determination of both predatory and productive governmental interventions. This framework must admit the political economy perspective of public choice theorists (all predatory, no productive activities) and the conventional welfare economics perspective (all productive, no predatory activities) as two special cases. In this new paradigm, institutions play a central role.

Variations in transaction costs and political power and influence mean that it must be possible to customize the new paradigm for the culture and customs of each country. In the proposed paradigm, current policies are viewed as a rational outcome of a political economic process. This political-economic process is one where the public sector can be viewed as a "central coordinator." A hierarchy structures the relationships between the authoritative center and the subordinate peripheral participants. The decision agents constituting the center are not oblivious to their own material well-being, social status, political power, etc. As a result, the center in this organizational setting is exposed to attempts by various interest groups to exert influence. In this framework, it has been shown, using a game-theoretic formulation (Zusman and Rausser), that if all power does not reside at the "center" and participants are in a position to reward or penalize the leadership, organizational failures naturally arise.

To illustrate this proposition, consider the classic case of regulatory organizations that attempt to manage the "tragedy of the commons" problem. Our results show that, while the center may fully internalize the common group interest, various self-interested participants who are accordingly narrowly rational in their attempts to influence can generate an organizational equilibrium that is suboptimal. Nevertheless, the establishment of this regulatory body will lead to a result that is superior to the pure predatory outcome but worse than the purely productive outcome. In essence, to the extent that the decision center internalizes at least part of the overall social interest, collective action improves upon the market-determined solution.

In this paradigm, good governments realize that their actions result in burden and gain sharing which may be unequally dispersed, that political power is unequal, and that because of limited information it is not possible to identify a priori the creative innovators or sectors that will prove to be the engines of growth from those that will not. Good governments also recognize the critical importance of "credibility." Would food riots have occurred in Egypt or bus fare and energy price riots in Venezuela if either of those two governments had had credibility? Did the South Korean government have more or less credibility when AID was actively involved in the structuring of that country's economic policies? A similar question may be asked today of Honduras and Egypt. Recent advances in game theory applications have shown the importance of the role of precommitments to government credibility. Properly designed precommitments for which it is impossible to reverse course have been shown to lead to intertemporal policy consistency. Credibility of commitments is indeed crucial to the implementation of significant reforms.

In the context of public policy reform, the mixed productivity/predatory paradigm offers a number of insights and refutable implications. Review of the history of major reforms in public policy throughout the world, whether developed or developing, shows that reform is motivated

[3] In the Froelich, Oppenheimer, and Young framework, leaders compete with other potential leaders for ascendancy and, once in office, maximize their surplus or profit by providing collective goods against taxes, donations, or purchases promised in the election process.

by one or more of the following events or forces: a major change (usually a precipitous deterioration) in the economic environment, a creative new design in implementation of policy mixes and/or compensation schemes, and/or the emergence of new political factions or major institutional changes.

A major change in the economic environment (e.g., the first 1980s oil crisis in Indonesia; the 1986–89 economic crisis in Poland, the Soviet Union, and East Germany; and the 1985 hyperinflation in Bolivia) shifts the possibility frontiers and leads to new mixes of productive and predatory policies. The design and implementation of new policy mixes and compensation schemes can alter the obstructionist behavior of various interest groups and their resultant deadweight cost in any rational collection of policies. South Korea's public policies are a wonderful illustrative example. The design and implementation of compensation schemes in Canada in response to the free-trade agreement with the United States is also illustrative. Developing better compensation schemes may be thought of as finding improved means to negotiate the allocation of society's welfare. In the search for reforms that augment the total size of a country's economic pie, predatory compensation schemes may be necessary. One of the political economic costs of implementing growth-promoting reform policies may be that associated predatory compensations must be made available to obstructionist interest groups.

Finally, major organizational and institutional changes can cover the full gamut: law and order, property law and property rights, contract law, laws governing exchange, the provision of public goods, conflict of interest, etc. At the core of any sustainable policy reform is the underlying constitutional framework. Changes in the relative benefits and costs of organizing those who would benefit are also major means of generating sustained reforms. Increasing the responsiveness of beneficiary groups to changes in their welfare allows the public sector to move in the direction of less wasteful combinations of productive and predatory policies.

Unless the "governing" criterion function that rationalizes the mix of predatory and productive policies is changed, unsustainable alterations in policy should not be termed "reforms" at all (Rausser 1982, Rausser and Foster, this issue). To move from a current mix of policies to sustainable reforms entails the movement from one policy equilibrium to another. This movement can be sustained through the emergence of new hierarchies and markets. In fact, one major market is the market for reform itself.[4]

Concluding Remarks

Throughout the developing world, the integration of political and economic forces is essential in understanding and prescribing roles for the public sector in order to achieve economic reform. Critical to this integration is an appreciation of the microforces within organizations and the central role played by transaction costs in any paradigm designed to explain current policy or prescribe policy reform. In the economics profession, there is a growing appreciation of these basic propositions. To the extent that public policies lower transaction costs in the private sector, collective behavior of the government pursues productive political economic interventions, expanding the size of the country's economic pie. To the extent that public policies serve powerful interest groups through predatory political economic schemes, portions of the country's economic pie are reallocated with varying degrees of waste. What has not been recognized in previous paradigms but is formally admitted by the paradigm suggested here is that these types of policies go hand in hand; frequently, predatory policies are offered as compensation to those that are harmed as a result of implementation of productive policies. Hence, predatory behavior becomes one of the political economic costs that must be borne when implementing growth-promoting policies, especially those that reform existing policies in effect to serve influential interest groups.

The integrated productive and predatory framework outlined in this paper not only offers an explanatory hypothesis for differing political economic equilibriums but also provides the basis for operational prescription. This prescription facilitates the search for a more equitable solution to public problems, the search for basic consensus on the nature of the public interest, and the creation of public trust based on a shared

[4] It should be kept in mind that the demand for reform can be realized most easily through constitutional-democratic processes which can reward or penalize officials or governments for the overall performance of their economic policies. The Hobson's-choice alternative is authoritarianism which, although it can sustain good economic policies by turning a deaf ear to protests, can also repress the demand for reform. The latter outcome is by far the most frequent among authoritarian governments.

sense of legitimate authority. The framework explicitly recognizes the task for public policy economists emphasized by Aaron in his Richard T. Ely lecture at last year's AEA meetings (p. 13), "to identify policy rules that are robust and are important not only economically but, in a fundamental sense, politically."

Policy Reform and Economic Development: Discussion

Yair Mundlak

My comments deal with the subject matter discussed in the papers and not with the actual performance of the agencies in question. I will comment only on two major issues, the role of knowledge and on the mapping of the effects of macro policy onto the growth process. This is intended to supplement the discussion in the papers, which I found to be insightful and recommend for reading.

Why, with all the knowledge with respect to macro policy projected by the papers, do countries get into deep problems? Also, and not independently, will countries which have restored stabilization remain stable or, alternatively, will macro crises recur? The following discussion accepts the position presented in the papers, that our knowledge of stabilization has increased. Thus, if it is only knowledge that matters, then we should expect a much better performance in the future than in the past. What is the scope for such improvement?

Trying to answer these questions requires broadening the framework to include the political economy aspects of the problem. Following Rausser, a distinction is made between benevolent and predatory governments. A benevolent government is one that plays the role of the social planner, whereas a predator exploits the system. Why should they have different policies? After all, a predator that plans to stay in power should also be interested in a strong economy because such an economy offers more opportunities for exploitation. Thus, a government need not be benevolent in its motives in order to have an interest in the well being of the economy. On the other hand, a government need not be predatory in order to damage the economy. To discuss this point, the question of political survival must be considered.

To extend the discussion, we sketch the behavior of governments within a framework of rational choice. We begin with the social planner and ignore motives of income distribution. By assumption, the social planner aims at maximizing the expected discounted value of the stream of utilities derived from per capital private consumption, c_t, $E\Sigma\beta^t u(c_t)$, where β is the discount factor, determined by the consumers, and E is the expectation operator. The maximization is subject to the resource constraint of the economy, which is not spelled out here, nor do we spell out the instruments used to affect the choice of c_t. For this objective to be fulfilled, the first-order conditions require that at each t, $u'(c_t) = \beta E u'(c_{t+1})$. This condition does not identify the government in power because it is immaterial.

The social planner is an altruist benevolent. At the other extreme, we can think of a government which (a) wants to stay in power and (b) extracts resources for noneconomic activities. Its utility depends on c_t as well as on the size of its operation, $g_t(i)$, and the transfers, $s_t(i)$, where i identifies the government. Its behavior is determined by choosing a time path for (c_t, $g_t(i)$, $s_t(i)$) so as to maximize $E\Sigma\beta^t(i)u[c_t, g_t(i), s_t(i)]$. The government has a subjective probability distribution of survival which depends on $[c_t, g_t(i), s_t(i)]$, and its discount factor is not necessarily identical to that of the social planner. The political benevolent is an intermediate case which avoids extracting rent for himself but uses g and s as instruments to enhance its probability of staying in power. Populism can be included in this case. The predator will try both to exploit the system and to stay in power. What comes out of this exercise is that the less secure he is about his political survival, the more he will exploit the system today by increasing $s_t(i)$ at the cost of weakening the economy, even though it is in his interest to have a strong economy. Recent events have shown that such transfers are quite robust to a large subset of ideologies. This implies that they may persist in an ideology-free era as well.

The purpose of this comment is to indicate that we can expect to have a wide range of modes of government behavior, depending on the util-

Yair Mundlak is with the University of Chicago and the International Food Policy Research Institute

ity function and the prevailing political and economic environments. We have analyzed government behavior within a micro framework, but the government is not just another agent in the economy which, by the law of large numbers, has practically no influence on the economy. A government which deviates considerably from the policy of the social planner often spells disaster.

The question is whether our ability to evaluate the consequences has a positive effect on the policy change. Judging from other areas of human behavior, such as consumption of drugs, my guess is that knowledge helps but by itself cannot eliminate deviations from the policy of the social planner. From all this it becomes clear that problems of stabilization are not likely to become obsolete.

We turn now to the second topic: from stabilization to growth. There are three important signals which are affected by macro policies and which affect growth: The real rate of exchange, the real rate of interest, and stability. The real rate of exchange affects sectoral incentives according to the sectoral degree of tradability. For instance, agriculture is more tradable than nonagriculture and therefore is more susceptible to deterioration of the real exchange rate. The rate of interest affects sectors according to their capital intensity, measured by the capital share. Finally, instability increases risk.

To evaluate the consequences of these signals, we can think of an agent who wants to maximize the present value of the expected returns to his operation, or more generally the expected utility, subject to the constraints which are in part private and in part public, such as infrastructure and the institutional set up. All three variables mentioned above enter into the framework and as such affect the decisions on resource utilization. Aggregating over individuals, we obtain sectoral behavior, which can be further aggregated to obtain the behavior of the economy. The pertinent constraints are determined by the level of aggregation. Note, however, that when the economy is open, it competes with the rest of the world for resources, and therefore the domestic profitability affects the rate of domestic resource accumulation.

An increase in per capita output is obtained by increasing capital and physical and human input per unit of labor, the participation rate in the labor force, and by technical change. Technical change is strongly associated with capital accumulation. A distinction is made between the available technology and the implemented technology. Low-income countries do not use the same techniques that are used by the rich countries because they lack the resources to do so. Thus, the implementation of the available technology depends on available resources. Consequently, through this chain of events, improving domestic incentives encourages capital accumulation and therefore growth. This conceptual framework translates itself to empirical analysis which can quantify the effect of macro policies on growth. A recent study (Mundlak, Cavallo, and Domenach) of economic growth in Argentina during 1913–84 shows that such effects are substantial.

Policy Reform and Economic Development: Discussion

Stanley R. Johnson

Donor and other agencies/institutions more indirectly involved in development assistance are increasingly emphasizing policy reform as a prescription for economic growth. For coordinating assistance programs and for the developing nations which must ultimately deal with these agencies simultaneously, it is important to understand the associated policy reform paradigm and the scope of the policy activity. Thus, this session is especially timely. And the authors have provided thoughtful reviews on policy reform approaches and the empirical information on possible impacts.

The discussion of the papers has three themes: policy space, operating paradigms, and indicators of success. Most attention is given to policy space because the major point of the discussion concerns an associated problem of institutional design.

The policy space for the International Monetary Fund (IMF) is identified by concerns about external and internal imbalances and stabilization. However, the interests in the timing of policy change and intermediate term economic growth appear to be leading the IMF into the domestic policy arena and economic development. World Bank programs have focused on equitable economic growth among sectors and nations. Major policy instruments have been loans for sector and infrastructure development. But problems with loan repayment and debt servicing have led the bank to become more involved in macroeconomic and fiscal policy.

The U.S. Agency for International Development (USAID) has had an apparent divided attitude toward policy intervention. Significant politically motivated development assistance moves through USAID. Alternatively, the USAID budget, not constrained by political interests, has primarily supported technology and adoption, infrastructure development, food assistance, and other instruments argued (albeit weakly) to be benign relative to developing country policy. However, with the emphasis on private sector development, USAID has directly attempted to impose policy reform. And, with the "November Report" and related developments, the broad nature of this evolving sense of the policy space is becoming more clear.

The problem indicated by this cursory assessment of the policy space is the significant overlap. This overlap implies major problems for targeting development assistance efforts and, to say the least, for the developing nations "benefitting" from multiagency policy interventions. Is an overlap in the policy space a sign of institutional failure? Should policy reform initiatives be better coordinated? How could such coordination occur? And, should attention be given to redefining or even combining the agencies?

The second theme is operating economic development policy paradigms of the agencies/institutions. For the IMF, the operating paradigm is orthodox macroeconomic and financial policy. To the extent that the IMF is involved in domestic development, the policy approach appears to have standard microfoundations. The World Bank also uses a policy framework that is within the confines of modern economic theory, concentrating on sector development and intersectoral relationships. And, to the extent that the Bank has been drawn into macroeconomic and international policy, the policy approach appears to be standard. For USAID, the apparent evolving paradigm is anything but orthodox. This operating paradigm extends beyond neoclassical policy economics to directly address questions of institutions and the political economy of nations.

Perhaps this broadening has been stimulated by frustrations with a USAID policy reform paradigm that is more limited in scope. If the paradigm cannot reveal why the policy that is to be changed evolved in the first place, how can it guide approaches to reform? It is likely that for

Stanley R. Johnson is Director of the Center for Agricultural and Rural Development and a professor of economics, Iowa State University.

Journal Paper No. J-14032 of the Iowa Agriculture and Home Economics Experiment Station, Proj. No. 2681.

the IMF, World Bank, and other institutions more involved in economic development a broader policy paradigm will emerge as a result of this and associated policy change questions.

The third theme is indicators of success. Without a clear operating paradigm, it is difficult to develop consistent performance measures. The performance measures indicated by the IMF and World Bank suggest that the orthodox policy paradigm implicit in their approaches is being stretched by the indicators. For example, among the indicators identified by the IMF were a restricted role for government, more reliance on markets, and higher economic growth. For the World Bank, the performance indicators included improved income distribution, private sector involvement, and other aspects of institutional reform. USAID has perhaps a less well-defined set of performance indicators but a broader implied development policy paradigm. Whereas the indicators advanced by the World Bank and the IMF suggest an expanding paradigm, those of USAID suggest further refining of the broader policy paradigm for economic development.

The papers suggest emerging questions on the organization of the institutions directly and indirectly supporting economic growth of developing countries. Are the countries receiving consistent advice and direction in policy reform? To what extent do the recommended policy changes involve institutional and political issues beyond the scope of the operating paradigm? Does a broader development paradigm imply a rethinking of the organization current regulatory and assistance agencies?

Books Reviewed

Arrow, Kenneth J., ed. *The Balance between Industry and Agriculture in Economic Development.* Proceedings of the Eighth World Congress of the International Economic Association, Delhi, India, vol. 1, Basic Issues. New York: St. Martin's Press, 1988, xxii + 297 pp., $55.00.

This first of five volumes is divided into two parts: "Plenary Papers" and "The Historical Perspective." Part 1 includes eight invited addresses which discuss agriculture–industry relations from a variety of perspectives. Part 2 has four chapters on the treatment of the subject in economic thought and two on the experiences of Spain and Italy in rural industrialization.

Arrow's introduction focuses on the analytic usefulness of agriculture and industry as "opposed categories" in the analysis of economic growth. Rao's inaugural address casts grave doubts on the existence of systematic relations between sectoral proportions and economic development. He concludes that advances in technology rather than increases in industry's relative share of the gross national product (GNP) is the key to rapid economic growth. In his presidential address, Arrow traces how certain developments in neoclassical economic theory affected economic development theory justifying biases in favor of industry. Pointing at problem areas emerging from better empirical knowledge, he then highlights implications for development planning and policy. According to Schultz, modern economic growth spawns disequilibria that have agricultural connections. But prevention of disequilibria is not the real issue. It pertains to making economic agents equilibrate efficiently through human capital formation and the right kind of economic organizations as well as incentives.

Ishikawa examines the implications of the lateness in industrialization of Asian economies by focusing on two features of their agriculture: virtually intact village communities and customary economies. Sen draws lessons for Africa and India from each other's experiences in the prevention of famines and gender bias. Bogomolov discusses why agriculture exhibits less dynamism than industry and then outlines the institutional reforms underway in socialist economies to improve the balance between the two sectors. According to him, the question of an appropriate balance between the sectors, however, cannot be tackled in isolation from global realities of unequal economic development and the influence of the developed countries' policies on the world market conditions. Both Lakdawala and Singh examine the agriculture–industry relation in the context of India's capital-goods-oriented growth strategy and the policies followed to implement it within a democracy. Singh also questions a rigid adherence to standard postulates which emphasize the role of agriculture in economic growth, particularly in a global environment of increased possibilities for both import of capital and trade.

In Part 2, Roncaglia's main thesis is that "abstract concepts useful at a specific stage of history, for the analysis of specific issues, may lose validity over time owing to changes in the economy and in the relevant issues" (p. 157). He demonstrates this by discussing the conceptual prehistory of representing the economic system as a process centered on the dichotomy between agriculture and industry (i.e., "productive" and "sterile") sectors. Thus, this dichotomy may not always be appropriate to analyze the complex problems of development in the present day world. Presenting the essence of Quesnay's and Adam Smith's arguments, Eltis concludes that "twentieth century economies may therefore find that they are applying industry-boosting arguments which derive from propositions Smith established in conditions where Quesnay's reasoning is more appropriate" (p. 176).

Bharadwaj traces the agriculture–industry relation in the political economy framework of Quesnay, Adam Smith, Ricardo, and Marx with a focus on the generation, appropriation, distribution, and utilization of surplus. The theoretical distinction between agriculture and industry recedes in the neoclassical paradigm concerned with the relative-price-guided allocative efficiency of resources. But the political economy viewpoint and the agriculture–industry dichotomy have been revived in the analysis of developing economies. Pointing to the different kinds of exchange involvements of different classes of producers and the diverse exchange systems that get formed on the "market," Bharadwaj concludes that one of the main tasks of research is in constructing a framework that takes into account the institutional variations in production and exchange relations that influence and are influenced by the process of accumulation. Sachs also questions paradigms and theories used to analyze the complementarities and trade-offs between agriculture and industry within the context of "a commoditised economy" and the division of labor between countryside and city. Finally, Vasques-Barquero and Fua discuss historical experiences of Spain and Italy in the structural transformation of rural areas which minimized the destabilizing impact of industrialization on social order and agriculture.

Various contributions in this volume thus relate to three main questions. First, how useful is classification of the economy into agriculture and industry sectors in discussing economic growth? Second, which issues are pertinent and what are the complexities in them in discussing the balance between these two sectors in the context of growth in the contemporary developing world? Third, what are the implications of these questions for economic theory and also for

development planning and policy? Viewed from these angles, this volume is full of both sobering truths and thought-provoking insights.

Gunvant M. Desai
International Food Policy Research Institute

Bhagwati, Jagdish. *Protectionism*. Cambridge MA: MIT Press, 1988, xiii + 147 pp., $16.95.

If Bhagwati's book is any indication, the Ohlin lectures are bound to become an important part of the political economy literature on trade. Bhagwati initiated the Ohlin lecture series in 1987, and the book is drawn from those talks. The book offers something to all audiences—policy makers, undergraduates, and graduate students (who will find basic theoretical concepts put into an historical and political context). His aim is to describe the forces that influence current political thinking about trade policy. In the process he demonstrates that the welfare principles supporting free trade still hold up remarkably well, even in today's changing trade environment.

Bhagwati weaves several themes together in these lectures and covers a wide range of issues. A central theme is that trade policy is formed through the interplay of current ideology, political and economic interests, and institutional factors. For instance, to explain the role of ideology in policy formation, he considers the post-Depression, free-trade bias in the United States. This bias was nurtured by theoretical literature, which, in turn, was reinforced by real-world examples such as the economic losses suffered by the United States from the Smoot-Hawley beggar-thy-neighbor tariff policies. To show the role of political and economic interests in forming trade policy, Bhagwati cites how, in the era of the Cold War, liberal U.S. trade policies were seen as a way to enhance national security. Institutional factors such as the establishment of the GATT and the post-Smoot-Hawley shift in tariff-setting authority from Congress to the executive branch also contributed to a free-trade bias in the United States.

Analagously, Bhagwati describes the forces behind recent increases in protectionism, embodied in popular calls for reciprocity, "fair trade" or "level playing fields." He discusses the rise in non-tariff barriers, such as voluntary export restraints (VERs) and voluntary import expansions (VIEs)—a term he has coined to describe the protectionism he perceives in U.S. unilateral trade actions such as Section 301 and Super 301 cases. He notes the similarities in arguments for protection at both ends of the manufacturing spectrum: the traditional low-technology, low-wage goods such as textiles in which other countries have comparative cost advantages, as well as the high-wage, high-technology goods that are increasing under pressure from Japan and other East Asian countries. Bhagwati exposes the flaws in "fair trade" arguments and criticizes increasing political pressure for the United States to seek quantitative, "results-oriented" trade solutions, such as the U.S.–Japan semiconductor agreement, which may simply divert trade to the United States rather than opening up foreign markets. Bhagwati provides insights into and from recent theoretical, empirical, and topical literature, ranging from strategic trade theory to "manufacturing matters."

Another theme of the book, based on work with Douglas Irwin, is that the pattern of protectionist sentiment in the United States bears strong similarities to the British experience in the 19th century. For example, the arguments in favor of maintaining the Corn Laws are uncannily similar to today's popular arguments favoring fair trade over free trade.

The book is filled with morsels of information that will surprise many readers. For example, many will be surprised to learn that Japan exports less than 15% of its GNP, compared to over 20% in the United Kingdom, over 25% in Canada, and nearly 35% in South Korea. (The U.S. exports less than 10% of its GNP.) In addition, there is an excellent, if compact, bibliography on theoretical, empirical, historical, and institutional trade policy literature.

The book is also filled with humor that often teaches. My favorite is the description of the economists' reliance on counterfactual analysis: when an economist is asked how his wife is, he replies, "Compared to what?" (p. 56n). In another case, expressing optimism in the continued political viability of free trade, Bhagwati cites his faith in the "Dracula Effect: exposing evil to sunlight helps to destory it" (p. 85).

There are minor points to quibble with in these lectures. For example, the data are unnecessarily out of date, often stopping around 1980; some institutional terms are not defined, such as RTAA legislation; and some arguments could be tighter. Readers will probably gain more from the book if they are already familiar with trade literature and current trade policy matters such as the current GATT Uruguay Round of multilateral trade negotiations or the ongoing Super 301 trade actions legislated in the 1988 Trade Act. Even then, readers may find themselves looking up certain GATT articles cited to find out what they cover. But all in all, this is a fun, informative book that sends the clear message that the foundations of free trade are still sound.

Boland, Lawrence A. *The Methodology of Economic Model Building: Methodology after Samuelson*. London: Routledge, 1989, x + 194 pp., $45.00.

If an interesting book is defined as one that at least occasionally stirs the emotions and even gets one riled, this book passes the test for me. At various times I was excited, bored, fascinated, confused, in admiration, and in disagreement. At times, for instance when dealing with shoulder logs, such as page 176, "hardly any mainstream economist will read anything more than [the title of a paper dealing with philos-

ophy of science] . . . no matter how well your paper is written, no major journal will waste its time or funds having it reviewed," I felt that I could understand why the author experienced fifty-five rejections (p. x) before his first article (on the identification problem and the validity of economic models) was published (by the *South African Journal of Economics*). Perhaps here too is a partial explanation of why in the bibliography (sic—a "bibliography" in which Fritz Machlup's book on *Methodology in the Social Sciences* doesn't rate a mention!), there are more citations to the works of mechanical engineer turned mathematical economist-cum-philosopher/methodologist Boland than there are to the works of Nobel laureates (who range from Einstein to Haavelmo).

Boland's central topic is how economists have applied Karl Popper's views of the need for falsifiable theories. He relates methodological debates about falsifiability and testability to wider debates on empiricism and the truth status of models in natural and social sciences. In doing so, he argues that the practice of model building in economics reflects more the methodological prescriptions of Paul Samuelson than the falsificationism attributed to Popper. Boland's eight substantive chapters are sandwiched between a scene-setting prologue and a confessional epilogue (titled as the book subtitle, to the likely chagrin of Samuelson).

Part I on "Applications of the Popper-Samuelson Demarcation" gets into some technical elaboration of the P-(for Popper) dimension in models.

Part II on "Popper-Samuelson Demarcation vs. the Truth Status of Models" has a wide-ranging review of the conventionalist controversy and, notwithstanding what Boland (p. 108) alludes to as "this somewhat tedious exposition," there are some fascinating insights. One analogy of particular novelty is the reincarnation of the Samuelson-Bator-et al., "social choice problem," of production possibilities curve through to the utility possibilities envelope (UPE) and the social welfare function (SWF) as the "paradigm choice problem" in which the final diagram has axes of simplicity and generality with a methodological possibilities function corresponding to the UPE and a verisimilitude function corresponding to the SWF. In an aside of interest to technological fundamentalists, Boland (pp. 113–14) notes relative to "failures" of welfare theory that "clearly, the more interesting (and pressing) problem is to find the means of expanding the various possibilities frontiers."

Part 3 is "Exploring the Limits of the Popper-Samuelson Demarcation" and features three provocatively titled chapters: 6, "Informative mathematical economic models"; 7, "On the impossibility of testability in modern economics"; and 8, "Model specifications, stochasticism and convincing tests in economics."

Chapter 8 was for me the best, harboring as it does both the high and low points for Boland's treatment. The high point (section 2.2) is the author's main vehicle for deriving operational procedures from his critique through the idea of testing with models of counterexamples (along with models of the theories under test) and thus arriving at one of four test results (namely, model inconsistency, corroboration, refutation, or ambiguity, p. 150). The low point is the following subsection 3: "Stochasticism and econometric models."

I found the hard line taken on stochasticity (of both reality and models), such as (p. 152), "there is always a serious danger of intellectual dishonesty in asserting that the environment is stochastic," to be totally unconvincing. I predict that many readers will part company at this point, especially if they have a considered investment in either econometrics or the economics of uncertainty and the quantification thereof. The issue reappears with aggression again in subsection 4.4: "The irrelevance of the probability approach," where he says (p. 164) that "So far, I have not said anything about probabilities. Many readers will find this irritating. . . ." Indeed, I did, for the just-noted reasons; but even the first sentence is not literally true, as back on page 115 reference was made to "maximizing expected (sic) probability." If my prediction above proves true, it would seem reasonable for Boland at some stage to reconsider the matter of environmental stochasticity and thus also whether (contrary to the publisher's cover blurb) the more-than-twenty-year research project is yet really complete.

Boland rightly says (p. 139) that "It is always very difficult to write about methodology." As one who has seen undergraduates' eyes glaze over at the -isms and -ologies that pervade the literature of the philosophy of what we aspire to do as scientific economists, I feel that Boland has done a reasonable job of expressing his arguments in language that students will welcome if not exactly relish. Perhaps the easy style can be illustrated through the following selections:

"Weakness [of axioms] has a lot to do with generality and universality . . ." (p. 27).

"Despite the lofty platitudes embodied in [the Popper-Socrates] philosophy, many economists may still see the worship of falsifiability as a misplaced desire for the hole instead of the donut!" (p. 84).

"Deciding which variables are to be included in a model, and deciding which of them are to be exogenous, are the most fundamental methodological decisions that a model builder must make" (p. 8).

"A stochastic model is one which systematically allows for the movements of the target . . . and follow[s] from a methodological decision *not* to attempt to explain anything completely" (p. 21).

"I have shown enough . . . to illustrate that some methodological decisions that model[ers] . . . might make for the convenience of their mathematical analysis can lead to extremely unfortunate methodological consequences whenever one also is concerned with the requirement of testability" (p. 79).

"The fact is that the economic theory used in econometric studies is usually very primitive" (p. 82).

The acceptance of [the neoclassical] paradigm [of 'liberal philosophy'] stops the potential infinite regress . . . and hopefully avoids the two problems of subjective truth—namely dishonesty and self-delusion" (p. 134).

At one of my low moments in my reading, I posed the question of whether Boland's book should enter the acquisition portfolio of the student of economic methodology who, as always, has a bounded budget. In particular, what if the bookshop stocks Samuelson's *Foundations* . . . and Popper's *Logic* . . . as well as Boland's. At that moment, I decided Samuelson's was a must and, if there was budget for only one more, Popper's should complement it. On reflection, perhaps this was too harsh and, at any rate, Popper's is sure to be in the library whereas Boland's may well not be. Certainly Boland's book will prove useful to instructors, and thus presumably also to serious students, in courses involving questions of method in economic research. For agricultural economists as a particular subset of "students of methodology," however, it is likely that they will derive more value per dollar invested from Glenn Johnson's (1986) book.

Chan, Sucheng. *This Bittersweet Soil: The Chinese in California Agriculture, 1860–1910.* Berkeley: University of California Press, 1986, xxv + 503 pp., price unknown.

Chan addresses an important and relatively neglected facet of the history of California agriculture—the significant role played by the Chinese immigrants during the second half of nineteenth century and the early part of twentieth century. This is a remarkable piece of dedicated scholarship. In a major, original piece of research, the author tells the story of a people's courage, hardship, and successes in a lucid style. The book will force many of us, both experts and laymen, to revise our notions about many important events in American socioeconomic history, including the history of economic development of California, the history and politics of immigration in this country, the history of farmworkers, and the role of Chinese immigrants in America.

This effort is not entirely new; yet, thanks in large part to the accidental discovery of a set of previously unused data, the author is able to describe these events with a great deal of sophistication. This is the first part of a two-volume work. The second volume will investigate why the anti-Japanese movement focused on the Japanese farming population in California.

The author sets for herself the task of investigating several questions: Why did the Chinese immigrants come to America, and in particular to California? What obstacles did they face on their way and once they arrived here? Where and how long did they stay in California? What contribution did they make? Why did they succeed as long as they did? What prevented them from succeeding more than they did? When and why did they leave California agriculture? What if they had stayed longer? All of these are subsumed under the overarching theme: What historical role did the Chinese immigrants play in the agricultural development of California in the years 1860–1910?

The book includes eleven chapters; an appendix on sources; an extensive bibliography on county, state, and federal archival materials; and many historical maps and photographs.

Although this study did not originate in a new data set, the fortunate discovery of a set of documents that had never been used before in studies of California's agricultural history provided impetus to the study. The author's experience in locating these documents is an excellent example of dedicated scholarship. The data dictated the scope of this research. The study begins in 1860 because it is the earliest date systematic data are available on Chinese in California agriculture, and it ends in 1910 because the role of Chinese immigrants had become more or less institutionalized by this date.

The first chapter establishes the thesis convincingly; namely, that the nineteenth-century Chinese emigration to California was only one aspect of a much larger immigrant stream—a Chinese Diaspora of truly impressive dimensions. Responsible for this massive immigration were both "push" and "pull" factors, the most important of the latter being the lure of gold. In the next few chapters the author gives a history of California's political fortunes; the important factors that determined the number of Chinese immigrants settling in California at different times; and the entry into, and later dominance of, the vegetable agribusiness by these immigrants. Truck gardening and vegetable peddling were the two agricultural roles the Chinese immigrants found most suitable. The last statement in chapter four captures the essence of this success story: "The Chinese had come to mine gold; for a few of them, the nuggets they found turned out to be green" (p. 157).

Chapter five examines the substantial contributions the Chinese farmworkers made to California agriculture. The reclamation and agricultural development of the New World Delta was done primarily with the help of Chinese workers. The author's examination of the relationship the Chinese tenants had with their landlords, the different patterns of tenancy, and the economics of Chinese farming in the delta

reveals the knowledge and dedication of the Chinese farmers.

The next chapter introduces the "Potato Kings"—Chinese tenants who had become so successful in the New World Delta area that they went on to become large landowners themselves. The contribution of Chinese farmers to the wine industry and their involvement in the cultivation of fruit and speciality crops is the focus of chapter seven. Chapters eight and nine discuss the literature on the controversial thesis that the cheap and plentiful supply of the Chinese farmworkers was responsible for the creation of land monopoly in California. The author shows that, contrary to this thesis, the Chinese farmworkers played "multiple roles" and were often far from docile. Chapter ten examines the contribution of the Chinese contractors and merchants, who, although not directly involved in farming, greatly facilitated its smooth operation. In the last chapter, the author shows that the view that the Chinese communities failed to assimilate with mainstream America because of their adamant refusal to give up their native culture is largely a myth. In fact, the successful Chinese communities in America were in many ways markedly different from the parent communities in China. Chan concludes that the real significance of the Chinese participation in California's agriculture lies in the legacy of the diverse and integral role they played in the development of the state's agriculture for six or seven decades.

The book is not without flaws, although these are minor in nature. A few typographical errors remain here and there. After studying the treasure trove of new information the author has unearthed, one cannot help but wonder if more sophisticated statistical analysis could have yielded stronger conclusions. I also find the role of Chinese women to be underreported. Did the Chinese women play any role in California agriculture? Was it economic or cultural barriers that prevented them from joining their men overseas? These questions are neither asked nor answered.

This is an important book. Scholars in diverse areas—history, sociology, political science, agricultural economics, labor economics, and public choice theory—will benefit from this work. Most important, the author's lucid presentation will ensure a much wider audience than the academic.

Folmer, Henk, and Ekko van Ierland. *Valuation Methods and Policy Making in Environmental Economics*. Amsterdam, Netherlands: Elsevier, 1989, 259 pp., $89.00.

This book is a collection of twelve papers from a 1987 international conference on Environmental Policy in a Market Economy. Several common threads connect these papers and help this volume avoid what I call the "Old McDonald's Farm syndrome of edited volumes: here an essay, there an essay, everywhere an essay, essay." These common themes include the importance of knowing the public's value of environmental services to manage efficiently water quality (chap. 2 by d'Arge and Shogren), air quality/acid rain (chap. 5 by Navrud, chap. 6 by Dickie and Gerking, chap. 7 by Shecter et al., and chap. 12 by Maler), and renewable resources such as endangered species (chap. 3, Johansson) and forests (chap. 4 by Johansson et al.). The second major theme is methodological comparisons between a variety of hedonic methods (HM) and contingent valuation methods (CVM) for valuing water quality (chap. 2) as well as air pollution and human health (chaps. 6, 7) and mortality (chap. 8 by Herzog and Schlottmann).

The third theme of this volume deals with problems in performing cost-benefit analysis (CBA) in its currently practiced partial equilibrium form rather than in the more correct general equilibrium format. Chapter 9, by Johansson and Lofgren, deals with performing CBA in an economy characterized by disequilibrium prices and both classical and Keynesian unemployment. Chapter 10, by Nentjes, proposes a synthesis of CBA and macroeconomic impact models which he calls "Macroeconomic CBA." His approach involves CBA estimates of the direct benefits and costs of reducing pollution and then use of the cost data in a macroeconomic model to simulate the impact on aggregate economic activity, the general price level, and balance of payments. The third paper on this general theme is Randall and Hoehn's development of the types of errors in summing independently derived valuation estimates to arrive at a total value of multipart packages of public programs. While the authors' demonstration of these errors has recently appeared in the *American Economic Review* (Hoehn and Randall), this chapter provides suggested empirical approaches that can be used to adjust independent valuation estimates obtained in a partial equilibrium framework.

The chapters in parts 1 and 2 of this volume represent a snapshot of several environmental valuation research issues of the 1980s: valuing nonmarket resources under uncertainty (chap. 3 on alternative levels of preservation of endangered species), comparison of recreation use values with existence values for environmental improvements (chap. 5 on alternative fish populations associated with acid rain mitigation and emissions control), comparison of CVM with hedonic property value methods (chaps. 2, 7) and improving the microeconomic foundations of valuation methods (chaps. 6, 8).

This type of volume typically has two audiences: researchers in the book's topic area(s) and as a supplemental reader in graduate courses. This book fills a small niche for each of these audiences. For researchers interested in uncovering a wealth of unpublished empirical valuation studies, particularly in the Scandinavian countries, this book is worthwhile. For researchers interested in state-of-the-art valuation methodology, this book contains little that has not

already been published by many of the same authors in journals or other books. From a graduate student's point of view, however, this book provides some logistical and expositional advantages over the original journal articles and books. The exposition in this volume of hedonic models, predichotomous choice era CVM and general equilibrium and disequilibrium issues in CBA would be more understandable than the often terse journal article counterparts. Thus, if one had a graduate natural resources survey course or seminar that touched on this wide-ranging set of issues, this book would be a good match. However, for researchers and courses focusing primarily on environmental valuation, Mitchell and Carson's recent book on CVM provides far more depth, is more current, and provides a broader discussion of techniques (including the travel cost method, a commonly used valuation technique scarcely mentioned in Folmer and van Ierland's book).

In sum, I did find the book interesting reading and a useful reference work. It is rewarding to discover five new valuation case studies. Maler's "Acid Rain Game," which applies game theory to evaluate the potential for cooperation between European and Scandinavian countries, would serve as a good starting point for evaluation of other international environmental problems, such as maintaining genetic diversity or tropical rainforests. Thus, the book is a useful addition to an environmental economist's research library; it will invariably save future trips to the main library stacks. In this sense, the book's option price exceeds its purchase price.

Kendrick, David A. *Feedback: A New Framework for Macroeconomic Policy.* Dordrecht, Netherlands: Kluwer Academic Publishers, 1988, vi + 147 pp., price $29.50.

David Kendrick has been one of the leading lights in the development and application of optimal control methods to problems in economics. In this book he gives a verbal and graphical description of control methods, much like Stephen Hawking's description of physics and the universe. Unlike Hawking's book, Kendrick's subject is much narrower and much more readable to the uninitiated.

Kendrick's major topic is the concept of feedback. In a nutshell, feedback implies that the actions a manager or decision maker takes are functions of the current level of those variables describing the condition of the system under control. To illustrate this idea, the book uses the U.S. macroeconomy as its source of empirical examples. For example, he describes the unemployment compensation scheme recommended by the Council of Economic Advisors during the Kennedy administration, in which the level of benefits was tied to the level of unemployment in the economy at a given point in time. Benefits increased as conditions worsened, so the policy had the effect of an automatic stabilizer.

While the economy currently has several mechanisms that function as feedback rules, the book develops the proposal that more feedback mechanisms would be desirable. To advance this thesis, Kendrick presents a framework for deriving optimal feedback policies. This framework consists of setting goals for the economy, describing the dynamics (econometric model), and dealing with the uncertainty inherent in controlling any economic system.

As all modelers of large economic systems know, determining what constitutes an optimal performance is vague. Kendrick does not try to set such an agenda but shows how modelers can vary goals and then simulate the system and let policy makers identify the desired paths. Such an approach is certainly not an original proposal; but the author discusses how engineers, who have used control extensively, end up doing much the same thing. The net effect for economists is that they need not feel nearly as ad hoc as they might perceive themselves in undertaking such practices. One problem Kendrick does acknowledge is that for the U.S. economy there is not necessarily one explicit objective function shared by all decision makers (e.g., the president, Congress, and the Federal Reserve Board). How to address this problem and still derive feedback rules for the economy is not fully resolved.

In discussing dynamics of economies, the author illustrates the important impact of decision lags that characterize economic policy making. That is, recognition of a problem and resolving how to solve it are one type of lag in an economy as well as the lag in effectiveness once actions are taken. The former lag is a strong argument for more automatic stabilizers in the economy. In his conclusions Kendrick argues, "We have been experiencing a rough ride in the U.S. economy in recent years. Some of that rough ride was not necessary. Feedback rules could have smoothed the ride somewhat by providing frequent, quick, and small corrections to problems rather than infrequent, slow, and large policy changes" (p. 127).

A very forceful argument is made by the author for the use of confidence intervals in presenting forecasted results. The author acknowledges that uncertainty has an impact on macroeconomic policy through the effect of unanticipated events (e.g., the oil price rise), uncertainty about the true structure of an economy, and inability to observe the true state of a system accurately (e.g., the actual rate of unemployment). In describing some of the limitations of feedback methods, he discusses methods of policy formulation when there is uncertainty about which

model should be used to compute control levels when the true model cannot be definitively identified. Somewhat surprisingly, no discussion is given of the use of filters to estimate the true state of the system.

Other limitations of the control or feedback approach are recognized. In particular, the problem of agents in the economy (producers and consumers) reacting to policies in unanticipated ways is discussed. More formally, the problem is that of rational expectations, and the author recognizes some ways of resolving this. One is that such adjustments are relatively minor, so they can be ignored. Whether such a course of action is indicated is an empirical question that remains to be resolved. A second approach is to use game theory, and such approaches are comparatively complex. Simplification of game approaches may make such analysis empirically workable.

This is a short book and relatively easy and enlightening to read. Bright undergraduates would have no trouble understanding it. It was worthwhile also as a review of some big issues in macroeconomics. It is curious that nowhere in the book is feedback in an optimal control setting equated to how solutions are derived from stochastic dynamic programming problems. Nor does the book discuss the impact of uncontrollable exogenous variables. However, such criticisms are minor; the book is not meant to be inclusive of all aspects of feedback. It serves its purpose of educating the reader about feedback and suggesting interesting ways that feedback could be applied. The book is a good candidate for introductory reading in a dynamic optimization course, but not the main textbook.

Hawking, Stephen W. *A Brief History of Time*. Toronto: Bantam Books, 1988.

Lipton, Michael, with Richard Longhurst. *New Seeds and Poor People*. Baltimore MD: Johns Hopkins University Press, 1989, xiv + 473 pp., price unknown.

Michael Lipton and Richard Longhurst (LL) have an important message in this book: that agricultural research might be better directed at the needs of the poor if more deliberate efforts were made to think about the possible implications for the poor before the research were conducted. The book is directed at those who decide what agricultural research should be undertaken; and, although the title mentions seeds and the authors use their abbreviation for modern varieties (MVs) throughout, the book actually deals with the entire range of agricultural technologies and their impacts.

LL have reviewed an astonishing amount of literature to produce this broad-scale treatment of the effects of technological change in developing country agriculture. They begin with a description of varietal development, which amounts to almost a minicourse in plant breeding, then examine the distributional impact of modern varieties, their impact on labor use, and their impact on nutrition. Dissatisfied with findings on the apparent direct effects, LL follow with a chapter that integrates the effects, ranging from neoclassical general equilibrium through political economy, the neolithic revolution, and finally to international agricultural research. This is followed by a chapter on the future of modern varieties covering the "four main challenges of the 1990s" for agricultural research: rural population growth, sub-Saharan Africa, biotechnology, and international issues. A final chapter draws conclusions.

Agriculturalists will be pleased that LL have many good words for agricultural technology. For example: "if social scientists had in 1950 designed a blueprint for pro-poor agricultural innovation, they would have wanted something very like the MVs: labor intensive, risk-reducing, and productive of cheaper, coarser varieties of food staples." For those wishing references to empirical support for this view, LL have chapters on the relationship of new technologies and farm size, tenure, labor use, consumption, and nutrition. In all, LL show that in the main, new agricultural technology has had a pro-poor effect.

However, LL have far more to say about future research because many developing countries continue to be populated by masses of poor, rural people. Why have the technological advances not drastically reduced the numbers of these poor people? In their view, because the green revolution was not revolutionary enough: "MVs are an evolutionary technique not one that requires (or stems from) a transformation of rural power. An evolutionary technique—especially if used first by richer, less risk-averse farmers, with better access to information and inputs—tends, when introduced into an entrenched power structure, to be used so as to benefit the powerful. . . . Social scientists now see more threats to poor people's food access, whether from population growth or from technical change, as operating to reduce entitlements to food, whatever the impact on its availability" (p. 401).

Despite this underlying difficulty, LL claim that "the scope of agricultural researchers for improving their impact on policy, and in particular on poor people, is quite large." In their view, agricultural researchers need to focus on seven issues (p. 403):

1. Establish clear, published research priorities that favor the poor and "encourage nonconformist and interdisciplinary challenges to current research paradigms." 2. Those priorities would "consolidate, extend and redirect past improvements in the efficiency of food plants in handling water, nutrients, light and pests." 3. Those efficiency gains cannot be achieved in the short run if they are not sustained and lead to reduced efficiency in the long run. 4. The weak impact of MVs on certain crops or in certain agro-ecologies endangers many poor people and should be re-

dressed by agricultural researchers. 5. Agricultural researchers should be more concerned with improving food "entitlements" of the poor and not so concerned with increasing food "availability." 6. Agricultural research requires a more appropriate approach to human nutrition—"protein requires much less emphasis from researchers, the energy needs and absorption of vulnerable groups, much more." 7. International and national agricultural researchers will have "to develop new approaches in natural and social sciences; greater readiness to analyze the interactions of MVs with total systems (of power, of ecology, of economic transactions); and more awareness of history."

This reader is left wondering whether LL have more faith in the capacity of agricultural technology to address issues than is justified. They seem to believe that just about any desired social change can be produced by changing plants. An annoying characteristic of the book is its errors about technical agriculture; one hopes the mistakes do not cause technically knowledgeable research managers to turn away. For example, the green leafhopper, not the brown planthopper carries tungro virus (p. 80). Oryza nivara is but one of many species of wild rice, not "the wild rices" (p. 93). Bacterial nitrogen fixation uses nitrogen from the air, so it is puzzling to read a plea for research that is "less soil-extractive than bacterial nitrogen fixation" (p. 375). One only wishes that the Food and Agricultural Organization of the United Nations did, indeed, collect "standardized farm management data" (p. 141), for then much of the gymnastics required to compare studies across countries would be unnecessary.

I had difficulty with two other characteristics of the book: It makes frequent use of interjectory and parenthetical phrases, sometimes in combination; and it is written in a style that raises a problem in one sentence or paragraph, then knocks it down in the next. On issue after issue, one gets the sense of observing an intellectual tennis match with exhausting relays but no decisive point. Finally, sentences are unduly long and complex: no reader should be made to suffer through ninety-nine-word sentences with thirteen punctuation marks!

LL have a message that might, if readers could get to it, influence the way agricultural research is carried out. Unfortunately, it is unlikely that this book will have that effect.

Robert W. Herdt
The Rockefeller Foundation

National Research Council, *Alternative Agriculture*. Washington DC: National Academy Press, 1989, 448 pp., price unknown.

This book, *Alternative Agriculture*, could well be the landmark publication heralding a new decade in which concerns for the environment will shape an alternative philosophy of farming. It is a report of the Committee on the Role of Alternative Farming Methods in Modern Production Agriculture by the prestigious Board on Agriculture of the National Academy of Science. This Committee of highly respected scientists from land grant universities and other public and private institutions was formed in 1984 to study the science and policies affecting adoption of alternative production systems in the United States. Their report has given scientific credibility to the concept of an alternative agriculture and has become the focal point of debate between critics and defenders of conventional systems of farming.

The first chapter of the book, agriculture and the economy, outlines the trend in American agriculture toward larger more specialized farming operations. Government policy, including agricultural research and education, is seen as a major factor supporting this trend. Greater specialization and larger farm size have been means of achieving greater production efficiency. "The primary goal of agricultural research and education policy has been to increase farm production and profitability while conserving the natural resource base. Achieving higher crop yields per acre has traditionally been viewed as the best way of doing both" (p. 77).

The second chapter documents a litany of unanticipated problems that have arisen as specialized farming operations have become increasingly dependent on external purchased inputs such as commercial fertilizers, synthetic chemical pesticides, animal antibiotics, and borrowed capital. Financial vulnerability, loss of genetic diversity, water quality risks, soil erosion, food safety risks, and rising input costs are among the problems the committee associates with conventional systems of farming.

The third chapter outlines science and research that supports alternatives to conventional systems of farming. Alternative agriculture is characterized as "a systems approach to farming that is more responsive to natural cycles and biological interactions than conventional farming systems" (p. 135). The committee states that "alternative farming is based on a number of accepted scientific principles and a wealth of empirical evidence" (p. 135). A representative sample of principles and evidence is provided under such headings as crop rotations, plant nutrient management, tillage, soil biota, animal health systems, and pest control in crops, with each section focusing on alternatives to commerical inputs.

In chapter four an attempt is made to assess the economics of alternative farming systems. The committee recognizes the lack of empirical studies comparing profitability of alternative whole-farm systems. They rely instead on evaluation of farming practices and methods typically associated with alternative agriculture such as integrated pest management, diversified farming systems, crop rotations, and lower costs of purchased inputs. They conclude that "research has begun to demonstrate the economic benefits of alternative farming systems and how current policies impose incentives and disincentives for

selection of various types of farming systems" (p. 241).

Section two of the book outlines eleven case studies that illustrate a range of alternative farming systems currently in operation in the United States. The committee makes no claim that these case studies provide scientific evidence that alternative agriculture could replace conventional agriculture in the United States with no sacrifice in productivity or profitability. The case studies are used instead to illustrate that a wide range of alternative farming systems have been found to be successful under actual farming conditions.

They conclude that "farmers who adopt alternative farming systems often have productive and profitable operations." But they also state that "research should be undertaken to predict the long-term impacts of various levels of adoption of alternative farming practices" on all aspects of agriculture and rural communities (pp. 8, 23).

The book is well written and uses terms that will be easily understood by most agricultural scientists, regardless of disciplinary training. This book is must reading for agricultural economists or anyone else who seriously wants to understand the current issues of agriculture and the environment.

John Ikerd
University of Missouri

Parikh, Kirit S., Gunther Fischer, Klaus Froberg, Odd Gilbrandsen. *Towards Free Trade in Agriculture*. Dordrecht, Netherlands: Martinus Nijhoff, Publishers, 1988, xi + 357 pp., price unknown.

This four-author monograph is the detailed report of a major research project to quantify the likely effects of an outbreak of free trade in agricultural products. World-wide in scope, this effort was mounted by analysts of the International Institute for Applied Systems Analysis (IIASA) located in Laxenburg, Austria. At the book's writing, the authors were all staff members of the Food and Agricultural Program within the institute. The central idea was to employ IIASA's vast linked system of eighteen national and fourteen country-group models to explore how various scenarios of agricultural trade liberalization, achieved through negotiation, might alter world prices, trade volumes, and a host of economic and social indicators in affected nations, rich and poor alike. The potential connection between the content of this book and the ongoing GATT Round of multilateral trade negotiations ought to be patently obvious to anyone even mildly familiar with today's international trade policy debates.

The models which are stitched together to form the webbing of this estimated system are general equilibrium in form with their main focus of empirical detail in food and agriculture. Consequently, they feature rather aggregate relations in their industrial and financial sectors. Still, they are general equilibrium and trade balancing in both the national and international arenas. National and regional price, production, and trade policies for agriculture are built into the original reference system so that the effects of their deliberate removal can be gauged.

Five basic trade liberalization scenarios were investigated and compared to a complex reference scenario. The latter was designed to reflect actual and assumed economic conditions in the 1980–2000 period including no overt moves toward freer trade. The five scenarios involve agricultural (and only agricultural) trade liberalization by (*a*) the United States only, (*b*) the European Community only, (*c*) the OECD nations only, (*d*) major developing nations only, and (*e*) all market economies.

Two broad categories of outcomes were computed for individual countries whether or not they participated in a given liberalization scenario. The first is a set of specific outcomes in standard economic measures such as GDP, the trade balance, terms of trade, a food price index, total acreage harvested, and numerous others. The second is a group of "welfare" measures such as GDP per capita, calories per capita, life expectancy, numbers of hungry people, and two measures of relative income per capita. This second category does not include any of the standard consumer or producer surplus measures of modern welfare analysis.

A sensitive reviewer does not reveal either the outcome or full plot of a novel. In that spirit, I will not now give away the conclusions of this complex and admirable work. It is enough to say that the empirical results are mixed, yet not inconsistent with the major tenets of trade theory and most a priori reasoning about agricultural and trade policy. The results strengthen the view, widely held among economists, that agricultural trade liberalization is not likely to be an international welfare bonanza, but its achievement would be a worthwhile step forward.

The book begins with two introductory chapters that discuss basic issues in agricultural trade policy analysis, the character and extent of farm trade distortions in the modern era, and their impact on national economies. Most readers of this volume surely will be acquainted with this material from other sources, but its recapitulation here is not out of place.

The third chapter presents the analytical approach and attempts to make understandable the intricate mechanism of IIASA's linked simulation system. This is an important and very difficult task. In my judgment, the inherent complexity of the system got the upper hand on the authors. The reader of chapter 3, without other experience with these models, will not really learn how they are specified, estimated, and interconnected. One can obtain a general overview of the whole scheme and insight into the operation of a representative country model but virtually no specifics of any one model. This leaves the reader uneasy. It is not at all hard to identify this flaw yet very difficult to say how to fix it short of doubling the size of the monograph.

Chapter 4 is a detailed exposition of the basic reference scenario against which all the alternative liberalization packages are compared. It includes the base calculations of all the economic indicators and welfare measures employed in later analyses. The various liberalization scenarios are described and dissected in chapters 5 through 8. Chapter 9 contains a summary of the main findings and some not-very-sharp policy conclusions. Among the four technical appendices is a very helpful country-by-country synopsis of how the alternative liberalization schemes benefit or punish individual economies.

This book is written, organized, and set out in a professional, workmanlike manner. It contains huge gulps of data and results presented in seemingly endless tables. That the authors, nevertheless, were able to wrestle this material and their findings into a single, readable monograph is a remarkable and very useful achievement.

James P. Houck

Petit, Michael, Michele de Benedictis, Denis Britton, Martijn de Groot, Wilhelm Henrichsmeyer, and Francesco Lechi. *Agricultural Policy Formation in the European Community: The Birth of Milk Quotas and CAP Reform.* Amsterdam: Elsevier Science Publishers, 1987, 165 pp., $63.25.

Hollingham, Michael A., and Richard W. Howarth. *British Milk Marketing and the Common Agricultural Policy: The Origins of Confusion and Crisis.* Hants, England: Gower Publishing Co., 1989, 220 pp., $89.95.

Burrell, Alison, ed. *Milk Quotas in the European Community.* Wallingford, England: C.A.B. International, 1989, 214 pp., $45.00.

The reason for reviewing these three listed books simultaneously is evident from their titles. Milk quotas and the Common Agricultural Policy of the European Economic Community are two themes common to each publication. However, the publications reflect substantially different emphases and have only limited complementarity.

The basic objective of the Petit et al. book is to provide an understanding of why agricultural policies in developed countries are what they are. The complex decision process that led to the adoption of milk quotas by the EC in its March 1984 compromise reforming the Common Agricultural Policy is the "case study" chosen to bring insight to the policy development process. As such, a relatively intense review of the sequence of negotiations during the July 1983 through March 1984 period is described. The hierarchy of the decision process is specified in considerable detail across five of the (then) ten EC member countries, the Commission, the Council of (Agricultural) Ministers, and secondary parties. The five leading milk-producing nations in the EC—France, West Germany, United Kingdom, Netherlands, and Italy—were selected as foundation actors in the decision process. The book benefits from being jointly authored by academics from each of these countries.

In the early 1980s, it almost came to the point that if the European Community were going to survive, CAP reform of the dairy program was mandatory. Petit's book does a thorough job of scrutinizing the policy-making process in "the formation and confrontation of different national attitudes to these proposals, and the eventual emergence of a compromise agreement on the action to be taken" (p. 2). The authors advance the book as a research report as compared to a detailed assessment of the decision process. Hypotheses are advanced and concepts from oligopoly theory are utilized. However, the hypotheses actually are handled more as assumptions; and the conclusions chapter, therefore, moves in the direction of (*a*) summarizing some key elements of the CAP decision process, and (*b*) rationalizing the research processes utilized. As such, the reader is left to infer why policies are what they are from the total exposition. The book can be a useful reference for a graduate agricultural policy course.

The monograph by Hollingham and Howarth represents an excellent overview of the milk-marketing situation in England and Wales. The stated objective of the book is to provide "a factual description of the nature of the confusion and conflict existing [in the British milk industry] during 1985 and early 1986 and its manifold and frequently interrelated causes" (p. 4). In fact, the book serves a much broader usefulness in describing institutions, events, and market situations than either the title of the book or its stated objective imply.

There are seven chapters to the book. Chapter 2 highlights the dairy problem in the EC in the 1970s and 1980s—increasing supply/static demand—with useful detail on intervention milk price equivalent, export restitutions, co-responsibility levies—and finally the April 1984 adoption of the quota program. Chapter 3 traces in interesting chronology the development of marketing institutions and the changing structure of Britain's dairy industry from the failure of producer cooperatives in the price-depressed 1920s up through the increased production levels and tighter import restrictions as the U.K. moved toward its 1973 membership in the EC. A full chapter is devoted to the 1973–77 transition of the British milk industry into full compliance with the dairy program of CAP. The alignment of U.K. and EC prices required specific monetary measures. Also, the powerful role of the Milk Marketing Board in Britain was viewed skeptically by EC, and the Milk Marketing Scheme Legislation in Britain was amended to comply with EC policies.

The remaining chapters "constitute the core of the report and look at the liquid market and the manufacturing market respectively since Transition" (p. 5). Liquid milk was a complicating issue as Britain moved into the EC because liquid utilization in Britain in the early 1970s was 56% compared to a 17% average for the continental members. The chapter flows un-

evenly, leaving the reader uncertain as to whether changes are being forced by EC regulations or whether the dynamics of the marketplace are the catalyst. The chapter on Britain's milk-manufacturing industry initially addresses multiple pricing/cross-subsidization issues. Multiple pricing is an extension of classified pricing in that milk is priced not only according to product but is further priced according to the eventual market for that product. These issues are traced in revealing detail through arbitration and arraignment in the European Court of Justice. Students and researchers having a specific interest in milk marketing and dairy policy in Great Britain will find that the book provides an excellent history and overview.

The book entitled *Milk Quotas in the European Community* is easily the most useful of the three publications for the U.S. audience. For persons interested in dairy policy, supply management, and quota issues in general, the Burrell book should be must reading. With the advent of milk production controls in the EC in 1984 and the application of quotas in different ways among the member countries, the EC program presents a rich experience to draw upon in pursuing the do's and don'ts, and many of the short-run implications of quota programs in the milk industry.

The book is the proceedings (fifteen research papers) of a seminar held at the University of London in December 1988. Agricultural economists from seven of the more northern member nations author the papers. Papers are organized into four sections: (1) impact of quotas on milk producers, (2) implications of milk quotas to other farm enterprises and to the milk-processing industry, (3) quota transfer options and implications, and (4) aggregate impacts of milk quotas on the European Community.

The milk quota program currently in place in the EC will operate through 1991 and then be extended, modified, or terminated for 1992 and beyond. The 1984–91 system has essentially tied milk quotas to land so that quota transfer only occurs with land transfer. However, sufficient flexibility exists so that some member countries have effected rules for transfer arrangements through partial ownership transfer and through leasing schemes. At the same time, the French warn that the presence of quota markets becomes a major factor in forcing the permanence of quotas. Several of the presentations, at least implicitly, point toward the merits of going to a market system, Canada style, for quota transfer. There is general acceptance that the immediate objectives of the quota program have been accomplished: lower milk production, reduced (subsidized) exports, maintenance of dairy farm income, and reduced program expenditure. Concern with fossilization of the structure of the milk producer sector has diminished, although provisions generally have been directed at eliminating small operations, favoring medium-sized dairy farms, and placing some limits on large dairy farms.

Cessation (outgoer) schemes, somewhat similar to the Dairy Termination Program in the United States, have been a significant tool in freeing up quota initially, primarily to reallocate that quota for various restructuring objectives. Impacts on regional shifts, effects on other agricultural enterprises, equalization of levies to minimize penalties, and milk quota valuations are among other key topics addressed. Some of the important issues that will have to be addressed prior to 1992 are noted including (*a*) the market oriented CAP-GATT evolution versus the "permanence" of quota program, (*b*) problems with maintaining structural change over a longer time period with quotas, (*c*) excess capacity in the total agricultural sector, and (*d*) the basic problem of what price should be established as the quota price for milk.

In the United States, the issue of supply management in the milk industry is chronic. The European experience provides some fundamental insights to quota effects. Readers of this excellent volume should include everyone making inputs into dairy policy. Graduate courses in agricultural policy will find it to be a valuable reference.

Portes, Alejandro, Manuel Castells, and Lauren A. Benton, eds. *The Informal Economy: Studies in Advanced and Less Developed Countries.* Baltimore MD: Johns Hopkins University Press, 1989, viii + 327 pp., $39.50.

The word "informal" means many things to many people. In this book, the term refers to activities which are "unregulated by the institutions of society, in a legal and social environment in which similar activities are regulated" (p. 12). Starting from this central concept of informality, the book reports on studies of such activities in Latin America (Guadalajara and Mexico City, Montevideo, Bogota, and La Paz), in the United States and Western Europe (New York, Miami, and Los Angeles; Valencia and Madrid; the Emilia-Romagna region of Italy; and Great Britain), in the Soviet Union, and in Penang State, Malaysia. Like most analyses of the informal sector, the focus of these studies is almost exclusively urban, although much informal activity undoubtedly takes places in rural areas.

The individual chapters report on primary research, much of it ongoing, on the characteristics of informal activities in these highly diverse circumstances. The authors come from several disciplines: sociology, political science, urban planning, and economics, among others. It is both the strength and the weakness of the book that the editors have not sought to impose consistency on the nineteen contributors. The result is a rich potpourri of ideas with a great diversity of approaches and methodology, of definitions, terminology, and ideology.

One of the continuing problems with the analysis of informality is that the concept is not easy to use in empirical research. One generally cannot tell by looking or by simple classification procedures whether an activity operates in accordance with all the rele-

vant regulations; this means that an interview is often required to determine whether an activity should be classified as formal or informal. It is often not a question of "yes or no" but of "more or less." This has led some of the contributors to adopt rules of thumb in their empirical work: informal enterprises are those with less than thirty workers (chap. 14) or less than ten workers (chap. 1). The discussion of the Soviet Union includes within the informal or "second" economy all production on private account, whether legal or illegal (p. 168, footnote 2). All of this leaves one uncertain about the precise set of activities that are really under study in the volume.

The individual contributions are uneven in quality. This reviewer found the chapters on Los Angeles and Miami (chaps. 6, 13), Uruguay (chap. 4), Bogota (chap. 5) and Italy (chap. 10) to be particularly interesting. For most readers, though, the most important contributions will be the first and last chapters, where the editors undertake a valiant if only partly successful search for generalities and commonalities among the diverse findings of their contributors.

The book makes clear the great variety of circumstances where production takes place outside of the regulations. In some cases, such activities have expanded in the face of—and perhaps in response to—widespread and onerous rules and restrictions (e.g., the Soviet Union); in other cases (e.g., the United States), one would be hard pressed to attribute the growth of informal activities primarily to an oppressive regulatory framework. In some cases, studies in the book suggest that informal activities have grown as a result of stagnation in the formal economy (Great Britain, Bolivia); in other cases, the most vigorous growth in informal activities has taken place in ways that are linked to dynamic growth among formal enterprises (Italy, Miami). This great diversity, well documented in the chapters of the book, helps avoid sterile questions as to whether informality per se is good or bad. Rather, one is led to ask about the circumstances under which informality is likely to be beneficial for the citizens of a particular city or region. The analysis makes clear the extraordinary complexity of the answer, influenced by a web of social, political, and economic forces which are only beginning to be understood.

Of course, the outcome of that inquiry provides the starting point for the next question: what are the policy implications? What should one do in order to promote desirable types of activities while controlling or restricting others? While this is neither the principal aim of the book nor in most cases the principal area of expertise of its contributors, the question is addressed obliquely in many of the chapters and is the subject of the concluding essay by the editors. Their answer is interesting and important. It indicates that, wherever informal activities have been successful in generating positive benefits to all participants (employers as well as workers), the state has made an important, positive contribution to that process. "A necessary if not sufficient condition for dynamic informalization is precisely getting the state *into* the economy in support of small-scale entrepreneurial initiatives. A positive official posture toward these activities, plus training, credit, and marketing support programs, emerge, in every instance, as a *sine qua non* for their development" (pp. 306). Warning against the danger of believing that the growth of informal activities provides a case for "getting the state out of the economy," they argue the need for "innovative state responses to a novel economic trend" (p. 307).

The studies reported in this book make clear that informality is not exclusively a third world phenomenon; rather, informal activities play a significant role in countries at all levels of development. A comprehensive analytical framework for the examination of such activities has not yet emerged. In the meantime, careful empirical studies, done without preconceived theoretical or analytical molds but encouraging diverse analysts to describe this part of the world as each sees it, may be the way forward. This is precisely what this book provides.

Roberts, Ivan, Graham Love, Heather Field, and Nico Klijn. *U.S. Grain Policies and the World Market.* Policy monograph no. 4, Australian Bureau of Agricultural and Resource Economics. Australian Government Publishing Service, Canberra, 1989, xvii + 286 pp. (Available in the United States and Canada from ISBS Inc., 5602 NE Hassalo St., Portland OR, 97213-3640.) Price unknown.

This thorough examination of recent U.S. grain policy by the Australian Bureau of Agricultural and Resource Economics (ABARE) follows similar analyses by ABARE of the agricultural policies of the European Community (BAE) and Japan (ABARE). The purpose of these reports is to "contribute to the debate necessary to attain policy reform internationally, through provision of information and analyses" (foreword). This series of reports is aimed more to readers in the subject countries than to Australians. The premise behind the series is that objective analysis of domestic agricultural policy in the subject countries, aided by quality presentation, will help convince the target audience that present policy is flawed and should be changed—for the good of the target country. The fact that Australia would benefit from rational policy change in the subject countries is the justification for ABARE's considerable research investment in the three studies.

The authors make a significant contribution to the vast literature on U.S. grain policies. Most of the subplots of analysis in their story can be found elsewhere in that vast literature. To this they add their own original analysis, especially of international implications. They explain in economic terms how U.S.

grain policy works (emphasizing wheat policy in the 1980s), evaluate that policy relative to its stated objectives, and offer alternatives for the future. Their main contribution is to weave all the subplots together in an international setting to tell a story of a policy that, in their view, failed. Some U.S. analysts, however, would argue that they missed the Achilles heel of U.S. grain policy by stressing its world market implications. They would argue that it is the inequitable distribution of program benefits and the undesirable structural impacts on rural areas that would more likely lead to internal political pressure for change.

Their story is told in 171 pages of text, but the key points are developed with more rigor in over 100 pages of appendices. The text is divided into three parts. Part 1 gives an historical perspective to U.S. grain policy. Part 2 covers the international consequences of that policy, and how other grain exporters have responded. In part 3, U.S. grain policies of the 1980s are evaluated and policy alternatives for the future are proposed and evaluated. Part 3 concludes with a chapter on how the U.S. political process shapes grain policy.

The authors have written in a style to communicate to an audience with undergraduate microeconomic training. The transparency of their analysis is refreshing. In the appendix, the economic theory consists of diagrams of shifting supply and demand curves. Some single-equation models are estimated. Where they think that their analysis is based upon weak assumptions, they use sensitivity analysis. Thus, it is relatively easy for readers to follow the analysis and to identify assumptions and interpretations with which they might agree or disagree.

Here is a sneak preview of some of the conclusions. Policy analysts around the world debate whether U.S. grain policy actually increases or reduces grain output, i.e., do production controls offset the impact of production subsidies? The authors conclude that, "had US grain programs been discontinued from the beginning of the decade, aggregate US grain production from 1981 to 1987 could well have been much the same as it actually was" (p. 86). But they point out that during the 1980s the program costs were high for the U.S. Treasury and considerable instability was added to world grain markets. Policies stimulated too much production in the early 1980s. Consequently, surplus stocks were dumped on the market in the late 1980s in the form of generic certificates and Export Enhancement Program subsidies. The authors estimated that the latter caused a minor inconvenience to the EC and hurt Australian wheat growers. Their policy-of-choice for the future would be decoupled and tradable direct payment entitlements to producers.

I recommend the ABARE report to readers interested in understanding U.S. grain policy. It would be a good supplemental reading in an advanced undergraduate or M.S.-level agricultural policy class. A strength and unique feature of the book is the emphasis on international implications of U.S. policy as seen by analysts in a country that competes with the United States in that same market.

Schmid, A. Allan. *Benefit Cost Analysis: A Political Economy Approach.* Boulder CO: Westview Press, 1989, 354 pp. $29.50.

Both the title and the W. J. Samuels' forward to Allan Schmid's book suggest a work that is much more narrowly focused than it really is. Although the coverage of the distributive issues that arise in cost-benefit analysis is quite thorough. *Benefit Cost Analysis: A Political Economy Approach* is comprehensive enough to serve as a general guide for those involved in public investment analysis and as a text for a course in applied welfare theory. Schmid states the theme of the book in the first chapter as one which, "instead of taking income and rights as independently given and to be implemented by benefit-cost analysis (BCA) in a Pareto-better fashion, we will see income, rights and the analytic rule of BCA emerge as interacting parts of the same structure" (p. 2). The author attempts this integration by working "out the practical implications of second-best theory, which accepts the fact that government cannot achieve desired distribution with lump-sum taxes and, indeed, that public spending is one instrument used to achieve a desired distribution" (p. 3).

Beginning with the second chapter, the book is organized in the same way that one might prepare a report on the costs and benefits of a public investment project. Chapter two is devoted to the theory of public investment in which the question of what types of investment should be made by the public, rather than the private sector, is addressed. Chapters three and four concern project evaluation, which Schmid defines as the identification of the inputs and outputs of the project. The next three chapters (5–7) examine the problems associated with assigning a monetary value to the various effects of a project. Chapter five discusses valuation of a project under the assumption that it will not alter current relative prices. Adjustments to such a valuation because of market failures is considered in chapter six. Chapter seven examines adjustments to such valuations for nonmarginal (price

changing) projects. Distributive issues inherent in any choice of projects are discussed in chapter eight, and alternative investment criteria and choice of the appropriate discount rate are the topics of chapter nine. Chapter ten discusses the effects of uncertainty. The final two chapters (eleven and twelve) discuss decision making in the political arena.

The author presents the material in a thoughtful and logical manner, which makes the book very readable. I found the discussions of consumer surplus (chap. 7) and the problems posed by budgetary constraints (chap. 9) especially well presented. Chapter 8, however, is probably the most thought provoking. Here, the author outlines his opposition to using equity weights to resolve concern about the distribution of benefits and costs. He argues instead that distributive issues must be resolved by assigning property rights. Schmid distinguishes, therefore, between policies that merely change the distribution of income and those that redistribute property rights (p. 158).

Few books (or reviews) are, of course, entirely above reproach. Although generally well written, the discussion is repetitious in some places and even confusing in a few others. (An example of the latter, on p. 168, is Schmids' description of free riding as the result of high transactions costs.) The terminology tends to become a bit eclectic in some instances. Examples of this problem in chapter two include the use of the term Pareto-better rather than Pareto-superior; the description of public goods as high exclusion cost, joint impact goods rather than goods with the characteristics of nonexclusion and nonrivalry; describing the compensation for loss of a property right as willingness to sell rather than willingness to accept payment; and the references to the truncation problem in empirical research as one where there is "a failure to control for the effects of maturation and testing" (p. 50). In all these cases, it might have been better if the author had indicated (as he does in other instances) the alternative terms for the concept under discussion. Finally, the bibliography could have been improved by including a greater number of the more recent works in benefit-cost analysis. (Works published since 1984 constitute only 6% of the total.) For example, inclusion of some references to William J. Baumol's work on the concept of fairness (see, for instance, his *Superfairness*, 1987) would seem appropriate given the importance Schmid affords to the interrelatedness of efficiency and equity questions. Nevertheless, I recommend Schmid's work both as a useful addition to one's personal library and as a text book in courses on applied welfare theory.

Seibel, Hans Dieter, and Michael T. Marx. ***Dual Financial Markets in Africa: Case Studies of Linkages Between Informal and Formal Financial Institutions*****. Ft. Lauderdale FL: Verlag Breitenbach Publishers, 1987, 143 pp., price unknown.**

This book describes schemes to link informal and formal financial markets in Africa. The authors first present some conceptual considerations regarding the structure and characteristics of both informal (IF) and formal markets (FF). The latter fall under the control of the government, while the informal markets are atomized in size and scope and largely outside government control. Next, they summarize five case studies in four countries of linkages between formal and informal institutions under diverse economic and sociological conditions. The selected countries for case studies were Ivory Coast, People's Republic of Congo, Togo, and Nigeria.

The Ivory Coast is a liberal country with more than 9 million inhabitants and fifty to sixty indigenous ethnic groups. The focus of its agricultural policy is production for both internal consumption and export. The predominant informal financial institutions in rural areas are hired work associations, rotating savings and credit associations, and nonrotating savings and credit associations.

The People's Republic of Congo is a poor and underpopulated country with about 1.7 million inhabitants. Two types of IFs are practically universal in the country: rotating savings and credit associations and insurance savings arrangements, mainly for burial purpose. Some forms of IF were not found in rural Congo because of the low level of monetization. Women participate extensively in IF in rural Congo, and there are only four formal institutions in the country providing a limited amount of agricultural loans.

Togo is also a very poor country with about 3 million inhabitants. The major IFs are the rotating savings and credit associations, the daily deposit systems (*eye speakers*), and a combination of the two. The formal financial institutions in the country include several commercial banks, three development banks, one savings bank, and the national social security fund. The authors report that the formal sector has been largely unable to serve small farmers and small business people.

The size and complexity of Nigeria's economy and its large population pose a different scenario for comparison of formal with informal finance. The formal sector is characterized by a large number of state-registered cooperative societies. There are more than 17,000 of these cooperatives with 1.7 million members; the prevailing types are producers, marketing, and saving/credit cooperatives. The total number of members in IF groups in Nigeria, however, is estimated at 20 million. This shows a surprisingly strong dependence on informal financial markets, in spite of the expansion of FF in recent years. Also impressive is the large number of types and variations of IF in Nigeria.

The last two chapters in the book are the most interesting. In chapter 3 the authors suggest a way of

linking formal and informal financial markets. They stress the need to overcome the lack of personal relations between IF members and bank branches. They then propose a survey and mobilization campaign as a basic methodological tool tested both in Nigeria and Ivory Coast. The survey's purpose is to develop data concerning: (*a*) information on the existing IFs and their relationships with other organizations; (*b*) data on government development programs; and (*c*) insights on prevailing social, political, cultural, and economic conditions. Another purpose of the survey is to interest the potential participants of both sides (IF members and bank representatives) in considering linkages.

The last chapter provides guidelines for the development of formal and informal financial institutions in Africa. In the authors' view, linking informal and formal financial institutions requires changes in the concerns and behavior of the two parties. For the FF, such changes may be considered a downgrading; while, in the case of IF, these changes are mostly upgrading. Downgrading techniques of FF may increase the efficiency of banks, and upgrading procedures of IF may be carried out as a grassroots development strategy without the interference of banks. No formal ties are likely to exist between the two institutions.

The authors present some provocative suggestions regarding the activities and organizations of IF and FF. However, this section might have been expanded and developed in a more analytical fashion. Some of the suggestions are presented in a concise form and are likely based only on the authors' experience in financial development. The book contains useful information on informal finance and also provides suggestions on how to better link formal and informal financial markets in low income areas.

University of São Paulo
Piracicaba, Brazil

Shaffer, Ron. *Community Economics: Economic Structure and Change in Smaller Communities*. Ames: Iowa State University Press, 1989, 322 pp., price unknown.

Microeconomic theory of the firm and consumer are the familiar building blocks of traditional economic analysis; Shaffer, in his book *Community Economics*, has undertaken the task of developing a similar set of basic tools for analyzing community-level economic activity. Because communities are composed of individuals and firms operating within a larger regional and macroeconomy, each of these theoretical orientations can contribute to our understanding of how communities function and how economic information can be used to improve their situation. This book is particularly timely given the current level of interest in rural development by national, state, and local policy makers as well as the critical nature of issues facing rural communities. The book narrows the discussion of community development to a focus on the role of economics in furthering community goals. It also differs from previous textbooks in the rural development field, such as *Micropolitan Development* by Brinkman and Tweeten, in that it offers many practical analytical tools for practitioners in the field.

The book's organization makes a logical progression from a review of regional economic development theories into an examination of the goals, policies, and programs to support economic development, followed by an examination of special topics in community economic development such as the role of government, capital markets, and the functioning of labor markets in community development. The concluding section deals with methods of analysis, including impact analysis, economic base, and input/output models.

While a theoretical background is important in guiding researchers, the lack of a generally accepted unifying framework for economic development has not prevented state and local economic development officials from pursuing a wide variety of economic development strategies. These strategies can be classified as guided by demand-oriented and supply-oriented theories according to the scheme presented by Shaffer. His review of theories focuses on those which have direct policy handles or relevance for state and local policy makers. However, the continuing problems of rural areas suggest that the current array of economic development theories is not providing appropriate guidance for policy makers. As an alternative, ideas, strategies, and theories from nontraditional sources, such as the international development field or other academic disciplines, need to be explored for potential to stimulate ideas on economic development in rural areas. Although Shaffer's section on components of a community economic development model raises critical issues that a comprehensive framework must address, he stays away from the challenge of developing that integrating framework in this volume.

Another challenge to achieving a generally accepted economic development framework is the fact that many practitioners in the community and economic development arena are heavily involved in organizational and implementation activities, while losing perspective of the theoretical foundations for their activities. While this book provides a reminder of the role and contribution of development theory for practitioners, Shaffer also provides several chapters on organizing and implementing community economic development programs. A practical corollary to the theoretical section is the discussion of five generic strategies to promote community economic development: (*a*) attract new basic employers, (*b*) improve efficiency of existing firms, (*c*) improve ability to capture dollars, (*d*) encourage new business formations, and (*e*) increase aids/transfers received from broader governmental levels.

Although fairly general, these five strategies are a

useful way to begin organizing and considering economic development choices. They also provide a recurring theme throughout the book.

Other practical information for community development workers is contained in the chapter on implementing community economic development programs such as organizing development groups, setting goals, prospecting, and targeting for industries. For business analysts interested in retail and service development issues, the book offers relevant discussion on central place concepts for small area analysis including: trade area analysis, gravity models, service and trade thresholds, and sales potential calculations.

Several important and controversial issues in community economic development are also given special discussion including the role of capital markets and the appropriate role for government in the economic development process. These topics have been debated extensively among policy makers and professionals in the economic development field, and Shaffer provides a well-rounded discussion and extensive bibliography on these issues.

While Shaffer provides a comprehensive and well-balanced discussion of the chosen set of issues, additional topics of vital concern to rural areas might also have been included, such as issues in the provision of public services and infrastructure concerns in rural areas. The best feature of the book is the scholarly blend of the theoretical foundation and principles of community economic analysis into a set of guidelines and tools for practitioners in this area.

Although this book is developed from classroom lecture notes, much of the material is based on Shaffer's years of community development experience. Very few books in the regional economics area are able to combine a comprehensive discussion of community economic development theory with positive, practical contributions to practitioners in the field. *Community Economics* should serve as a useful training and reference book for students, researchers, and practitioners in the community economic development field.

Daniel M. Otto
Iowa State University

Simpson, James R. *The Economics of Livestock Systems in Developing Countries*. Boulder CO: Westview Press, 1988, xxii + 297 pp., price unknown.

Simpson's book aims to provide a framework for evaluating livestock production investments in developing countries. He argues that livestock production is different enough to warrant separate treatment from standard analyses of agricultural investments. The book's audiences are technically oriented economists needing a general reference on the subject and animal scientists learning about economic approaches to their fields. I agree that the topic merits separate treatment and think the choice of audiences is appropriate, but I believe major revisions are necessary before the book finds a wide readership.

The book emphasizes cattle production, with secondary reference to swine, goats, and sheep. After introducing the intellectual background to his theme—systems analysis, research methodology—Simpson classifies cattle systems as extensive or intensive; the contrast between the two is the book's organizing theme. Within each class he lists the principal characteristics as activities (e.g., cow/calf or dual purpose), institutions, herd size, and feed systems.

Simpson then presents standard discussions of microeconomic theory, with case histories from agricultural production: enterprise budgeting, whole-farm analysis using programming techniques, and partial budgeting. Those techniques are applied to cattle systems in whole-farm analysis and subsequently to the problem of fattening cattle to slaughter weight. After reviewing production systems for goats/sheep, buffalo, and dairy cattle, Simpson reverts to the methodologies for capital budgeting, project analysis, simulation, and farming systems research. Simpson expounds the methods in enough detail that readers might usefully follow the book's examples in practical work, and this is its principal virtue.

The most general shortcoming in the technical chapters is failing to consider risk, either in project analysis or in choice of technique. While economists are obviously familiar with risk in project analysis (and have many good references on the subject), animal scientists probably are not. Also, the treatment of simulation is sketchy. It fails to distinguish between biological models and economic ones. Given that the data for simulations of biological processes are scarce in developing countries, Simpson might have presented methods and results of economic simulation models more thoroughly, especially in light of his intended dual readership.

Other specific deficiencies in the method chapters include a tendency to treat the herd size or stocking rate as fixed in investment analysis. This is not always right, especially in extensive systems where increasing herd size or stocking rate is usually the cheapest growth path. The book does not mention economies of scale in animal production, especially those associated with herding labor. The assumption that such economies do not exist is a vital one to linear programming, for example, and yet it is not noted at all. Nor is the joint production problem mentioned in extensive meat and milk production. The conflict between the two is decisive for herd management where milk is a subsistence good.

The book lacks perspective on how the choice of technique—its main theme—fits into the evolution of production systems. While the main classification is, rightly, intensive versus extensive systems defined by stocking rates, the book returns only intermittently to that theme. The choice of analytic technique is not seen as a function of the system studied. This situation is reflected in the production systems picked to show particular analytic techniques. The

case histories seem to have been chosen largely because they were available and sometimes contain discursive material that adds little.

There is not enough in the book on what makes poor economies unlike rich ones. Because the purpose of the book is to treat the developing country livestock industries separately from developed ones, this oversight is puzzling. Outstanding differences are higher transaction costs in factor markets, production diversification in response to those costs, and the absence of insurance markets (particularly for transactions in breeding stock). Simpson adduces disparate noneconomic objectives (pp. 29, 227, 230) but fails to prove that these objectives exist (e.g., prestige) or that they affect resource allocation ("prestigious" herd expansion inducing suboptimal offtake and overgrazing). With respect to the motives for herd expansion and low offtake, Simpson does not consider Jarvis's argument that what appear to be irrationally low offtake and overgrazing are really profit-maximizing responses to the low feed costs found in many poor countries. Another illustration of this failure to draw out the consequences of differences between rich and poor economies is the book's inadequate treatment of seasonality where input markets are thin or absent.

The bibliography omits such important works as Lovell Jarvis's book on Latin American livestock and Stephen Sandford's on third world pastoralism. It also has some annoying typos and is dated in a few instances.

Sandford, Stephen. *Management of Pastoral Development in the Third World.* Chichester: John Wiley & Sons, 1983.

Ward, Ronald W. and Richard L. Kilmer. *The Citrus Industry: A Domestic and International Economic Perspective*. Ames: Iowa State University Press, 1989, 180 pp., $22.95.

Ward and Kilmer's goals are to provide the reader with "insight into the infrastructure of the citrus industry . . . and to provide a case study illustrating the complexities typical of many agricultural markets" (p. vii). The book has ten chapters organized in four sections: I, "Production and Distribution; II, Pricing and Risk"; III, "Market Development, Industry Cost, and Value"; and IV, "International Trade." Although the authors refer to the book as a text, it may be more useful as a descriptive reference introducing the reader to the industry or perhaps as a basis for a case study.

A case study of the citrus industry could be useful for many reasons. Of particular interest are the six primary factors identified by Ward and Kilmer as causes of changes in the industry: (*a*) changes in processing technology, (*b*) Brazilian citrus industry growth and resulting increased international competition, (*c*) weather patterns (freezes), (*d*) consumer demand for convenience, (*e*) increased emphasis on brands, and (*f*) changes in market shares and increased government involvement in decisions (p. x). One might suggest that disease and pest concerns, i.e., citrus canker, Mediterranean fruit fly, may also be an important source of change in the citrus industry. Many other industries share the same change-inducing factors, and readers could learn a great deal from understanding how these factors have been interrelated to effect change in the citrus industry. While Ward and Kilmer urge the reader to "recognize the interdependence among these factors" (p. x), the authors should accept more of that responsibility. Indeed, at the end of the book, it would have been appropriate for the authors to give their appraisal of how the factors inducing change in the industry are likely to be interwoven to effectuate future change in the industry.

Much of the book is based on reviewed research papers and other works by the authors and other faculty members at the University of Florida, particularly those associated with the Economic Research Department of the Florida Department of Citrus. Other sections report research results that appear to have not been reviewed and may be available in unpublished mimeographs, staff papers, and consulting reports. The variety of sources used and the varying qualities of review to which those sources have been subjected make the book at times discontinuous and occasionally redundant. One example of the redundancy can be found on pages 82 and 139 where duty-drawback provisions and their implications are described.

It is difficult to describe the type of reader that the authors had in mind. Most of the book contains largely descriptive data with limited statistical analysis. Yet in tables 7.1 (p. 103) and 9.1 (p. 137) somewhat complex statistical results are presented with only limited explanations.

The book is data intensive. Of the 165 pages in the body of the book, there are 45 tables and 46 figures. This information is useful for reference purposes; however, at times I was moving through page after page of tables wondering where the next portion of text would occur. Many of the detailed data might have been placed in an appendix. A list of tables and figures would help the reader find information.

Some data series appear to end at approximately the time period when the cited studies were originally presented. While asking the authors to update the analyses that were previously completed would be unreasonable, it does appear that updated data could have been presented in several instances. The authors' assessment of the continued validity of results from the previously completed research studies would have been useful. Many of the series were complete

to the 1985/86 season, with occasional references to the 1986/87 season.

The usefulness of extensive review of Florida processor concentration as of 1978/79 (p. 21) without comparisons to updated information about Florida and other domestic processors as well as Brazilian processor concentration is difficult to justify. The industry has at least one additional major branded product and higher volume of reprocessing outside of Florida. Because of the changes, it is not clear that Florida is still a particularly useful market definition for which to measure concentration. The authors recognized this point when they suggested that "The ability of a few Florida processors to exercise price leadership is no longer possible (or has been limited) . . ." (p. 132).

The authors properly identify the significant role that the Brazilian citrus industry has played in determining the fate of the processed product industry in the United States. The book could have been improved by including more current information on the Brazilian industry. Much of the section describing the Brazilian industry is based on papers written in 1978.

Because of the extensive jargon used in the citrus industry and the number of organized groups in the industry, it would also have been helpful if the authors had prepared a glossary of terms and industry organizations for inclusion in the book. Examples of the types of confusion that could have been clarified by a glossary are the authors' referrals to the Florida Canners Association, FCA, (pp. 50, 52, and in tables 3.1, 3.2, figure 4.3) whose name was changed to the Florida Citrus Processors Association, FCPA, as referenced in table 3.4. A glossary or appendix defining the various units of measurement used for both fresh and processed citrus also would have been useful.

The authors took on a challenging task in a dynamic industry that has changed rapidly. Because of the rapid rate of change, it is unlikely that anyone could write a book and have it as current as they would like at the time of publication. As a result, the usefulness of Ward and Kilmer's work is restricted primarily to that of a historical reference that leads the reader to many of the data sources and suggests many of the proper questions that need to be asked.

Oklahoma State University

Errata

In the February 1990 issue of the *Journal*, there was an error in the article, "Utilization, Profitibility, and the Adoption of Animal Draft Power in West Africa," by William K. Jaeger and Peter J. Matlon, page 46.

The first sentence in column 1 under the heading "Previous Work Reconsidered: The Harvest 'Constraint'" should read as follows:

"The analysis presented here is consistent with most prior literature and field surveys, which generally found evidence of area expansion effects with the introduction of animal traction but only limited support for yield effects (Barrett et al., Sargent et al., McIntire, Lassiter).

The reference to McIntire was inadvertently omitted from the reference list. It should be:

McIntire, John. "Two Aspects of Farming in Central Upper Volta: Animal Traction and Intercropping." *ICRISAT Village Studies Rep. No. 7.* Ouagadougou, Republic of Upper Volta, 1981.

The second group of errata are for errors in the May 1990 issue of *AJAE*, in article number 1, "Preferences of Citizens for Agricultural Policies: Evidence from a National Survey," by Jayachandran N. Variyam, Jeffrey L. Jordan, and James E. Epperson.

On page 259, table 1, statement 1 should read:

"The family farm must be preserved because it is a vital part of our heritage."

On page 261, equation (1) should read correctly:

$$\eta = \Gamma X + \zeta,$$

Finally, on page 262, equation (3) should read:

$$\Sigma = \begin{bmatrix} \Lambda \Gamma \Phi \Gamma' \Lambda' + \Lambda \Psi \Lambda' + \Theta & \Lambda \Gamma \Phi \\ \Phi \Gamma' \Lambda' & \Phi \end{bmatrix},$$

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter, the author(s) must state (*a*) that the material in the manuscript has not been published, is not being published or considered for publication elsewhere, and will not be submitted for publication elsewhere unless rejected by the *Journal* editor or withdrawn by the author(s); (*b*) that the material in the manuscript, so far as the author(s) knows, does not infringe upon other published material protected by copyright; (*c*) that the employer of the author(s), if any, either does not assert an ownership interest in the manuscript or is willing to convey such interest to the American Agricultural Economics Association (AAEA); and (*d*) that submission of the manuscript gives the AAEA exclusive right to publish, to copyright, and to allow or to deny reproduction of it, in whole or in part. If the applicability of point (*a*) is unclear, the author(s) must explain.
2. **Author's identification.** To protect their anonymity in the review process, authors should not identify themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on $8^1/_2$-by-11-inch standard weight white paper with margins on all sides of at least $1^1/_4$ inches.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of the *Journal.*
5. **Data and Documentation.** Authors are expected to document their data sources, models, and estimation procedures as thoroughly as possible, and to make data used in their analyses available to other researchers for replication purposes. If for legal or proprietary reasons, the data can not be made available to all potential users, this limitation should be noted. Submission of appendices, model documentation, and other supporting materials with the manuscript is acceptable in order to facilitate the review process.
6. **Mathematical notation.** Use only essential mathematical notation; it is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable.
7. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type all footnotes, double-spaced, on a page following the article. Footnotes should be only explanatory and not for citations or for directing the reader to a particular work. This information can be incorporated into the text.
8. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of a sentence, a parenthetical reference is unnecessary unless page numbers or a date are needed. A style sheet on references and citations is available from the editor.
9. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
10. **Figures.** For accepted manuscripts camera-ready figures must be prepared using professional techniques that are suitable for photographic reproduction. Typescript is not suitable.
11. **Four copies.** Send four fully legible copies to the editor. All copies should be inspected for completeness and quality of reproduction.
12. **Abstract.** Instructions for the preparation of an abstract will be sent when a manuscript is accepted for publication.
13. **Page charge.** Major support for this ***Journal*** comes from page charges of $55 per printed page, or fraction thereof, payable by the supporting institution or granting agency. Payment does not affect acceptance, scheduling, or form of publication. Instructions for payment are sent with galley proofs.

American Agricultural Economics Association

President/Sandra Batie, VPI and State University

President-Elect/Warren E. Johnston, University of California, Davis

Secretary-Treasurer/Raymond R. Beneke, Iowa State University

Past-President/Lester V. Manderscheid, Michigan State University

Directors

Walter J. Armbruster, Farm Foundation
Vernon R. Eidman, University of Minnesota
Gene Futrell, Iowa State University
Lawrence W. Libby, University of Florida
John A. Miranowski, USDA/Economic Research Service
Richard K. Perrin, North Carolina State University

Objective

The American Agricultural Economics Association (AAEA) seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy.

AAEA

—publishes the *American Journal of Agricultural Economics*, the *AAEA Newsletter*, *Choices*—The Magazine of Food, Farm, and Resource Issues, and, periodically, a *Handbook-Directory* of AAEA members;
—plans and conducts an annual meeting of the membership;
—sponsors awards for Distinguished Undergraduate Teaching, Distinguished Extension Programs, Distinguished Policy Contribution, Publication of Enduring Quality, Outstanding Journal Article, Quality of Communication, Quality of Research Discovery, Outstanding Master's Thesis, and Outstanding Ph.D. Dissertation;
—recognizes prominent agricultural economists as Fellows;
—operates the AAEA Employment Service for agricultural economists.

Membership and Subscriptions

AAEA is a professional society for agricultural economists and others who are interested in agricultural economics. A nonprofit organization, AAEA is committed to furthering knowledge about the economics of agriculture, rural communities, and natural resources.

Membership in the AAEA will bring you *Choices*, the *AJAE*, the *AAEA Newsletter*, and other occasional AAEA publications, permit you to use the AAEA Employment Service, and allows you to attend the annual meetings.

Calendar year dues are: $45, regular members; $22.50, senior (retired and 65) and junior (student) members; $67.50, family members; $150, industry members. Lifetime membership is available for members who are at least 55.

Subscription prices: *American Journal of Agricultural Economics*—$65 per year ($73 overseas); single copies, $14.50. *Choices*—The Magazine of Food, Farm, and Resource Issues—$32.50 per year ($52.50 overseas); single copies, $10. *AAEA Newsletter*—$12 per year ($17 overseas).

For further information about the American Agricultural Economics Association, contact the AAEA Business Office, 80 Heady Hall, Iowa State University, Ames, Iowa 50011-1070 (515-294-8700).

AAEA Annual Meeting
Kansas State University
Manhattan, Kansas
4–7 August 1991

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to:

Peter J. Barry, Editor
Department of Agricultural Economics
University of Illinois
305 Mumford Hall
1301 W. Gregory Drive
Urbana, Illinois 61801

Communications concerning book reviews and books submitted for announcement in the *Journa* should be sent to the book review editor:

Dale W Adams
Department of Agricultural Economics
Ohio State University
2120 Fyffe Road
Columbus, Ohio 43210

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultur economics. Thus, acceptable manuscripts should have a relationship to the economics of agricultur natural resources, or rural and community development. Contributions, methodological or applie in the business, extension, research, and teaching phases of agricultural economics are equally e couraged. The ***American Journal of Agricultural Economics*** (ISSN 0002-9092) is published month in February, May, August, November, and December by the American Agricultural Economics A sociation, 80 Heady Hall, Iowa State University, Ames, Iowa and printed by Edwards Brothers, Inc Ann Arbor, MI. Second-class postage is paid at Ames, Iowa, and additional mailing offices. Po master: Send address changes to the American Journal of Agricultural Economics, 80 Heady Ha Iowa State University, Ames, Iowa, 50011-1070.

Subscription

Subscription cost is $65 per year plus foreign postage; members receive copies as part of their me bership fee of $45 per year.

1990 Fellow

Helen C. Farnsworth Professor of International Agricultural Policy, Stanford University, 1976–present.

Director, Food Research Institute, Stanford University, 1972–present; Professor, Food Research Institute, and Department of Economics, 1972–present.

Senior Associate Dean, School of Humanities and Sciences, Stanford University, 1988–present; Associate Dean, School of Humanities and Sciences, 1985–88.

Deputy Director, Development Advisory Service, Harvard University, 1970–72; (Director of Research, 1966–70); Assistant Professor, Department of Economics, Harvard University, 1963–66.

Chairman, Board of Trustees, International Rice Research Institute, 1989–present (Member, 1987–88); Member, Board of Trustees, International Maize and Wheat Improvement Center, 1980–87.

Member, Board of Trustees, Winrock International, 1984–present; Chairman, Board of Trustees, Agricultural Development Council, 1979–83.

Member, Presidential Commission on World Hunger, 1978–80.

AAEA Quality of Communication Award, 1984; AAEA Award for Outstanding Article in the *American Journal of Agricultural Economics*, 1971.

Editor, *Food Research Institute Studies*, 1977–present; Advisory Council, *CHOICES*, 1986–87; Editorial Council, *American Journal of Agricultural Economics*, 1968–72; Associate Editor, *Quarterly Journal of Economics*, 1963–72.

Consultant, Agency for International Development, Ford Foundation, International Bank for Reconstruction and Development; Senior Food Policy Advisor, Government of Indonesia.

Walter P. Falcon has compiled a distinguished record of research, teaching, administration, and service in the international agricultural policy and development arena. Born in Cedar Rapids, Iowa, Falcon received his B.S. in agricultural economics from Iowa State University. He went on to Harvard University, where he earned M.A. and Ph.D. degrees in economics. Falcon remained at Harvard for nearly a decade, first in the Economics Department as an assistant professor and then in the Development Advisory Service (now the Harvard Institute for International Development). In 1972, Falcon moved to Stanford University as director of the Food Research Institute.

Among Falcon's publications are six books and more than fifty articles, reviews, and reports. His research reflects a lifelong interest in and commitment to international economic development. Early work focused on Pakistan. He was a member of the White House–Interior Department Panel on Pakistan, whose 1964 report was one of the first modern analyses of the conjunctive use of surface and groundwater and its role in the agricultural development of the Indus Basin. In 1978, he co-authored a major retrospective look at both the policies implemented and the remaining problems in the Indus Basin.

Technology transfer issues have also figured importantly in Falcon's research. His 1970 as-

sessment, "The Green Revolution: Generations of Problems," was one of the first articles to bring together the controversial issues of production effects, marketing needs, and potential social consequences of technical change with the perspective of someone who had been involved extensively in the field.

Falcon also has been co-principal investigator of six studies of major commodity systems, each of which examined the objectives of national food policies, the forces constraining those policies, and the consequences of those policies on commodity trade and the prospects for country or regional development. Work on the cassava, corn, and rice market systems in Indonesia all resulted in books, as did the study of rice market systems in West Africa. The study of the political economy of rice in Asia comprised two monographs.

Hundreds of Stanford students have learned about American agricultural policy in his annual course. He is currently involved in a Ford Foundation project to revise the undergraduate curriculum at Stanford to include significantly more international material and perspectives. This year he added his own new course, The World Food Economy, for undergraduates. He has been the mentor, either formally or informally, to virtually every Institute graduate student. Falcon's commitment to teaching is perhaps nowhere more evident than in the series of short courses on food policy analysis he and two colleagues created for senior government officers from five ministries in Indonesia. Their lectures were the foundations for the award-winning book, *Food Policy Analysis*.

One of Falcon's most important contributions to the profession has been as an administrator, where he is truly an institution builder. As director of the Institute, he has undertaken major funding initiatives that have enhanced significantly the productivity and visibility of its faculty; have broadened its disciplinary core to include nutrition, demography, and resource policy; and have financed its commitment to training both first and third world economists. His abilities as an administrator have not gone unnoticed, either in the university where he is now senior associate dean in the School of Humanities and Sciences, or in the international community where he is now chairman of the board of trustees at I.R.R.I. and a member of the board of Winrock.

Perhaps the ultimate reflection of his many skills is in his continuing role as a senior food policy advisor to the Government of Indonesia. Because of his insightful analyses and forthright discussions of key issues, combined with remarkable interpersonal skills and the political sensitivities required of an expatriate advisor, Falcon has been invited to return every year for more than twenty to assist several ministers in the analysis of food and agriculture issues.

Together, Falcon's contributions are extraordinary—researcher and policy analyst, teacher and mentor, and administrator and institution builder. All are in the finest tradition of exceptional service by AAEA Fellows.

John E. Lee, Jr.

1990 Fellow

Administrator, Economic Research Service, U.S. Department of Agriculture, 1981–present
Member, Executive Committee of the Administrative Board, USDA Graduate School, 1983–present
Instructor, USDA Graduate School, 1983–present
Member, Executive Committee Social Science Agricultural Agenda Project (SSAAP) 1987–present
Member, Joint Council on Food and Agricultural Sciences, 1981–present
Member, USDA Committee on Biotechnology in Agriculture, 1987–present
Member, Great Plains Agricultural Council, 1981–present, member Executive Committee, 1986–89
Member, USDA Policy Coordination Committees for Science and Education and for Natural Resources and Environment, 1982–89
Member, Steering Committee, study of "Productivity in the Food Industry," President's Council on Productivity, 1972–73
Chaired AAEA Membership Committee, 1975–77
Editorial Council of AJAE, 1971
Director, National Economics Division, 1979–81; National Economics Analysis Division 1976–79; Commodity Economics Division, 1973–76; and Farm Production Economics Division, 1971–73, ERS/USDA
Chief, Agricultural Finance Branch, ERS/USDA, 1967–71
Agricultural Economist, ERS/USDA, 1962–67
Teaching Fellow in economics, Harvard University, 1961–62
Instructor and assistant in agricultural economics, Auburn University, 1958–59

John E. Lee, Jr., has influenced the agricultural economics profession through innovative leadership of the largest group of agricultural economists in the world. He provides inspiration and support for a wide range of activities of the American Agricultural Economics Association, effectively links work of agricultural economists in and out of the Economic Research Service with national policy making, aggressively advocates the importance of funding social science research and education in government councils, and champions the need for publicly employed economists to serve the common good by assuring widespread access to the information needed for enlightened public and private decision making.

John Lee has devoted his career to the U.S. Department of Agriculture's Economic Research Service. Starting as an agricultural economist working on production adjustment problems, he quickly gained the confidence of his colleagues and supervisors. In turn, he accepted increasingly important responsibilities as chief of the Agricultural Finance Branch, director of

four divisions, and, then in 1981, administrator of the Economic Research Service.

The premise guiding John Lee's professional career is that an informed public, aware of the full consequences of alternative courses of action will most likely assure that the agricultural and rural economies perform in the interests of the larger society. In that context, he argues that agricultural economists have special responsibilities to analyze implications of alternative public policies, technologies, and courses of action and to make these implications "transparent" to policy makers and the public.

Lee's commitment to excellence parallels his commitment to present unbiased research results in the face of controversy. That dual emphasis on excellence and independence has vastly increased the demand for and influence of ERS's work.

Lee's championing of research excellence and relevancy is mirrored by his support of professional activities including those of the American Agricultural Economics Association, the International Agricultural Trade Research Consortium, Resources for the Future, and the Great Plains Agricultural Council. He is an influential member of the Joint Council for Food and Agricultural Sciences and is an articulate spokesman in that Council and in USDA for the rural social sciences.

John Lee maintains a strong interest in education. He is a member of the General Administrative Board of the USDA Graduate School, serves on the board's Executive Committee, chairs the graduate School Futures Committee, and teaches a popular class in agricultural policy.

John Lee's commitment to public service, sustained professionalism, superb managerial skills, and innovative leadership account for his record tenure as administrator of the Economic Research Service and his success in enhancing the reputation of that agency in difficult times.

Fulbright Scholar, Australia, 1987.
Sr. Staff Economist and Special Consultant, President's Council of Economic Advisers, 1986–87.
Assistant Professor: Department of Agricultural Economics, University of California, Davis, 1971; Associate Professor: University of California, Davis, 1972; Professor: University of California, Davis, 1974; Department of Economics, Iowa State University, 1974–75; Graduate School of Business Administration, Harvard University, 1975–78; and Department of Agricultural and Resource Economics, University of California, Berkeley, 1979–present.
Visiting appointments: University of Chicago, 1973–74; University of Illinois, 1972; Hebrew University, 1978; Ben Gurion University, 1978; Ford Foundation Visiting Professor, Argentina, 1972.
Senior Fellow, Resources for the Future, 1985.
AAEA Quality of Research Discovery Award, 1976; Honorable Mention, 1980; AAEA Quality of Research Discovery Award, 1986.
AAEA Outstanding Journal Article Award, 1982.
WAEA Outstanding Published Research Award, 1978.
Chairman, Department of Agricultural and Resource Economics, 1979–85.
Chairman, Giannini Foundation, 1982–84.
Faculty Excellence in Teaching Award, Harvard University, 1978.
Editor, *American Journal of Agricultural Economics,* 1984–86; Editorial Council, 1977–80.
Editor, *Advances in Agricultural Management and Economics,* Springer-Verlag, 1988–present; Associate Editor, *Journal of Dynamics and Control,* 1978–82; Associate Editor, *Journal of the American Statistical Association,* 1973–82.
Chairman, Vice-Chairman, and Secretary of the Western Agricultural Economics Research Council, 1980–83.
Board of Directors: Agripac, Inc., 1979–present; Fulbright Scholar Awards Board for Economics, 1989–present; Giannini Foundation, 1979–85; Law and Economics Consulting Group (principal), 1988–present; SFA, Inc., 1988–present; TriColor Line, Ltd., 1990; Universitywide Energy Research Center, 1988–present.
Research recognition awards from national and international organizations exceed 14 (1976–present).

Research advisory committees or task force assignments for 15 U.S. and foreign governments, ministries, departments, or agencies (1978–present).

Keynote speaker or plenary session presenter exceeds 35 at major scholarly research conferences or symposia (1976–present).

Gordon C. Rausser, Robert Gordon Sproul Distinguished Professor, University of California, Berkeley, has become one of the major statesmen of our profession. A man of boundless energy, his cumulative and continuing contributions have established him as a world-class professional. Rausser was reared on a farm in California's San Joaquin Valley, a farm he managed from 1967 to 1973. He received his Ph.D. degree from the University of California, Davis, in 1971, and at that same institution he held his first professional appointment.

Over the course of his professional career, Rausser has become one of the effective and demanding mentors of Ph.D.s in our profession. Moreover, he has been responsible for developing at least four new areas of research and has been one of the pioneers in another nine areas. As a result, in 1972, 1976, 1978, 1980, 1982, 1986, and 1987, he and his collaborators were selected to receive the Outstanding Published Research Awards by the AAEA or the WAEA.

He has written more than 200 scholarly contributions in such areas as applied econometrics; financial and monetary economics; industrial organization; natural resource economics; public policy and economic regulation; statistical decision and information theory; exchange rates and agricultural trade; macroeconomic linkages with agriculture; and, most recently, in the areas of political economy of policy reform and new institutional economics. In many of these areas, his Ph.D. students have received departmental, university, or AAEA Outstanding Dissertation Awards.

Rausser's economic research is of the highest order: (*a*) he was the first economist to apply adaptive control methods to public policy, which formed the basis for one of his major books; (*b*) his work in evironmental economics was the first formal incorporation of information and measure theory, treating explicitly the inherent dynamic and stochastic behavior of environmental stocks and flows; (*c*) his collaborative research on commodity futures markets represents one of the first empirical treatments of rational expectation formation processes; and (*d*) he was the first to vigorously examine endogenizing governmental behavior, constructing political preference functions, and conceptualizing PESTs and PERTs. He, as much as anyone else, has made the political economy of policy a relevant research area for our profession.

Rausser is an inspirational and enthralling speaker, a characteristic which has enhanced his leadership effectiveness in research, teaching, and administration. Only three illustrations of his leadership contributions will be cited here. First, during one of the most critical periods of the Berkeley department's organizational life, he served as chairman for almost seven years. He accepted his responsibility at a time when almost one-half of the faculty was still to be recruited and almost all of the physical capital needed replacement. His leadership was instrumental in selecting outstanding faculty, refocusing limited resources, raising private research funds, redesigning the instructional programs, and enhancing the department's credibility on the Berkeley campus.

Second, whenever crises have arisen on the Berkeley campus, Rausser is generally asked to serve in one capacity or another. In one instance, he chaired an economic review council for the entire Berkeley campus, emphasizing the Department of Economics. His council presented a number of recommendations that have led to a steady and remarkable improvement in the department's performance.

Third, of paramount importance has been Rausser's role in designing and forming new institutions; the success of more than one research center can be attributed to his intellectual leadership. For example, as Chief Economist of A.I.D., Rausser used his scholarly work in the political economics of policy reform to develop an extension program for its implementation, leading to the establishment of the Institute of Policy Reform, the Economic Development Consortium, University Centers of Research Excellence, and the A.I.D. Research Fellow Program.

The weight and significance of his contributions to scholarly research, academia, the U.S. government, international organizations and agencies, the AAEA and other professional economic and statistical associations, and to the development and nurturing of Ph.D. students and junior faculty members are extraordinary. His *pro bono* activities and his unselfish contributions to public service and university administration have few equals.

Warren E. Johnston

1990–91 President

Professor, Department of Agricultural Economics, University of California, Davis, 1974–present
Assistant Professor to Professor, Department of Agricultural Economics, University of California, Davis, 1963–74
Director, American Agricultural Economics Association, 1985–88
Chairman, Department of Agricultural Economics, University of California, Davis, 1981–87
University of California Pacific Rim Program, New Zealand, 1989
Fulbright Research Scholar, New Zealand, 1976–77
Research Fellow, Alexander von Humboldt Foundation, West Germany, 1969–70

Warren Johnston was raised on a family-owned diversified crop and livestock ranch near Winters, California, just fifteen miles from the University of California, Davis, the university campus where he first completed undergraduate studies and where he would later spend his academic career. His father's family were early California pioneers; his mother's were immigrants from Czechoslavkia, giving him an early and abiding appreciation of his agricultural roots and an immense curiosity about people, cultures, and institutions. Undergraduate studies were interrupted by three years of military service, including graduation from the U.S. Army Language School in Monterey in 1954 and two years as an interpreter/translator in West Germany. He finally received his B.S. degree in agricultural economics from the University of California, Davis, in 1959 and subsequently earned his M.S. (1963) and Ph.D. (1964) degrees in agricultural economics at North Carolina State University under the direction of George Tolley.

His research interests have often followed his continued interest in farming and ranching and have included collaborative work with noneconomists, building on the early physical and biological science emphasis of his undergraduate training in pre-veterinary medicine and pharmacy. Mainly, his research has involved issues relating to the structure of commercial agriculture or to natural resources and often to those at the interface between agriculture and resources management and policy. Throughout his research career, his interests have included work on agricultural land markets, on the changing structure of U.S. and international agriculture, and on agricultural and natural resources policies. His research contributions included early inquiries in the economics of outdoor recreation, on economies of farm size, on energy use in agriculture, and on the economics of aquaculture. As an example of multidisciplinary research accomplishments, his work with researchers at the university's Bodega Marine Laboratory on the North Atlantic lobster (*Homarus americanus*) ultimately led to publication of *The Bioeconomics of Aquaculture*, a book in which Johnston and his co-authors sought to better integrate economic, biological, and engineering subsystems into a framework for evaluating aquacultural production systems.

Johnston's accomplishments include recognition as an Alexander von Humboldt research scholar at the University of Hohenheim, where he collaborated on the first economies-of-size study applied to West German crop farms. He has had two awards to support research at Lincoln University, New Zealand, first as a Fulbright Senior Scholar and later as a participant in the University of California's Pacific Rim Program, and he continues to study structural adjustments following the removal of subsidy and assistance policies to New Zealand agriculture. He has served on two committees of the National Academy of Sciences and participated in a joint workshop between the U.S. and Polish academies on environmental and ecological consequences of agricultural development.

Johnston's service to his university has included frequent academic governance, faculty, and administrative appointments in the department, college, and university. He has guided the department's graduate program, served as acting dean and as department chairman, was chairman of the Executive Committee of the Giannini Foundation of Agricultural Economics, has coordinated California Sea Grant Program activity in marine policy, and served on the Water Resources Center Coordinating Board.

Professor Johnston and his wife, Donna, a 4-H "sweetheart," reside in Davis, California.

Structural Change and the Recognition of Diversity

Warren E. Johnston

Our inability to understand what is going on in rural America stems from the fact that we have been unwilling to devote the necessary research resources to the structural problems to gain a comprehensive understanding of them. —C. E. Bishop

It's not a question of putting Humpty Dumpty back together again—much of the wall is no longer there. —Robert D. Muldoon, former Prime Minister, New Zealand (Tutwiler and Elliott, p. 49)

Perestroika is not a new reality for North American agriculture. Structural adjustments in agriculture, in rural communities and regions, and in economic activities associated with the production and trading of agricultural commodities are made frequently in response to recurrent changes in economic and political conditions. Increased interdependence of agriculture with other sectors within the national economy and worldwide (Tutwiler and Elliott) amplifies the need for understanding the consequences of structural change, including the organization and control of the sector. Macroeconomic and international external sources have also been acknowledged as among the major leading forces necessitating significant adjustments in the agricultural sector (Schuh 1976, Warley).

The theme of adjustments to changes in response to internal and external stimuli merits our attention as we consider agriculture, the empirical subdiscipline of agricultural economics, and the American Agricultural Economics Association. The hypothesis is that changes in agriculture and in rural areas have affected and continue to alter the subdiscipline of agricultural economics, changing the focus of research, teaching, extension, and decision-making activities.

Both agriculture and agricultural economics have become more diverse in major aspects of endeavor. A major challenge is to provide reasonable stability while adapting to change. The contemporary setting includes the potential of major restructuring of agricultural policies in developed western economies and the nearly certain restructuring of policies in the USSR and Eastern Europe. The paper concludes with a discussion of implications of structure and diversity characteristics of agriculture and of the profession of agricultural economics upon the association.

Introduction

We know that individuals and firms respond to stimuli, and so it is in response to the stimuli of past experiences, current interests, and challenges that I develop the perspective of this paper. Among recent stimuli is Jim Bonnen's (1989) description of agricultural economics as an empirical science "based on a balanced emphasis of (1) theory (including disciplines other than economics), (2) statistical and other quantitative measurement techniques, and (3) data." These three (theory, quantitative methods, and data) describe "the three-legged stool that supports empirical tradition."[1] My agricultural roots immediately reminded me of the classical three-legged milk stool of the sort usually found in antique shops. I also imagined how much more stable a three-legged stool would have been than the apparatus that we used on the ranch—a chunk

Presidential address.

Warren E. Johnston is a professor of agricultural economics and a member of the Giannini Foundation of Agricultural Economics, University of California, Davis.

Giannini Foundation Paper No.

Special thanks go from the author to Hal Carter, Dick Howitt, Jim Wilen, and Carole Nuckton for constructive criticisms. They are absolved by the usual disclaimers.

[1] Many facets of agriculture, agricultural economics and the association also seem to reveal or characterize themselves in triplets, e.g., the threefold characterization of agricultural economics research as disciplinary, subject matter and problem-solving (G. Johnson, Bonnen 1986), and the classical threefold characterization of teaching, research, and extension as the missions of a land grant university.

of 4 × 4 redwood fencepost with the 1 × 4 nailed to the top. The instability of our one-legged T-seat was particularly noticeable when one responded too quickly to the stimulus of a whisking tail in a muddy barnyard.[2]

A more enduring construct is that reasonable stability, with flexibility to make the right "move" at the right time are among the goals that we desire for the agricultural sector and within the practice of agricultural economics and our professional association. Most of us have much of our formal training in the discipline of economics. We are mainly applied scientists interested in agricultural and rural issues, many of which are interrelated with national and international economic and political policies. There are others whose interests run conversely, being primarily interested in national and international issues which are interrelated with agricultural and rural policies. Either way, the commonalty of our interests is agriculture, broadly defined. Our observations and interpretations of the real world or our visions of the future condition our behavior.

Our perspective of structural change and ability to recognize diversity depends crucially on the comprehensive understanding sought by Bishop. We need to understand and evaluate change with reference to an identifiable benchmark or baseline condition. But because baseline conditions also change, subsequent observations can be deceiving unless we periodically update our understanding of the condition from which change has ostensibly occurred.

To illustrate how what we "know," or what we think we know, changes over time and to serve as an introduction to an expanded discussion of changes in agriculture, agricultural economics, and the AAEA, table 1 presents a brief and selective description of the structural organization and performance of agriculture and the profession at three different points in time: (*a*) 1930, in the early stages of the Great Depression; (*b*) 1960, a period of relative stability following profound structural change induced by the Depression, World War II, and the Korean conflict; and (*c*) the 1989 status.

Structural change has been constant in its direction for both numbers of farms and their size. Farm numbers fell significantly over the six-decade period, and farms have grown in size, on average. In 1930, the census enumerated 6.3 million farms. Half fell from the roll by 1960, and there are now only about 2.1 million farms of all sorts, just one-third the number enumerated in 1930. Farm size grew slightly less than proportionately because of conversions or reversions of land to other uses.

Related agricultural endeavors also changed over time. Agriculture uses inputs and financing, processing, distribution, packaging, and transportation services, all originating beyond the farmgate. While both farming and food and kindred products manufacturing firms (the major manufacturing sector associated with agriculture) declined in number, the timing of their significant declines did not coincide. The number of food and kindred products firms changed little over the first period (1930–60) but were nearly halved in the next two decades (1960–82). Concentration and efficiency gains also led to larger firms, on average, with only a slight reduction in sector employment.

The demographics of rural areas changed significantly during both time periods. In contrast to the early agrarian nature of the United States still evident in 1930, farmers are a small minority in rural America today. Forty-four percent (53.8 million) of the U.S. population lived in rural areas in 1930, and the majority of them actually resided on farms. In 1960, there was the same number of rural residents (53.8 million), but because of national population growth the percentage of the U.S. population living in rural areas declined to 30%. The proportion residing on farms was only 7%. About 26% of the U.S. population now resides in rural America, nearly 10 million more than in 1960, while those living on farms now amount to only 2%. Within sixty years rural America has changed from having a majority living on farms, sharing agrarian values, to the present situation where about twelve of every thirteen rural residents do not live on a farm. One-quarter of the nation's population shares rural residency but holds widely divergent values and perspectives, not always sympathetic to agricultural interests.

Change has also occurred in the profession of agricultural economics. Association membership numbers increased fourfold between 1930 and 1960 in response to enhanced professional opportunities created by New Deal agricultural programs and by postwar employment increases in government agencies and at land grant universities. The majority of the membership still declared specializations in farm management, production, or marketing in the early 1960s. It now appears that only about one-quarter to one-

[2] A recent reading of George Ladd's monograph may have had something to do with the evolution of these thought processes; nevertheless, I implore you to hold him blameless.

Table 1. Representative Changes in the Structure of Agriculture and the AAEA

Structure Indicators	Units	Year 1930	1960	1989
Number of farms	(1,000 farms)	6,289	3,158[a]	2,088[b]
Average farm size	(acres)	157	352[a]	462[b]
Food and kindred products (SIC 20)				
Establishments	(number)	48,796[c]	41,619[d]	22,130[e]
Employees	(number)	n/a	1,699[d]	1,488[e]
U.S. population	(million)	123	181	249
Rural population	(%)	44	30	26
Farm population	(%)	24	7	2
AAEA regular/individual members	(number)	622	2,321	3,623
—with farm management, production, or marketing specializations	(%)	n/a	51[a]	27[f]
AAEA June 30 nominal assets	($1,000)	9	90	1,124
AAEA June 30 real assets	(1989 $1,000)	99	367	1,124
Real assets per member	(1989 $1,000)	159	158	310
JFE/AJAE submissions	(number)	n/a	203	337

Sources: 1930, 1959, and 1987 Census of Agriculture; 1931, 1958, and 1982 Census of Manufactures; Economic Report of the President; annual reports of the American Agricultural Economics Association and American Farm Economics Association.

third of our membership reflect those same primary interests in 1989. The number of regular members and the number of *AJAE* journal submissions have increased proportionately (by about 50%) over the 1960–89 period, while real assets per member have more than doubled, permitting expansion of services to an increasingly sophisticated and diverse membership.

These changes, in rural American and within the profession, illustrate how the environment in which we operate as professional agricultural economists has changed significantly within this century. Because the cumulative impact of changes ultimately affects the nature and mix of association activity, the next section expands on selected characteristics of structural change and increased diversity in agriculture and rural areas.

Agriculture

There is abundant evidence concerning the nature, magnitude, and rapidity of structural change at farm firm, commodity group, state, and national levels (see, for example, Heady et al.; Carter and Johnston; Stanton; U.S. Senate; Brewster, Rasmussen, and Youngberg; Buttel, Lancelle, and Lee; Reimund, Brooks, and Velde; Wilkening and Gilbert; Reif; Hallberg et al.; U.S. Department of Agriculture; Brooks, Kalbacher, and Reimund). Most contributions are by agricultural economists; but other social scientists, in particular, rural sociologists, political scientists, and historians, have effectively participated as well. Canadian analysts have also contributed to the understanding of these phenomena in their own setting (Veeman and Veeman) and have made comparisons with the U.S. situation (Ehrensaft et al.), although Brinkman noted in the early 1980s that long-run cumulative implications of government policy on farm structure were not as generally understood for Canada as for the United States. Western Europeans have also contributed to the literature (Peters and Maunder, Gasson et al., Galeski and Wilkening, Shucksmith et al.). And more recently, we have been increasingly exposed to reports of the need for restructuring in Eastern Europe and the USSR (Galeski, Schmitt), where significant change is expected. The rather abrupt change and subsequent impact of "economic liberalization" policies in New Zealand reveal readjustment problems, some unanticipated, and structural consequences of the most abrupt policy change in recent history (Sandrey and Reynolds). Whether change will be equally abrupt in the emerging market economies of Eastern Europe, which are largely without adequate in-

frastructures and private property rights, is yet to be seen.

The last three U.S. farm bills (1977, 1981, and 1985) have required annual reports to Congress on the status of family farms. They contain a rich source of information providing an annual updating of structural change issues, including size, sources of income, ownership, financial characteristics, and economic performance of U.S. farms, in general. They synoptically trace economic conditions, policies, and consequences through the intense inflationary period of 1970s, severe financial stress in the sector in the early and mid-1980s, and the subsequent gradual improvement of economic outcomes forecast for the agricultural sector into the 1990s (U.S. Department of Agriculture).

Given the considerable documentation about structural change in the historical record, what are the merits of urging that additional attention be directed to the structure of agriculture? Two points are to be made. First, measures of central tendency do not tell the whole story about structural change as it is occurring in rural America—nor in firm or industrial performance statistics. Our major challenges often are those of responding to divergent rural clientele groups created by the diversity in farms and in the general condition of rural America. Heterogeneity seems to be an increasing phenomenon as firms and areas respond to external forces. That central tendencies are not the whole story is of no surprise to those drawn to the beauty of higher moments of statistical distributions. While arguments of higher moments do provide additional information, they also complicate analysis and generalizations, introducing margins for error and misinterpretation if not appropriately recognized.

Second, it is dangerous to overgeneralize from descriptions of well-understood structures close at home to those further removed. Significant geographical variation among U.S. census regions is shown in a recent USDA report (Brooks, Kalbacker, and Reimund), and the same is surely true in Canada.

As a small example of the dangers of overgeneralizing, consider table 2. Those of us in the West occasionally experience well-intended, but inappropriate, generalizations in pronouncements and policies emanating from east of the Mississippi and the Potomac. The table contains several common farm structure indicators from the most recent Census of Agriculture for U.S. agriculture and for California. Using the census definitions and given the common characterization of California's industrial agriculture, it is likely surprising to the eastern or midwestern expert that average farm size in California is smaller than the national average,[3] that there is a higher proportion of farms smaller than 50 acres and a smaller proportion greater than 500 acres in size in California, that a higher proportion reports a nonfarming principal occupation, and that California farmers report more days of off-farm work. California farms do have higher average values, do exhibit smaller proportions of individual or family types of organizations and higher proportions of partnerships and corporations, and do have higher proportions with sales of over $250,000. These seemingly conflicting observations reflect the complexity of comparisons involving California's growing numbers of small farms with those of lesser numbers of highly productive industrial farms of the type more commonly thought of as typifying California agriculture. Similar examples surely exist for other locales.

Diversity in Agriculture

Agricultural economists have long abandoned reliance on the concept of the homogeneous, single-product farm firm. Rightly so. The consequence of unrelenting structural change in rural America, among not only farms and farming-dependent regions but also among regions more integrated with other economic sectors, has increased diversity in organization and control of all forms of economic and social activity. We know that the agricultural sector now consists of a mosaic of specialized types of firms ranging in size and intensity from part-time operators of small farm units with only modest economic outputs, to large-scale, industrialized farms with significant economic presence in the agricultural sector and sometimes involved in nonagricultural activities, as well. The range of farm units includes commercial, part-time, and amenity farmers; they need not be mutually exclusive.

[3] Between 1974 and 1987, there was a 23% increase in the number of farms in California, while nationally there was a 10% decrease. The number of farms in all but the largest size group increased between the two censuses. (The decrease in the number of large farms may be related to requirements for commodity and water delivery programs.) In 1974, average farm size in California had been larger than that for the nation, but the significant increase in farm numbers in California together with an 8% decrease in the acreage of land in farms served to drop average farm size by 25%, and below the U.S. average.

Table 2. Selected Farm Structure Components, U.S. and California, 1987

	Units	1987 U.S.	1987 California
Average farm size	(acres)	462	368
Average value per farm	($)	289,387	583,668
Percent distribution of farm by acreage:			
Less than 10 acres	(%)	8.8	27.3
10 to 49 acres	(%)	19.8	34.2
50 to 179 acres	(%)	30.9	18
180 to 499 acres	(%)	22.9	9.6
500 to 999 acres	(%)	9.6	4.6
1000 to 1999 acres	(%)	4.9	3.1
Greater than 2000 acres	(%)	3.2	3.2
Percent distribution by type of organization:			
Individual or family	(%)	87	78
Partnership	(%)	10	15
Corporation	(%)	3	6
Other	(%)	<1	1
Percent distribution of farms by principal occupation of operator:			
Farming	(%)	54	50
Nonfarming	(%)	46	50
Percent distribution of farm operators reporting any days of work off farm	(%)	57	60
Percent farm operators working > 200 days off farm	(%)	35	37
Average market value of agr. products sold per farm	($)	65,165	167,300
Percent distribution of farms by value of sales:			
Over $250,000	(%)	4.5	11.5
$100,000–$249,000	(%)	9.7	9.1
$40,000–$99,999	(%)	13.8	11.2
$20,000–$39,999	(%)	10.8	9.9
$10,000–$19,999	(%)	12	9.9
$5,000–$9,999	(%)	13.2	10.2
Less than $5,000	(%)	36.1	38.3

Source: 1987 Census of Agriculture.

Similar diversity is found in other rural activities and among the majority of the rural population who live beyond the farmgate.

The recognition of this diversity amplifies the need for careful analysis of more complex issues and problems and certainly challenges those who seek answers for policy and decision makers. From the process of structural change emerge elements of diversity pertaining to the full spectrum of different types of farm units and sector support services and involving, as well, a rural population no longer tied as directly to primary agricultural production.

Growth in diversity is slowly dampening the political and economic importance of production agriculture in rural America. Rural populations increasingly hold views different from those of farmers about acceptable cultural practices and resource uses. Conflict about cultural practices, land use, water use, or externalities between rural nonfarm and agricultural interests occur more frequently and give rise to contentious issues at every level of government, from local to federal.

A Legacy of Commodity Policies

The continued focus on farm policy rather than a more comprehensive rural policy is a modern enigma, though food safety and environmental groups have joined with traditional commodity and agribusiness interests in more recent farm bill debates (Browne). Program benefits continue to flow disproportionately to the largest farms and landowners and to those supplying them with inputs and services. With decreased farm population and significant increases in

nonfarm rural residents, commodity programs have progressively less bearing on total economic activity in rural areas and on the general economic welfare of rural people.

Restructuring of U.S. farm policy, in response to widespread intent to move the international order to a market orientation and the necessity to meet cost-cutting targets, may bring an overdue test of our inordinate reliance on commodity programs. Like the milk stool example, more stability and flexibility might have characterized a more balanced farm and rural policy structure with people, resources and environment, and commodity legs, rather than having us balancing precariously on a single-legged commodity structure. Recognition of a more diversified institutional perspective might have also permitted the corpus of policy to shift gradually over time, putting more weight on the people and on the resource and environment underpinnings of rural areas. The whisk of world attention to commodity subsidy excesses may have us scampering to stay upright in the mire created by a too strong reliance on commodity policies.

More Abrupt Changes Ahead?

Impending change in the agricultural policies of both developed and Eastern European economies may hasten the pace of structural change for U.S. agricultural producers, with significant implications for those associated with the sector and for all of rural America. Agricultural economists will be challenged to provide wise counsel in the many different settings.

Most of our understanding of structural changes induced by policies has been of the more gradual, rather than of the more abrupt, type induced by sudden shifts in economic conditions, particularly when those shifts have not been buffered by adjustment policies. New Zealand is a current case study of the effects of rather sudden economy-wide removal of government economic assistance programs. Less diversified than U.S. agriculture, New Zealand's export-oriented sector is dependent on, and subject to, vicissitudes of world markets. The shift in economic policies occurred because it had proven impossible to completely shelter the nation's economy from external forces, including those of increased international interdependencies in capital and commodity markets. Change was required because the legacy of progressive government assistance and intervention culminated in a large fiscal deficit, a heavy burden of overseas debt, and an inevitable decline in the standard of living. How much longer and at what continuing massive levels of expense can even the larger, more prosperous developed nations deny these realities?

Beginning in 1984, change came with policy moves to devalue the dollar, remove financial controls, eliminate subsidies and incentives, including tax deductions and investment allowances, and generally eradicate all forms of government intervention through financial assistance, regulation, or public ownership of enterprises. The largest New Zealand farmer organization strongly supported economic policy reform because of a belief that interest and exchange rate changes would be favorable to agriculture and that the export-oriented agricultural sector would ultimately prosper by a releveling of the playing field with respect to other sectors of the national economy.

Early analysis is now available describing the still evolving readjustment of the agricultural sector to the sudden removal of widespread public economic interventions in all sectors of the nation (Reynolds, Chiao, and Robinson; Johnston and Sandrey; Sandrey and Reynolds; Johnston and Frengley). Thus far, the experience with "economic liberalization" policies in New Zealand shows us that extensive change over a relatively short period of time is traumatic, that impacts are extensive (both in magnitude and duration), and that strong will and resolve are required to stay the course. Economic improvement has not been quickly or easily attained. Farm incomes declined. Improved income prospects engendered by better 1989 prices for dairy products, sheepmeat, and wool appear to be now threatened by the current softening of world market prices. Farmers who responded to distorted price signals and miscalculated the long-run risk of assuming continuation of assistance policies are bearing the brunt of the economic hardship, not unlike the fate of overcapitalized U.S. grain farmers in the early 1980s.

In New Zealand, continued high interest rates, weak exchange rates and commodity prices, and adverse climatic events have taken a heavy toll on the rural sector. Necessary adjustments in the ownership and capital structure of farm business continue. The restructuring of many farms either to rid them of excessive debt or to transfer ownerships at lower levels of capitalized values has been frustratingly slow. Six years after the return to market conditions began, insolvent firms continue to farm and the financial problems of

the most severely indebted firms have now shifted from borrowers to lenders. The economic character of New Zealand farming communities has changed dramatically as public services have been reduced or eliminated and economic conditions have altered profitability of local enterprises. The extent of the distress has permeated all of New Zealand, yet the resolve of farmers continues in anticipation of substantial benefits from current GATT negotiations. Their hope is that they will be among the earliest to be positioned competitively to take advantage of liberalized trade prospects in a world with fewer distortions. We can only wait to see if their venture towards unilateral dismemberment of agricultural subsidies bears fruit.

While abrupt changes appear likely in Eastern Europe, they are unlikely to have major near-term effects on international commodity markets, largely because of an overriding need to meet domestic demands and because of a lack of public infrastructures to support especially rapid structural change. Reestablishing private property and family farm units (Schmitt) and establishing appropriate infrastructures present a challenge. The primary mission is to reestablish an agricultural sector capable of responding to price signals, and careful design of evolving institutional structures will be required for the successful development of a productive private agricultural sector. Overzealous promotion of the merits of a market economy may neglect adequate provision of public infrastructure investments required to support sector development and efficiency. It may also obscure the recognition that nonmarket "bads" (e.g., environmental degradation) may accompany sought-after market "goods" in the process of agricultural growth and development and that integration of agricultural and environmental policies is desirable (Johnston 1990). We now understand that the environment was not husbanded prudently under previous communist regimes (Ryszkowski); it would be tragic if it continued to be abused under Perestroika.

There are some positive probabilities that change in agricultural sectors could be more abrupt than our recent experience. A significant challenge, whether the economic or policy change be of the incremental or of more abrupt type, is to understand clearly the implications for structure, interpreting outcomes not only with respect to sector productivity but also with increased sensitivity to resources and people associated with agriculture, its related economic activities, and rural areas. The consequences of these changes can influence the organization and practice of agricultural economics.

Agricultural Economics

Not all efforts to examine agricultural economics and agricultural economists are devoid of humor (though most are). In a notable exchange of wit and analysis, Roger Gray and Bob Firch once described the ecological dependence of black-footed ferrets and prairie dogs. In the Gray-Firch interchange, prairie dogs are farmers and black-footed ferrets are agricultural economists. They pondered, among other things, how the systematic reduction of prairie dogs could occur with the simultaneous preservation of black-footed ferrets. Two decades later, we observe that agricultural economists have not only maintained their numbers, but their population has increased. Evidently black-footed ferrets have found new ecological niches within which they can survive. They have, in essence, expanded their dependency beyond just prairie dogs to include suburban rodents and sometimes their urban cousins, as well.

Agricultural economists have increased in number because they have adapted to broadened views of what is a relevant focus for their professional capabilities. The empirical science of agricultural economics has evolved from applied problem-solving interests to a more mature disciplinary, subject-matter, problem-solving paradigm. The evolution has not been without repeated internal scrutiny (see, for example, Farrell, Phillips and Dalrymple, Stanton and Farrell, Harl, Schuh 1984, Swanson, Hoch, Havlicek, Padberg, Rasmussen, Hildreth et al., Bonnen 1988, Just and Rausser).[4] Much of past serious debate has been over the ideal paradigm mix required to gain status, to accomplish objectives, and/or to maintain accountability. Our existence as only a field or subdiscipline has, to some, cast shadows of inferiority and raised questions about our reason for being. To others, the existence of applied research problems in agriculture and in rural areas, together with the

[4] The overview statement for the Iowa State postconference on "Agriculture and Rural Areas Approaching the Twenty-first Century" begins with: "Whatever else may be said about agricultural economics as a profession and the American Agricultural Economics Association as a professional society, it certainly must be granted that they are willing to engage in self-examination to better evaluate their future and to explain their needs to others. This . . . is far from an isolated example" (Castle and Hildreth). The report of the self-examination then goes on to fill about 550 book pages!

primary empirical underpinnings of agricultural economics and nonbinding disciplinary strictures, continues to open opportunities for meaningful professional contributions.

The elements providing unity for agricultural economics are (*a*) a concern with the empirical and (*b*) an appreciation of economic theory (Castle). We are no longer just farm economists, viewing microeconomic analysis and advice for the farm firm as the sole domain for our professional contributions. We have increasingly moved from single advocacy of farm issues to include consumer, taxpayer and public views, incorporating an expanded vision of opportunity for problems and issues "beyond the farmgate," analyzed at appropriate levels—local, state, national, international.[5]

Changes in agricultural economics are a reflection of the integration of the agricultural sector with national and international economies, but consequences of responding to a wider range of opportunities may present difficult dilemmas for individuals and institutions. To some, the broadened perspective involves a loss of identity, a subdiscipline or field losing its way. The alternative is to view agricultural economics as an applied profession responding to cumulative agricultural and rural changes and increased diversity, mirroring our professional capabilities with the emerging problems and issues as we best can identify them within the disciplinary, subject-matter, problem-solving paradigm.

There is creative tension. Diversity in individual and institutional views regarding the proper domain of agricultural economics will persist because of variations in problems definition, commitment, and expectations as they pertain to goals and mission objectives. Management and accountability for this expanded opportunity set present new challenges, but so will the potentials for significant improvements in our understanding of broader segments for agriculture and rural America.

Implicit is the premise that the subdiscipline or field of agricultural economics is primarily research orientated. Our applied empirical science orientation is reflected not only in the research milieu but also in the nature of our undergraduate and graduate programs, in our extension commitments, and serves as the basis for employment in private industry, in government service, and as consultants. Responses to the question, "What is agricultural economics?" differ in the perspectives of colleagues, departments, and other institutions as they create or use agricultural economics research. The skill and knowledge base has expanded considerably to a much broader set of subject matter interests. Consumer economics, environmental policy analysis, industrial organization, finance, management, labor and human resources economics, international trade, economic development, marine economics, energy economics, economics of poverty, community development, and agribusiness are now among components included in land grand and USDA agricultural economics programs, with increasing contributions from other institutions, as well.

The diversity of emerging issues in agriculture and in rural America, and beyond, challenges the profession. Rather than anticipating significant issues and problems, changes in agricultural economics programs have been gradual and incremental, often lagging their emergence. Meanwhile, departments and colleges have shifted to more balanced research responses to agricultural and rural problems. Comparison of the 1956 and 1987 AAEA handbooks shows significant change not only in the identification of membership specialties, but also substantial change in the distribution of the membership among fields (table 3).

Recognition of emerging issues and concomitant staffing needs has increased hiring opportunities from other disciplines or fields, i.e., economics, business, statistics, operations research, sociology, in efforts to expand teaching and research capabilities. Internally, many graduate programs have increased emphasis on economic theory and quantitative methods, perhaps at the expense of more general applied research methodology, history, and institutions. We still do not do well in exposing graduate students to noneconomic views of phenomena considered by economists or giving them perspectives about fitting economics and economic and social problems into space, time, and philosophical context (Castle). The once-held view that there is too much agriculture and too little economics in agricultural economics is undoubtedly less true today.

Agendas call for increased interdisciplinary or multidisciplinary research to shift the focus from short-run, narrowly drawn issues to longer-run, complex, and more controversial issues (Farrell). Unfortunately, such calls are likely to be thwarted by incentive systems that elevate disciplinary research over subject-matter and problem-solving research. Lack of orientation to ex-

[5] The legitimacy of expanding our scope and clientele is questionable only to the extent that we might deny access of professional inquiry to components of agriculture or those in rural areas, including the nonfarm rural population. The legitimacy issue should be of particular importance to those of us at land grant institutions.

periment station objectives and limited and differing mixes of federal, state, and extramural funding (Johnston 1985) make it difficult to offer marginal incentives for priority research agendas, particularly those requiring multidisciplinary efforts.

Demographic changes within the profession have resulted in appointments of staff with needed technical skills but often without ready facility with the history and institutions pertinent to, what are for them, new research settings. And for some, there is minimal interest in making that investment, given the lack of institutional incentives and rewards for commitment to long-run programmatic research endeavors. For some, the lack of rewards for collaborative or multidisciplinary research also inevitably increases the disciplinary research focus. To some observers, the narrow, modern "search for academic excellence" (Bonnen 1988) is also seen as part of the demise of the tradition of applied research, possibly upsetting the sought-for research balance.

Our empirical science reputation is threatened by the paradox of increased capacity to process numerical information and a decline in availability of data on many aspects of agriculture and rural America (Castle and Hildreth, Bonnen 1988). Further, our innovativeness with respect to the development of quantitative techniques flowing from applied research has diminished (S. R. Johnson). Instead, opportunistic (S. R. Johnson) or fashionable (Debertin and Bradford) research is pursued using readily available data (sometimes with little understanding of data limitations and underlying condition) or quick adoption of "in" methodologies, in a series of unconnected short-run investigations. These pursuits meet merit and promotion criteria but often fail to meet the need for long-run programmatic research advancements of importance to decision or policy makers.

These are among the structural challenges needing our serious attention as we seek to reestablish the relevance of agricultural economics and to regain a healthy balance between theoretical and applied analysis and a willingness to cooperate with experts in neighboring disciplines, meriting the Leontief kudos of 1971.

Structural Change, Diversity, and the AAEA

It then follows that professional associations of agricultural economics are ultimately influenced by changes in agriculture and in the profession

of agricultural economics. With external change comes a continual challenge to be responsive to needs of evolving and increasingly diverse memberships. We seek to provide excellence in the services desired by current members and are concerned that we may leave significant numbers of agricultural economists outside the associations because we do not provide services that support their interests.

For the most part, services provided by the AAEA have evolved in incremental steps, attempting to reflect changing specialization and more diverse subject matter interests of the membership. They have not been of the more abrupt type requiring extensive reorganization of effort. However, the ongoing nature of structural change and diversity requires that we periodically evaluate developments and our current portfolio of services, subject to resource constraints, in order to judge whether we are adequately responsive.

Indeed, the nature of mix of association services have been subject to frequent review.[6] Periodic examination of professional associations of agricultural economics is recurrent in presidential addresses (Hildreth, Harl), in invited papers (Gessaman, Johnston 1988, Just and Rausser) and in numerous committee reports, the most recent of which is before us from the Adaptive Planning Committee. Officers and business office staff wrestle with activity and meeting elements throughout the year. The organizational structure of the association, depending on elected and appointed "volunteers" and on business office management and support services, is best suited to gradual change of the sort that has modified association activities over the past decade. In addition, goals and activities must be transparent to maintain widespread membership involvement and support.

The association is significantly different than just a decade ago. The size of our membership and the widespread desire to participate in the summer meetings have led to greater reliance on private conference facilities, transferring the logistical burden from academic departments to professional convention and business office staff. The expansion of business office capabilities is an innovation that has greatly increased our ability to offer services and monitor association activity. That capability underlies the recent confidence with which the board has approached opportunities for program expansion.

Recommendations of standing committees and board actions have transformed our annual meetings into an innovative product mix of pre- and post-conferences and workshops based on subject matter, interest group and functional activity concerns, invited addresses, invited paper sessions (some jointly sponsored), organized symposia, poster sessions, joint social and professional luncheons and dinners, and expanded selected papers and students section activities. The cafeteria of choice is awesome.

Many of our standing committees have become increasingly active in program formulation and association matters as they have moved to meet increased subject matter and functional needs of the membership. For example, the extension committee has a pre-conference, an invited paper session, three organized symposia, and luncheon activities on this year's program. Teaching and research methodology workshops are offered from time to time. The Committee on Women in Agricultural Economics has evolved to develop major preconferences on topics of significance beyond CWAE membership, becoming a resource of association-wide benefit. The Committee on Opportunities and Status of Blacks in Agricultural Economics was prominent in the celebration of the 1980 Centenary at Baton Rouge last year. Industry and international committees include sponsorship of major speakers at their banquets, in addition to session and programmatic assistance. These are but selected examples of widespread involvement in association activities. Others exist; others need cultivation.

Educational and informational publications of the association have expanded beyond the *AJAE*, by increasing the scope and frequency of the *AAEA Newsletter* and by developing *CHOICES*, a vehicle that has received wide acclaim from members and lay subscribers. The AAEA Foundation is an emerging institution with considerable promise for supporting initiatives and projects complementary to association activities. The association is represented on national activities relating to social science research, federal statistics, and agribusiness and pre-college economic education, among others. We have jointly collaborated with other associations in meeting and program arrangements. We affirm our support of regional agricultural economics associations by participating in joint membership endeavors. We have continued interest in promoting professional relations with counter-

[6] Hildreth's identification of association services include those of information, education, legitimatizing services, employment services, and social activities.

part national and regional associations, and, where such organizations do not exist, we have lent our support to assisting their development.

In short, the association has been far from static in the development of program and services. And yet, we continue to search for ways in which the services of the association can be further extended toward subject matter interest groups and functional activities, supporting the diversity of interests in agricultural economics. The question persists: How can we best recognize the diversity of membership interests and concerns?

Structural Reorganization

Structural reorganization has been discussed as one way. In this regard, Hildreth's 1977 presidential address, "The American Agricultural Economics Association: Its Prospects," articulates two strategies for the organization of the association: (*a*) to define and meet the needs of society and members within the "central" core of the profession of agricultural economics and, alternatively, (*b*) to recognize the diversity of member interests by conversion to a federated form of organization wherein the association fosters "clubs" or interest groups. Presented in a dichotomous choice framework, the either-or alternative was left for the membership to ponder, as if they were mutually exclusive.

In my view, they are not, and we are the stronger for it. Strength defined by a central core with significant and meaningful complementary activity about that core need not be incompatible. Turf disputes over core may actually have created a vacuum wherein the focus shifted to address concerns about complementary activities that better acknowledge diversity in membership interests.

The nature of past debate about a general core suggests that we may have complicated the search by narrowly focusing on subject matter specializations within agricultural economics. For example, if one were to arbitrarily regard the locus of the "farm management-production-marketing" subject-matter specializations as the historic core of the association, the observation is that the defined core has eroded, decreasing from 51% of the membership to about 27% over the past three decades. One might then either lament that the "core" has become progressively smaller over time or complain that a minority now dominates an association that represents professionals with much more widely diverse interests and concerns. Which of the two positions is taken depends on whether viewed from within or from outside the arbitrary core. Small wonder that agreement about the general core is so elusive and so divisive!

Agricultural economists in public and private employment functionally contribute to teaching, research, extension, and decision-making activities. Many are involved in combinations of the above. I suggest that, instead of defining the central core by subject matter, we might be better served by defining it as that element implicit in the definition of our subdiscipline: the "disciplinary, subject-matter, problem-solving" research underpinnings of agricultural economics.

The Research Core

Research of one sort or another contributes to all functional activities of agricultural economists. Be clear that focusing on research activity as the general core is not equivalent to espousing "research elitism." Such is not the intention nor necessarily the result. On the contrary, it places a special burden on researchers to provide not only disciplinary excellence but also relevance for applied applications useful to other professional activities—teaching, extension, and decision-making in public and private settings. By first identifying the general core, we can then proceed to work towards complementary subject matter, professional interest, and functional activities that reflect the real diversity of the membership within the profession of agricultural economics.

Research supports important elements of our teaching of undergraduates and in the education of M.S. and Ph.D. students. The empirical orientation of our subdiscipline accounts for greater emphasis on quantitative analysis and higher degrees of application than is characteristic of most disciplinary programs in economics. We relate to real-world conditions and seek to make clear the connections between theory and applications. Full-time teachers of agricultural economics are influenced by their previous training, exposing them and their students to the empirical science of agricultural economics. Even though they may not be actively involved in research, they are nevertheless rooted there.

Applied research results and the ability to structure relevant educational programs characterize the extension activity of agricultural economists. Several land grant institutions have recently sought to better integrate extension with academic programs, thereby elevating the status

and generally expanding the applied research capacities of departments. Extension programs depend on a flow, not a stock, of applied problem-solving results in order to maintain relevance to rapidly changing and increasigly diverse clienteles. Relevant applied research, whether conducted by extension economists, by departmental colleagues, or by others elsewhere in the profession, is critical to successful delivery of a timely, relevant educational program for traditional and new clientele.

Research is also of importance to decision-making activities in public agencies, in private industry, and for consultants. Decision-making activity reflects understanding gained through study and observation, either directly, making use of research results for problem solving or policy decisions, or indirectly, using skills developed from formal and informal educational programs. While their activity may not necessarily yield new research results, it does provide feedback about research needs when effective conduits are established between decision makers and researchers. The association can enhance the relevancy of both decision-making and research endeavors if it recognizes the complementarity between research capability and decision makers' needs.

Thus, the field of agricultural economics is intrinsically associated with research emanating from an empirical subject-matter-oriented science, heavily reliant on data. Unlike attempts to define the central core by a limited set of endeavors, defining it instead as disciplinary, subject-matter, problem-solving research should not lead to a reduction in membership. However, the challenge is that membership numbers may well decrease if the narrow, modern disciplinary search for academic excellence is not balanced by applied research agendas, capable of transmitting applied research results to policy and decision makers, if individuals in the association do not recognize the importance of applied research activity. It is vital to our existence as agricultural economists that we do so. Whereas previous attempts to "circle the fences" around farm firm or rural economy subject-matter definitions would have perforce excluded significant proportions of our current membership and continued diversification of membership interests, recognition of a research core for the association permits inclusion of all subject matter specializations as well as the important functions of teaching, research, extension, and decision making performed by agricultural economists.

Advancing the Association

We, thus, end with a matrix containing subject matter specializations, professional interests, and functional activities. All are related to research. We need not make the exclusive choice of core versus federation modes. Both structures are well imbedded in the association. Drawing on that strength will help us to further define and refine the nature and mix of services that will openly attract agricultural economists. Our inability to communicate our open commitment to foster the development of subject matter and functional interest groups within the existing structure chiefly impedes the continued evolution of the association in meeting the various change and diversity challenged.

Toward that goal, we need to continually evaluate the structure of annual meetings and other services, reaching for excellence with the involvement of a full spectrum of membership. Three areas of attention may assist our goal. First, we need to continue activity supporting the empirical nature of our subdiscipline. While research decisions are made at the individual and institutional level and are subject to local interests and incentives, the AAEA can continue its commitment to maintain and strengthen economic statistics supporting research pertinent to agriculture and rural areas.

Second, annual meetings have been identified as important sources for conceptual thinking (Just and Rausser). We strive to enhance the flow of information at the annual meetings and have made gradual changes in program content in recent years. We will consider further modifications to increase informational flows. Suggestions include predistribution of selected paper and organized symposia abstracts and a review of invited paper policy to better integrate functional activities and increase the exchange of ideas and perspectives by all interests and ages. Reexamination of the policy for publication of research-based invited papers may be considered. We will continue to support pre- and postconferences and will seek ways to encourage and facilitate subject matter and professional group activity in workshops and organized symposia.

Last, the association publishes four informational and educational publications—the *AAEA Newsletter*, the *AJAE*, *CHOICES*, and, less frequently, the *Handbook-Directory*. The effort to recognize our increased diversity may lead us to reconsider possibilities for expanding the flow and legitimizing the status of informational and educational articles and materials not easily dis-

tributed under the current mix and publication policies. Just and Rausser suggested that the board plays a strong role in influencing the product mix of the profession. They encouraged it to consider sponsoring publication of forward-looking problem definition and heuristic applications of economic principles as enhancements of the current product mix. Extension methodology and pedagogic materials, teaching and extension case studies, solicited essays and literature reviews, and computer-based teaching materials are among other elements for which professional interest exists, without identifiable publication possibility within the association. Enhanced possibilities for the distribution of relevant materials for subject matter and functional activity professionals within the association publication mix may confer benefits analogous to the AJAE's role for research professionals.

Concluding Comments

The theme of this address has been that significant changes in agriculture and in rural areas continue and subsequently affect the decisions of agricultural economics professionals in their research, teaching, extension, and decision-making activities. Not only has change been profound, but diversity of interests has mushroomed everywhere.

Possibilities for more abrupt and disruptive change appear likely in the impact of biotechnological innovations, in environment pressures for reduction or elimination of chemical use in agriculture, in the clamor for redefining property rights in land and water, in contentious issues among rural Americans, including those erupting in the rural-urban fringe, and in the possible consequences of fiscal pressures and mounting budget deficits, to name a few. Agricultural economists clearly have a role in increasing understanding of and resolving these issues.

There is need to rekindle interest in applied empirical analyses of responses to induced change, whether economic or political, internal or external in origin. At the margin, the profession has advanced appreciably in sector and economy analysis. One senses that our ability to evaluate the distributional impacts of change now needs some shoring up with the increased recognition of diversity about us. Bishop, in 1967, suggested that agricultural economists had then become so imbued with micro problems that they were overlooking the transformation of rural America. Now, just two decades later, the challenge might be to address some attention to the behavioral responses of heterogenous elements responding to forces of change, particularly those of the more abrupt type for which we may have relatively little understanding. That research, hopefully, will provide a needed balance of commodity, people, and resources and environment dimensions, reflecting the wide spectrum of interests and concerns in rural America.

Agricultural economics has changed in its mix of disciplinary and subject matter. Significant challenges remain to be resolved by individuals and institutions about appropriate levels of research along the paradigm mix, adjustments in educational programs, designs of incentives and reward systems to encourage applied research and multidisciplinary activities, and assurance of quality data for sought-after applied research excellence.

The American Agricultural Economics Association has a central role in facilitating and promoting continued advancement in agricultural economics knowledge for its members and for society. It, too, is not immune from the forces of change emanating from the profession, which in turn has been influenced by rampant change in rural America.

The decade of the 1980s has been one of significant development in association services. The 1990s are full of challenge. Michel Petit concluded that the diversity among the international association's membership was probably one of its greatest strengths. The same is undoubtedly true for this association. With the ongoing nature of structural change and diversity everywhere, we must—and we will—continually evaluate developments and the association's portfolio of services, subject to resource constraints, in order to judge whether we are adequately responsive to the subject matter and the functional activities of our membership.

The spirit of *Perestroika* and of *Glastnost* are everywhere. We, too, will meet the dual challenges of "restructuring" and "openness" with the fullest expectations about the rewards that it will bring to us, its members, and to those we serve.

Agon and Ag Ec: Styles of Persuasion in Agricultural Economics

Donald N. McCloskey

It is a tradition that these addresses be given by an outsider. I speak as an outsider in praise of agricultural economics.

An outsider presuming to praise could be accused of condescension, but I assure you I come by a favorable opinion of the field honestly. I am practically an insider. Maternal relations own farms in Illinois, near Watseka. The same Roger Gray, of the Food Research Institute, whom President-Elect Johnston mentions in his paper, is my second cousin once removed. In England I have worked as an agricultural laborer. Once, in Vermont, I milked a cow. Ag econ is in my blood.

It is certainly in my brain: an economic historian had better think agriculturally, since the past was 80% agricultural. In a graduate course last spring, we spent a good deal of time discussing medieval sheep as manure spreaders, and I am finishing a book for Princeton on scattered parcels as portfolio balance in the fourteenth century. My education as an economist was much influenced by agricultural economists such as Theodore Schultz and by people working on the agricultural aspects of historical economics such as Robert Fogel. To cap it off, since 1980 I have lived in Iowa. That surely qualifies me as an expert on agriculture and its science, at any rate in the eyes of the *New York Times*.

My points of praise are four, with a moral to follow:

First, agricultural economics invented econometrics. You can look on this as a good thing or a bad thing; I consider it very good. The career of Holbrook Working alone would justify the claim, but one could mention, among others, the bevy of econometricians at Iowa State in the early 1940s, when that department was second only to Cambridge, England, among the world's collections of economics. Frederick Waugh served as president of this association in 1946 and was in the first graduating class of fellows; Mordecai Ezekiel was in the second graduating class. Marc Nerlove and Zvi Griliches cut their teeth on agricultural economics.

Second and more generally, agricultural economics takes economics seriously. When one thinks of the quintessential "applied economics," one thinks of calculations of the value of tobacco allotments or of the elasticity of demand for oleomargarine. One might claim that the perfect markets in most agricultural commodities were invitations to "believe in the market," and therefore to believe in the applicability of economics. But not everybody in agricultural economics believes in the market—Lauren Soth of the *Des Moines Register,* for example, another of your fellows and another student of T. W. Schultz, does not especially. Regardless of their ideology, agricultural economists, long before other economists, were serious enough about whatever argument was being used to put it up against the facts of the world. Economists are philosophers and engineers—certainly not the social physicists they imagine themselves to be. Agricultural economics was the first field of economics to take the engineering model seriously.

Third, agricultural economics, more than many other parts of economics, is serious about institutional details. The students of international trade, for example, hardly ever pause on their way to the blackboard to examine an institution. If economists are philosophers and engineers, they are also social historians. Most of what economists do is tell stories about the recent past, explaining why the Corn Belt went bankrupt in the early 1980s or why agricultural policy favors bigger farmers (McCloskey 1990). To do so sensibly, they need to know what they are talking about.

Fourth, agricultural economics is therefore

Invited address.

Donald N. McCloskey is University Professor, John F. Murray Professor of Economics, and a professor of history, University of Iowa.

more open to other fields than many other parts of economics. The department at Iowa State was once the Department of Economics and Sociology, harboring rural sociologists and home economists. As Vernon Ruttan argued a long time ago, the permeability of agricultural economics has been its advantage.

The moral I want to draw arrives at my strange title, "*Agon* and Ag Econ." *Agon*, as in "ant-*agon*-istic," is the Greek for "contest," as in the Olympic games. The Greeks, like American men, thought of their life in sporting terms, and so the word also meant any assembly where people meet to argue, as in a court of law or in a seminar at the academy. What is striking about the conversation of agricultural economics, viewed from the outside, and what may help to explain its success, is that it is polite—more polite than the conversation in macroeconomics, say, or even in economic history. There is amazingly little *agon* in ag econ.

You will know better than I what the reasons for this are. But, as an outsider to the field, I have a thought. I think the American and even midwestern origins of agricultural economics have something to do with it. Americans are less comfortable with *agon* than are Europeans. On this side of the Atlantic, we like to think of ourselves as getting together to raise barns and hold church picnics, achieving a common purpose by cooperating. The Civil War plays a surprisingly small part in the mythological life of Americans; and Canadians, who for this purpose share attitudes with Americans, never had a civil war. Europeans find such attitudes bizarre. Small wonder. Their civil war, which began in August of 1914, is only just coming to an end in 1990. Within Europe, other wars rage. The French since July of 1789 have not stopped fighting their revolution with each other. The recent bicentennial was an occasion for a flood of conservative reinterpretations. No wonder the Europeans, and most particularly the French, carry an antagonistic style of argument into the academy.

I would like to persuade you that this American and Canadian attitude is a good one, nothing to be ashamed of. In particular, the rhetoric of agricultural economics does not square with a European attitude toward argument. The European attitude shows up in economics in existence theorems and crucial tests of hypotheses—timeless, universal proofs using unreasonably narrow arguments. The form of argument came to prominence in the seventeenth century. Men had been killing each other in large numbers over such doctrines as transubstantiation, and it seemed therefore a good idea to discover grounds for certitude, even if narrow, that could prevent further bloodshed. Good for them. But the narrow arguments by themselves would not suffice to get you across a busy street in town. Properly, they would not change minds in the Ten-O'Clock-Club at the donut shop on Main Street. I would like to persuade you that the narrow and European styles of argument in economics should not persuade a reasonable person.

Actually, the most advanced thinkers in cognitive and computer science have grasped the point that common sense is required for thought. The computer scientist Doug Lenat, supported in Austin, Texas, by a consortium of big companies, has been trying for six years to teach a computer named Cyc the common sense necessary to handle the simplest real-world problems without human spoon feeding (Freedman). He reckons that Cyc will need 100 million pieces of information, 2 million of which have been fed in so far, with great labor. If the computer could read natural English, the learning would go much faster. But reading requires common sense, too, and in human terms Cyc is now only about four years old, too young for school.

The opposite view—that following some 3-by-5 card formula of "scientific method" is how to be a good scientist, or even a five-year old with the common sense necessary for reading, is prevalent among the normal scientists of most fields and even, I suppose, in agricultural economics. But the leading scientists do not buy into the childish hope for simplicity in life. The chemist and philosopher Michael Polanyi once characterized the 3-by-5 card notion as "voluntary imbecility." The psychologist Jerome Bruner, speaking of psychology in the late 1930s, wrote recently that, "For reasons that now seem bizarre, you *had* to convert contested issues into rat terms in order to enter the 'in' debates" (p. 29). The voluntary imbecility, this cutting off the richness of economic argument available to us if we do more than work our own little technique over and over again for the "in" debates, is slightly nutty. As we say in Iowa, it is a few bricks short of a load. The joke among psychologists these days about the narrowness of old-fashioned method is this: Two strictly behaviorist psychologists make love. One says to the other, "*You* enjoyed that. Did I?"

Neither I nor the cognitive scientists are saying that there is nothing at all in what I have called "European" styles of argument, or that to be properly North American we must become

illogical. I myself am a quantitative economic historian, and I thrill to the blackboard arguments as much as the next guy (I say "guy" advisedly, because our female colleagues in economics do not seem to get quite as much of a kick out of them). The European—one might say especially French—error is to reduce all argument to one especially simple kind, the formal proof. It is Descartes's program of the past four centuries. In its own terms it has failed. No science has in fact gotten along with the blackboard proofs that the Cartesian method holds up as the ideal.

Blackboard economics has had a long run. Like modernism in architecture, it is coming to a dead end. But economics will prosper. We in economics are going to broaden our arguments, without throwing away any of the gains from European precision.

Our official rhetoric, however, expressed in journal articles, is still pretty much stuck in a philosophy of science current in Europe around 1930.

In the August 1989 issue of the *American Journal of Agricultural Economics* there are twenty-four articles. Of these, fifteen have the standard outline of formal model followed by a serious empirical implementation, almost invariably regression analysis. Four of the twenty-four have no formal model yet engage in serious empirical inquiry (all four of these also use regression analysis). One other is a review article. Only two of the twenty-four have a formal model without any gesture at empirical implementation, and only two more have a formal model with merely illustrative implementation, directed at the new method proposed rather than a problem in the world.

The ratio of articles with serious empirical work to articles with a merely theoretical purpose is typical of the applied fields, such as labor economics or economic history. But of course the ratio is well above that in the so-called general-interest journals of economics. Wassily Leontief, a famous friend of agricultural economics, recently calculated that over half the articles in the general journals of economics and sociology were theoretical. What do you suppose the share of such articles was in comparable journals of physics or chemistry? Ten percent.

Compare the 1989 issue with the *Journal of Farm Economics* (as it was called before 1968) in 1929, sixty years before. What are the rhetorical differences between agricultural economics then and now? The ten articles in the August issue of 1929 hardly overlap at all in type with those of 1989. Only one article is a formal modeling and simulation of behavior, another (by Howard Tolley) is a piece of empirical accounting. There are five articles offering policy assessments and proposals, usually with an accounting framework. There is one outlook piece, one institutional description, and one extended appeal for more fact collecting. Only the four nonmodeling articles out of the twenty-four in 1989 look much like any of the articles sixty years before.

Most of the 1929 articles, however, use quantitative thinking. It is false to say that economics has become more quantitative over the past sixty years. Counting, after all, has been the character of economics since its beginnings in political arithmetic three centuries ago. Indeed, what is apparent in 1929 is something largely hidden in 1989, although it is there to be seen if you look hard enough: namely, that economics depends for much of its arguments on accounting. Accounting is the master metaphor of economics, determining most of its quantitative findings. It is an accounting decision, for example, to value family labor on farms at market prices. The decision alters radically how we view the efficiency of family farming.

The most striking change in method down at the practical level is of course that virtually all the empirical work in 1989 uses regression analysis. This a little peculiar when you think about it. When we as economists make policy arguments, we use accounting, as I just said, together with simulation—all the way from back-of-the-envelope calculations of elasticities to formal simulations on computers. But when we seek the facts of the world, we pretend that only the "experiments" suitable to regression analysis are appropriate. I once had a graduate student who thought that the very word "empirical" meant "regression analysis on someone else's data." Regression analysis seems to have a tighter hold on the empirical imagination in agricultural economics than it has in other applied fields, probably because of the agronomical origins of the statistics. R. A. Fisher, who named most of them, worked at an agricultural experiment station.

There are some problems with this rampant regressionitis. It means that agricultural (and other) economists do not scrutinize the other parts of their quantitative rhetoric, such as the accounting systems that force most of the results or the data collections that allow quantitative thinking in the first place. The very word *data* shows up a problem. The word means in Latin

"things given," which is the attitude of modern economists. Someone else is going to give them the facts. They would do better to think of the facts as *capta,* things to be seized and in the seizing examined closely for flaws.

And there is a quite serious, one might even say devastating, technical problem with the way economists use regression analysis, even the agricultural economists who pioneered its use in social science. Every one the twenty-one articles that use regression analysis in the 1989 issue of the *Journal* grossly misuse it. They take statistical significance to be the same thing as scientific significance. Professional statisticians have understood since, at the latest, 1919 that the two have little to do with each other. That a coefficient is statistically significantly different from zero says merely that a sampling problem has been solved. Some scientific problems are sampling problems, but most are not. Most are problems of how large is large. We decide as economic scientists whether a coefficient is large for our purposes; we cannot hand the task over to a table of Students-*t*. Some day, in other words, all the econometric work in the 1989 issue will have to be done over again because it depends on this confusion. Have you ever wondered why regression analysis in economics never seems to settle an issue as decisively as its rhetoric would lead you to expect? Here is why: statistical significance has almost nothing to do with scientific significance (see Boring; Neyman and Pearson, p. 296; Wald, p. 302; Arrow; Griliches; Freedman, Pisani, and Purves, pp. 501, A-23, and throughout; Kruskal; Leamer; McCloskey 1985; Denton).

The regression analysis, though, as much as agricultural economists love, honor, and obey it, is merely a detail of method. A deeper content analysis of the articles in 1929 and 1989 would show them to be more similar than my listing of nonoverlapping types suggests. Agricultural economics is still concerned at bottom with how farmers behave and whether their behavior is good for them or for anybody else.

Yet, the rhetorical spirit of the articles definitely changed in sixty years. The big change is the rise of Cartesianism. That is to say, the big difference between 1929 and 1989 is, oddly, philosophical. The push for "testable hypotheses" is palpable. Just below the surface in 1989 lies a commitment to a bankrupt model of scientific method. We economists all think that what we do is similar to what physicists do. Actually, we know next to nothing about how physics operates as a field. An article in the magazine *Science* in the fall of 1989 told how the physicists at the new Santa Fe Institute are amazed at what the economists there consider to be science. The economists, who are mainly theorists, think that science involves mathematical proofs of the theories and then the equivalent of econometric tests. In truth, the physicists could care less about mathematical proofs; even the theoreticians in physics spend most of their time reading the physical equivalent of agricultural economists or economic historians. Milton Friedman's famous article of 1953 on positive economics is most of what we economists know about philosophy of science, which we think prevails in physics. The more venturesome have acquired their erroneous 3-by-5 cards from somewhat fancier sources, such as Karl Popper or Thomas Kuhn (hastily read if read at all).

The methodological thinking of economists is a scandal. It is surprising that economists, who say that they admire physicists and philosophers of science so much, do not know what is going on in these fields. The narrow philosophy of science that underlies most of the articles in the *American Journal of Agricultural Economics* and its sister journals in other fields has been exploded for decades. The history and sociology of science have shown again and again that no scientist has followed it—that Pasteur, for example, kept double laboratory books and that Darwin had his theory before he examined the facts. An economics that really imitated physics would look a lot more like agricultural economics than like the latest formalism in the *Journal of Economic Theory*.

How have we gotten so far off base? Why has economics, and even agricultural economics, failed to hear the most elementary message from statistics or physics or the philosophy of science? Well, the same way we got to be so smart at what we do: by specialization.

You will hear from deans—I hear it from some of my own—the argument that what we need is more specialization, "building on strength." We are to be shoemakers sticking to our lasts. We are to build strong walls around disciplines, failing to emulate the breadth of learning in the older generation of agricultural economists or labor economists or economic historians.

Superspecialization in academic life is not natural or productive. It is caused by an administrative decision in favor of the invisible college, the college of one's narrow subspeciality. The faculty of the invisible college have become the only voters on tenure and salary. Outside opinions in letters of recommendation count for

more than the opinion of colleagues down the hall. With a changed audience, naturally, the written products and the policy thinking of the superspecialized fields have changed. The audience for most agricultural economics is not even other agricultural economists, not to speak of policy makers or (perish the thought) actual farmers. It is the handful of other specialists, for the purpose of their specialization and no other.

An anonymous respondent to a survey put his finger on what drives the character of academic journals now even in agricultural economics: the societies and their journals "have become agents to establish professional credentials for tenure, promotion or a job offer" (quoted in Just and Rausser, p. 1189). As Just and Rausser argue, "Many of our recent graduates spend most of their time wondering about the application they can make of standardized solution frameworks rather than finding interesting problems that require the development of customized frameworks" (p. 1179). That is how you get tenure when the visible college gives way to the invisible one.

The superspecialization in economics is not justified by results. If you think it is, tell me, please, what economics has learned since the War from the more spectacular superspecializations. No fair claiming the number of publications as what we have learned, regardless of whether they will matter to anyone in six months. I am looking for ideas that matter. We have learned more in economics from our continuing traditions of political arithmetic and economic philosophy. Human capital, the economics of law and society, historical economics, and the statistics of economic growth have come from economists who trade with the rest of the intellectual world.

The superspecialization in economics and elsewhere has been defended by an erroneous piece of economic argument. Specialization is an economic idea. But it is misused by academic planners (and even by some economists when they become academic planners) to justify high tariffs in academic life. The key economic point is this: specialization in itself is not good. In fact, Adam Smith himself (not to speak of Marx, you see) was eloquent on the damage that specialization does to the human spirit. What is good is specialization and then trade. As Adam Smith remarked famously, "Consumption is the sole end and purpose of all production; and the interest of the producer ought to be attended to, only so far as it may be necessary for promoting that of the consumer" (Smith, vol. 2, p. 179). There is no point in a feed grain farmer piling up corn and soybeans in the back yard unless he is going to sell them some day in order to consume the fruits of other people's specialization.

The trade in intellectual life is precisely the use of other people's work for one's own. It is what goes on in interdisciplinary activity, if the activity is something more than polite acknowledgment of the other's expertise, insulated carefully from disturbing one's own. If we actually read each other's work and let it affect our own, then we are well and truly following the economic model of free trade. If we do what most academics do—never crack a book outside their subdisciplines—then we are following the economic model of Albania, specializing in ox carts and moldy wheat. Modern academic life has whole fields specialized in ox carts and moldly wheat.

Understand, the argument is not against all specialization but against the failure at last to trade. It will be sweet work for one part of agricultural economics to talk long and hard about fitting translog production functions. A great many of the articles in the August 1989 issue, as it happens, centered on the translog. Maybe there is something important for economics in them. Like abstract general equilibrium and most econometric fittings, it is well worth a try. For the moment, for purposes of specialization, the researchers should stick with the figures from the Census of Agriculture and ignore what we know from agronomy or rural sociology or from the living of farm life. My argument does not attack systematic work. No one would wish to stop systematic specialization.

The problem comes when the narrow, temporary agreement hardens into a methodological doctrine for all time. Then the feed grain starts piling up unsold in the back yard and begins to get moldy. If the agricultural economists specializing in translog production functions make the temporary rule permanent, throwing everything that cannot be said in a translog function into a nonscientific outer darkness forever and ever on merely philosophical grounds, they are joining the voluntary imbeciles.

The failure of specializing modernism in psychology, economics, and elsewhere to fulfill its promises does not say it was a bad idea to try. And it certainly does not say that we should now abandon fact and logic, surface, and cube, and surrender to the Celtic curve and the irrational. We are all very glad to keep whatever we have

learned from positive economics or the running of rats or the latest identifying move in the econometrics of agricultural production functions. It says merely that we should now turn back to the work at hand equipped with the full resources of human reasoning.

The anthropologist Roy D'Andrade, writing about psychology, put it well: "One cannot expect to improve upon Freud by observing less about human beings than he did" (p. 39). We cannot expect to improve upon Smith or Keynes, or for that matter T. W. Schultz, by observing less about economies than they did. The point is economic again: we will do better with fewer arguments ruled out, with fewer arbitrary constraints on our intellectual maximization. It entails less sneering in academic life, less ignoring of chemists by physicists or of sociologists by economists or of statisticians by mathematicians or of agricultural economists by economic theorists. Considering that other scholars read different books and lead different lives, it would be economically remarkable, a violation of economic principles, if nothing could be learned from trading with them. The notion that something can be learned from trading with others merely applies consistently the economics of intellectual life. Just as differences in tastes or endowments are grounds for trade, disagreements about the causes of crime or the nature of capitalism or the causes of excess farm populations in rich countries are grounds for serious conversation.

The way to inaugurate the intellectual trade and intellectual modesty that will I hope characterize the world after modernism is to focus on rhetoric. It is an anti-epistemological epistemology that breaks down the walls between disciplines. The common ground is argument. We have discovered at Iowa that what professors have in common is not some subject or social problem but the art of argument. We have a group of over a hundred faculty in fields ranging from hydraulic engineering to late-medieval English poetry that has met a couple of hundred times winter and summer to scrutinize a professional paper by one of the group. Iowa's "Project on Rhetoric of Inquiry" has been expanding exponentially since 1980. Not epistemology or game theory or even econometrics, as much as I love them all, creates real conversations across disciplines. A focus on the rhetoric of science does, a focus on the very words of how we argue. A professor of Spanish cannot give her colleague in mathematics any advice on the substance of his paper. But she can point out to him that the form is part of the substance and can remind him that the appeals to authority so important in mathematics can be found in seventeenth-century Spanish plays. From this would come a revitalized social science, and a rehumanized one—without giving up even one of the quantitative insights from Ames or Cornell or Maryland.

The broadminded conversation in agricultural economics is a good place to begin. Agricultural economics, I say in praise, is more scientific than many parts of economics. It has a tradition of non-*agon*istic conversation that has produced thinking more important for society than the latest ruminations from the blackboard. As Johnston says, you should keep that sturdy three-legged stool for the future, ready for serious scientific milking, and with no quarreling among the legs.

Reflections on Poverty

Clifton R. Wharton, Jr.

Most Asian cultures revere age. In Korea, for example, when you become an elder at the age of 61, there is a special birthday celebration called a "Hwan-Gap." Afterward, the entire community treats the elder as a special person. And if male, the elder gets to wear a wonderful black stovepipe top hat called a "Gac."

By coincidence, I was 61 when you named me an AAEA Fellow two years ago. So today is my first occasion to thank you for my "Hwan-Gap," and my AAEA fellowship—your symbolic conferral of my Korean top hat!

The Asian reverence for age is rooted in the idea that with age comes wisdom. But as I stand before you today, and as I look back on many years of involvement in international agricultural development, I must confess that I do not feel wise. Quite the contrary. When I compare the way I feel today with how I felt forty years ago, when my development career was just beginning, I find myself far less confident, far more troubled. Then, I was sure I had the answers—some anyway, if not all of them. Now, I have mostly questions, and some uncertainty whether even those are the ones we really ought to be asking.

The Persistence of Poverty

From the beginning, the central target of my commitment to international agricultural development has been poverty in the Third World.

In the early days of development assistance, so many of us thought we knew the recipe for sound, self-sustaining economic growth in what we then called the underdeveloped world. From a peck of idealism, a pound of politics, and a pinch of hubris, we stirred into being a whole alphabet soup of technical assistance agencies. The U.S. government, private foundations, voluntary organizations, the United Nations and its associated ventures—all joined in the effort. What a marvelous brew! Or, to mix metaphors, what a splendid quest! King Arthur's knights had nothing on us. Ours too was a Holy Grail: the economic salvation of our less fortunate fellows by banishing the scourge of poverty from the earth once and for all.

I exaggerate a little, but only to make a point. We were all so confident . . . so committed. There was no doubting the justice, even the nobility of our ends. How therefore could we doubt that we would find means to achieve them?

But as I look back, I see at best mixed results to redeem all that confidence.

The aggregates do show progress in income and consumption for the developing nations as a whole (World Bank). Life expectancy is up; child mortality is down.

We also have our success stories. There are several "newly industrialized" nations—Korea, Taiwan, Singapore—with levels of affluence barely imaginable at the end of World War II.

But the more arresting fact is still that of obdurate, endemic poverty. Despite the success stories, there are other horror stories: in the Caribbean, in Latin America, especially in sub-Saharan Africa. The World Development Report 1990 estimates that there are more than one billion people in the developing world in poverty.

Why?

In the United States, real per capita income has reached levels no one would have dared predict forty years ago. Yet even here, poverty seems more, rather than less, entrenched, not only in the rural regions like Appalachia but also in the centers of virtually all our greatest cities. Instead of "exporting" affluence from the West, it is almost as if we have spent the last four decades gradually "importing" poverty from the Third World. And, indeed, when you walk through the South Bronx or North Philadelphia or Watts, California, or downtown Detroit, the sounds and images often seem not those suitable to the most prosperous nation in the world but disturbingly like what you saw forty years ago on the streets of Calcutta, Djakarta, and Port-au-Prince.

Why?

Despite the resources we have poured in over

Fellows address.

Clifton R. Wharton, Jr., is chairman and chief executive officer, Teachers Insurance and Annuity Association–College Retirement Equities Fund (TIAA–CREF).

nearly half a century, poverty remains in many sectors of the Third World. Here in the United States, too, poverty seems to have extended rather than pulled back its reach. You may be tempted to object that this is more a matter of greater visibility, via daily newspapers and broadcast news, rather than greater reality. Yet, data suggests that "since the mid-1960s at least (and ignoring the growth of in-kind transfers), there has been little progress in reducing the incidence of poverty among the [U.S.] population as a whole" (Sawhill). And in the United States, if not abroad, there is even reason to suspect that the individual experience of poverty for the poorest of the poor has gotten worse rather than better—more grinding, pernicious, and inescapable today than a generation ago.

Why?

Why is poverty so persistent? Why, despite all our efforts and resources, are we still struggling with poverty?

The Faces of Poverty

Economic development is a process. Poverty is a condition. Hence, the existence of poverty does not necessarily mean the absence of economic development. Development concentrates on a whole range of economic, social, cultural, and political variables. Deficiencies in some or all of them may account for the presence of poverty. But more and more, it appears that addressing them is no guarantee that poverty is going to go away.

What I find particularly striking is the changing relationship between domestic poverty and world poverty. The war on international poverty dates essentially from President Truman's "Point Four" in his 1949 inaugural address. The war on domestic poverty dates from President Johnson in the mid-1960s.

As I look back over the literature, I am struck by three aspects.

First, because most of the Third World nations were predominantly agricultural, the early attack on their poverty was concentrated in the rural areas. As a proportion of population, poverty usually afflicted the majority in these nations. In the late 1940s and early 1950s, the conventional wisdom was that two-thirds of humankind in these countries lived in poverty. They were rural and depended upon agriculture. In the 1950s, many of these nations began to experience massive rural-to-urban migrations which dramatically escalated their urban poverty, and the massiveness and pervasiveness of poverty persisted.

In the United States, on the other hand, poverty in the 1940s was heavily rural, and somewhat urban, but not nearly as massive a proportion of the total population as in the Third World. Urban poverty tended to concentrate among recent immigrants and distinct ethnic groups. In the rural deep South, poverty was overwhelmingly black; in Appalachia, white. Whether urban or rural, U.S. poverty was mostly that of the "working poor"—though during the great Depression half a generation before, unemloyment and rootlessness had played a much more prominent part.

Second, the disciplines which devoted attention to these issues tended also to be different. Agricultural economists, rural sociologists, and cultural anthropologists predominated in studying and acting upon foreign development. In the United States, the same groups were involved on the rural side of the equation, but general economists and sociologists dominated the dialogue on the macro and urban dimensions of poverty.

A third change has been in the differing perceptions of the nature of poverty between the United States and the Third World. Just as the faces of poverty differed in the late 1940s between the United States and the Third world, so did prescriptions for change. In the United States, with all its abundance, poverty appeared as an institutional rather than a resource issue, thus susceptible to amelioration through political change. There was an implicit assumption, sometimes quite contrary to the explicit rhetoric, that U.S. poverty was an aberrant thing, a weak countercurrent to the general prosperity.

Slowly, however, it began to dawn on the experts that poverty was not simply an anomaly. The wide range of programs that made up President Lyndon Johnson's "Great Society," principally the Office of Economic Opportunity, was the first explicit public acknowledgement that poverty in America was serious and deep-seated. Still, the problem was seen as basically correctable with the proper mix of programs and dollars.

In most of the Third World, by contrast, poverty seemed from the outside as much more fundamental, a by-product of population growth in collision with scarce resources, pre-industrial technologies, and institutions and value systems incompatible with the requirements of scientific

and material progress. We who were entering development following the end of World War II saw eliminating poverty in the less-developed countries (LDCs) essentially as one of the challenges of "modernizing" traditional societies. As in the United States, that meant political and institutional change, but it was not the kind of reformist, incremental change familiar in the United States. There were frequent discussions as to the feasibility of jumping over entire stages of national development: from feudalism directly to capitalism, from peasant agriculture to centrally planned industrialism.

Over the years, development efforts in the Third World concentrated on a whole range of economic, social, cultural, and political variables. The belief was that deficiency in some or all of them accounted for the presence of poverty.

There have been endless differences of approach.

Initially, basic western science and adapted technology transfer would be the key to everything. Next, we had the debate between free markets and socialism and state enterprise as the true path to economic nirvana. Then we talked a great deal about agricultural and industrial infrastructure, roads, rural and urban health care delivery systems, mass literacy, and educational elites. But what we often seemed to have in mind was a naive wholesale reinvention of entire societies, in the image of our own.

Next, there were approaches focusing on stimulating self-sustained economic growth as the key to eliminating poverty. Others pursued "microdevelopment," a single project, program, or bundle of efforts that would trigger systematic change. Extension, cooperatives, village-based development, supervised credit, all these and more had their advocates. Some looked for a magic potion, an innovation or technology—remember the early days of the "Green Revolution"? (Wharton 1969a). Some searched for a model to provide broad-based reform. Still others looked for the variables responsible for general economic growth, hoping for the "rising tide" that lifts all boats.

The evidence is clear that general economic growth has helped to reduce the incidence of poverty. This is particularly true if there are policies and programs which concentrate on making maximally productive the labor resource of the poor and if the poor are also provided with social services such as education, health care, and improved nutrition. Where this course has been followed, there has been success. This is especially true if coupled with a solid policy pro agriculture and pro role of the rural labor force.

But despite all the advances based on these approaches, the sad fact is that development has, more often than not, fallen well short of its goal of eliminating poverty in the Third World. My professional colleague, Woods Thomas, Dean of International Programs at Purdue University, has offered some thoughtful observations on what has been behind the shortcomings of development assistance projects in meeting the poverty challenge. Overall, he suggests:

- We haven't been able to provide the magnitude of resources needed, on a sustained basis, to make a difference.
- We have seriously underestimated the time required for development to work and to have a substantial impact on poverty.
- We have underestimated the difficulty external donors have had in "staying the course," and at times we overestimated their commitment to doing so.
- Changing sets of "interventions" have disrupted the development process, too often following short-lived "fads"—from technology transfer, to institutional transfer, to capital transfer, to international welfare, to environmental issues.
- Multiple development objectives—from international humanitarianism to economic self-interest to national security—have collided, often muddling the aim and undercutting the effectiveness of programs. —Wharton 1983

So the fact is that development has not always lived up to its hopes. And even when we see significant overall economic development in a nation or region, we also see that it often leaves stubborn pockets of poverty untouched. As a result, both advanced industrial nations and our "newly industrialized" successes still suffer the blight of enduring poverty—severe want in the midst of plenty, the dry rot of deprivation weakening the joists, joints, and rafters of abundance.

To account for this, some resort to biblical fatalism: "Ye have the poor always with you." True enough, if by "the poor" you mean those in the bottom 25% or 30% of a normal frequency distribution of income. Some will always have less than others. But this is an entirely inadequate, as well as heartless, way of looking at the problem.

We economists love to argue the merits of absolute versus relative measures of poverty and the degrees of inequality in the distribution of income. We can debate with considerable eru-

dition the view that a relative measure based upon a percentage of median income is preferable to a poverty threshold of basic needs adjusted for inflation. I will fully admit that the conceptual definition of poverty is important to understanding its scope and certain analyses of its dimensions. However, after all is said and done, I am still left with my question.

Why do we still have poverty?

If we shift once again to the United States and domestic poverty, the question is equally valid. Regardless of the definition used, absolute or relative, poverty declined for about twenty years and came to a halt after 1970, with estimates ranging from 6% to 18%. Why, in a nation and indeed a world of vast wealth and resources, poverty need exist at all? To be sure, some will perhaps always have more, while some have less. But what makes it inevitable that some must have virtually nothing at all?

The idea of a poverty threshold, a minimum below which no person can or at least should have to live, has wide political acceptance (or at least acquiescence) and currently underlies much of the U.S. welfare philosophy. Nevertheless, U.S. poverty seems to be getting worse both objectively, in the number of people "below the line," and subjectively, as a result of the growing exposure of the poor to the pathologies of ever more virulent crime, substance abuse, mental illness, and other forms of marginality.

And once again, the question is: Why?

Third World Poverty: A Taxonomic Overview

The recent history of international development—the years from 1960, say, to the present—has been in part the history of our growing understanding of its limits, complexities, and obstacles.

At the same time, we have learned to look at Third World poverty not simply as innate to "traditional," "pre-industrial" economies but as the result of conditions and forces that vary tremendously from setting to setting. Indeed, theoretical work now combines with a rich archive of field studies to offer a taxonomy or framework of such forces. And it may be helpful to mention here several of the ones that I believe have the most to tell us, not only about why poverty exists in particular areas, but also about why it has been so frustratingly difficult to eradicate.

Climate, Topography, and Natural Resources

An area's climate, topography, and natural resources form the substructure, if you will, for its economics. Absent offsetting forces, moist and temperate grasslands will probably see greater development than arid deserts or frozen tundras. Plentiful waterways irrigate potential cropland and provide natural trade routes; impassable mountain ranges impede movement and commerce, though they may also offer valuable security against hostile incursions from outside.

This is by no means to say that geography and natural resources are always overwhelming influences. But in many ways they are the bedrock upon which agriculture and the intervening factors rest. Other things being equal, the natural a priori can be the key to whether a society will thrive or struggle.

How much of the residual persistent poverty that we see in the Third World is the result of these factors?

History, Mores, and Socioeconomy

Following the natural environment, the next basic set of factors are those of an area's history, mores, and structural socioeconomy. The realities of the past often decide the possibilities of the present—a truth which in our earliest debates we sometimes considered the unbreakable "cake of custom." Later we came to modify that, concentrating on those leverage points that might hasten the transformation of tradition-based societies into modern ones (Wharton 1969b).

Likewise, the large structural features of an area's socioeconomy are always important. Population size, age distribution, geographic concentrations, and many related demographic factors correlate either positively or negatively with poverty. Most significant in the Third World has been the impact of the food/population equation coupled with the human/natural resource ratios. And of course it is foolhardy to look at any of these in isolation from mores: the pervasive strictures of behavior that may, over time, institutionalize poverty within the tangled webs of class and custom.

Values and Attitudes

In the early literature of economic development, there was a kind of caricature: the culture-bound, tradition-ridden, religiously channeled peasant

or villager, whose unwillingness to adopt or even tolerate modern ideas is the rock upon which otherwise viable efforts inevitably breaks up. Or, to put it more positively: the traditional figure whose rigid values and attitudes must be comprehended and somehow accommodated if development projects are to have a realistic chance of success. This inaccurate image gradually changed in recognition of the true underlying factors producing resistance.

Nevertheless, we did conclude that there are individual values and attitudes that are especially relevant for the elimination of poverty which are considered to be favorable toward self-improvement and pro development. These range from high achievement orientation and strong self image to high propensity to save/invest and the work ethic.

Some questions:

What are the aspirations of the permanent underclass, and how do they differ from the working poor? The rest of society? Which components in their "aspirational bundle" are subject to manipulation to stimulate a positive change and movement out of poverty? Which ones are significant from a policy and operational standpoint?

To what extent have programs of aid to raise levels of living above the poverty line created a new subculture of dependency where aspirations for further progress have been eliminated?

Political Will and Commitment

The role of the political process and political leadership in the attack on poverty is of central importance. This is true regardless of the form of political structure—democratic, oligarchic, dictatorship, etc.

Several years ago (1976) I pointed out that there are two political requirements for achieving significant sustained agricultural development: first, that the political leadership have a genuine commitment to the goal of agricultural development; and second, that they have an understanding of the process.

As is true in most politics, there are significant trade-offs between conflicting political goals in any attack on poverty. These are both internal within a nation and international among nations. For example, how the political leadership resolves the choices between greater governmental investments in the education of the rural poor versus improved urban transportation, or the choice between subsidized prices for domestic food grains versus imported food can have a dramatic impact on the success or failure of any attack on poverty.

Above all, there must be a political will and commitment to eliminate poverty if there is to be any likelihood of success. Those nations which have been the most successful in reducing the scourge of poverty have inevitably been those which have displayed a commitment to its elimination and the will to carry it out.

Given our understanding of development, despite its imperfections, how much of hard core or residual poverty is the result of a lack of political will for its elimination?

Knowledge, Education, and Human Capital

Finally—and, in my view, perhaps most important—there are the knowledge, education, and human capital available to a society. The centrality of human capital to economic development is documented in the literature of economic development, most brilliantly in the seminal work of Nobel Prize winner Theodore Schultz. In the present context, I would only note that the insufficiency of human capital—the lack of what I might call a "critical mass" of knowledge, skills, and collective educational attainment—seems almost universally implicated in truly persistent poverty. Indeed, when it is a case of the kind of intractable poverty that over time stymies both spontaneous growth and organized development efforts from within or without, human capital problems will almost always be found to be critical.

In my experience, to put it bluntly, it seems almost impossible for societies to be both smart and poor for very long. So even in a taxonomy that stresses variability, overdetermination, and multiple causation, I would stress the particular sensitivity of human capital as a kind of privileged factor among the many others.

The Convergence of U.S. Domestic and World Poverty

Admittedly, creating a taxonomy does not necessarily take us very far. Indeed, taxonomies and surveys often seem to raise more questions than they answer. For example, in a comprehensive survey of the empirical literature, Sawhill tested the efficacy of five key variables for explaining the persistence of poverty in the United States

from the 1960s through the mid-1980s. And her findings are instructive:

One, she found that demographic change is a good explanatory variable in the growth or reduction of poverty, but "virtually all of the effect is due to the growth of households headed by women with children"—an important segment of the domestic poor, but by no means the only one.

Second, the performance of the economy also is an explanatory variable in poverty reduction, especially among the non-aged. Even so, Sawhill found that "other variables have been operating to offset the effects of growth."

Human capital investment, though slightly positive, seems to have mixed results, to the point where "both the skeptic and the true believer can find support for their positions."

Behavioral and value change resulting from income transfers becomes an imponderable. It can be shown that income transfers themselves, more or less by definition, can reduce poverty. But does that create a "feedback" mechanism, creating more poverty by inculcating a psychic and behavioral "culture of dependency"? The explanation founders on the difficulty of establishing a causal connection between the income transfers themselves and the attitudes and behaviors supposedly fostered.

The growth of an "underclass" is definitely taking place, even though it is still a smaller fraction of the total poor population. More basically, to explain the persistence of poverty by pointing to the underclass is to try to make the question its own answer. It is profoundly unsatisfying to argue that the reason poverty persists is that we have a group of people who are acutely poor.

At the end, therefore, of Sawhill's exhaustive and thoughtful analysis, where do we come out? "Until more complete theories and models . . . are developed and tested, the answers to some of the questions raised in this article must remain partial and tentative."

So, here in the United States as in so many nations of the Third World, we find ourselves still without any really satisfactory understanding of why poverty persists.

Most striking is the growing convergence between U.S. domestic poverty and world poverty such that we appear to be moving to a situation where there are certain nations, areas, and groups which can be characterized as hard core, persistent poverty. Moreover, the most salient characteristic of domestic and world poverty is that it does persist; that it seems so endlessly resilient, so capable of thwarting our most ingenious efforts to eradicate it. And both here and in the Third World, we see more and more a kind of "poverty within poverty"—whether the "poorest of the poor" or the "urban underclass"—that forms a hard, self-sustaining core not only of indigence, but also of crime, substance abuse, illegitimacy, illiteracy, and other pathologies.

Persistence and hard-core pathologies appear basic, thus, to both domestic and Third world poverty. And this raises questions about possible other similarities and etiologies: What links are there between the "culture of despair" in Harlem, New York, and in a hillside favela in Rio de Janeiro? Are the self-reinforcing negative factors of poverty living levels—disease, ill-health, dependency, illiteracy, crime, unemployment, alcoholism, drugs—the same? Why is it that poverty afflicts disproportionately women, ethnic groups, minorities, and indigenous people, a pattern that is world-wide and growing? (In this regard, I commend to you the invited paper for this conference by Ralph Christy and Enrique Figeroa.) Is there something fundamentally different in hard core poverty from other forms of poverty?

A Two-tier Nation in a Two-tier World?

When I entered international agricultural development some four decades ago, the popular view was that ours was becoming a "two-tier" world, with potentially explosive consequences. The first tier was the 5% of the world's population, contained almost exclusively in the industrial West, that controlled 80% to 90% of the world's wealth. The second tier was "everybody else"—poor, hungry, nonindustrial, often postcolonial countries in Africa, Asia, and Latin America.

Forty years later, we still have a world of at least two tiers.

Yes, there has been development in the Third World. The recent World Bank report, *Poverty,* cites dramatic examples of nations where both economic and social indicators establish that growth and improvement in well-being have occurred. But the bank also reports that over one billion people have less than $370 per year and are still living in poverty, with the heaviest concentration in South Asia, East Asia, and sub-Saharan Africa. And while they project a decline in the poor in most regions by the year

2000, they also predict an alarming increase in poverty in sub-Saharan Africa to about a quarter billion!

Given the commitment, hard work, and resources that have gone toward development throughout the period, I come back to my original question.

Why?

Here in the United States, we seem on the verge of becoming a "two-tier" nation. Here too, the gap between the top and the bottom appears to be growing: "[Income] inequality has been growing within almost all demographic groups and occupational and industrial sectors, and it has been growing during recoveries as well as during recessions" (Sawhill). Even today, most poverty in the United States, including black poverty, is not the poverty of urban slums. Yet, winding down from a domestic economic boom that has been the most sustained since the end of World War II, we seem at a loss even to slow, much less reverse, the growth within our cities of permanent enclaves of hard-core poverty. And that poverty is rapidly becoming as intractable and debilitating as I have seen anywhere in the world.

Why?

I do not have the answer.

I am not even sure any more that we have the right questions.

And that is deeply discouraging, in and of itself. On the international side, after forty years of organized technical assistance and development aid, should we not have at least a better understanding of what the key causes of poverty are and, more important, their cures?

We know a great deal more about achieving development than we do about eliminating poverty.

After pouring millions of hours and billions of dollars into projects in scores if not hundreds of impoverished communities, would you not expect that we would have reached some broad consensus on how to break the cycle of poverty? Should we have developed a general theory or model? Or is it that hard core poverty is too difficult to attract the creative energies of our best minds?

And when it comes to domestic poverty, can we really not ask many of the same questions? After a decade of the Great Society, followed hard on by another decade of the Reagan Revolution, you certainly cannot say that we have not tried a broad spectrum of approaches. We have bounced from scattershot activism, to benign neglect, to the trickle-down theories President Bush once, in another life, called "voodoo economics." Should we not at least have a better sense of what is likely to work and where and under what conditions?

Why do we not?

Again: I do not know.

I do know that we have reached a stage where there is a far greater degree of universality to the faces of poverty both in the advanced nations and the Third World. We in the United States can no longer adhere to our peculiar idea that poverty here—the United States—is different from poverty there—elsewhere in the world.

In the early days of international development, as I have said, we Westerners thought we knew the solutions to their, the Third World's, problems. Over the last forty years, we have learned to our chagrin that we did not have all the solutions, after all. And in the last ten or fifteen years, we have found our problems looking increasingly like "their" problems, to the point where it has become a cliché to compare the urban terrain of the United States to the impoverished nations of the Third World.

Beyond the cliché there is an underlying reality, the reality of interdependence and globalization in our problems and their resolution. Nowhere is this more critical than the problem of the persistence of poverty. The universality of the challenge of persistent poverty may be the true test of our true faith in the age-old sense of "one world." Economic development abroad and economic revitalization at home are shared problems because they are the challenges of our shared future, our common destiny on a shrinking planet.

Conclusion

In the preceding discussion, I have asked a lot of questions. And I have freely admitted that I cannot answer them, even after an adult lifetime in which development has been an abiding professional and personal interest.

The final question I must ask myself, then, is whether there is room for optimism or whether we are doomed to failure. And that is a question I can answer: we must continue to seek the solutions that will reduce the incidence of hard-core poverty at home and abroad. To do less imperils not only the economic security of the world but, more important, the very lives of

millions upon millions of men, women, and children.

I hope I have been able to convey that, despite our frustration and mistakes, we have learned much over the years. Our task now is to take what we have learned, analyze it, and reapply the knowledge in a manner that avoids those past errors and strikes at the heart of the problem.

We now know that the job will take much longer than we once brashly thought. We know that gimmicks will not work. We know that the external resources required are much greater than we once believed. We know that the multiplicity of objectives driving development assistance are counterproductive. We know that the attack on poverty requires the political will and a sustained commitment. And we know that, if past breakthroughs are valid measures, solutions will take our most creative minds.

But these are challenges, not insurmountable obstacles. So I ask you, then, to join in a rededication, a rededication to a sense of confidence that we can win this battle against poverty, that we must win it, that we will win it.

Analyzing the Farm-Level Impact of Agricultural Credit (Richard L. Meyer, Ohio State University, presiding)

Rural Credit and the Mix between Permanent and Temporary Wage Labor Contracts in Pernambuco, Brazil

Julie Anderson

During the last three decades, urban-based temporary agricultural workers have grown in number and visibility throughout Brazil, provoking research into the forces that drive shifts in agricultural wage labor demand away from "permanent" (year-round) toward "temporary" (daily, weekly, or harvest season) arrangements (see UNESP). The mix between permanent and temporary employment is of great concern in the sugarcane-producing coastal zone of Pernambuco, where both temporary and permanent employees find steady work cutting cane during the four- to six-month harvest season, but only permanent employees have steady work during the rest of the year. Temporary workers released from agriculture during the slack season find little nonagricultural employment, so their incomes drop sharply; and such seasonal reductions in income are considered especially deleterious to the welfare of workers who have little ability to smooth consumption through borrowing.

Increased seasonality in agricultural employment, which takes the form of a reduction in permanent employment as a share of total harvest season employment, may generate broader social costs as well, by inducing seasonal increases in theft, prostitution, and urban unrest, and increased seasonal migration of household heads away from their families. Thus, inferences about the effects of agricultural developments on the welfare of both the rural poor and small town dwellers require examination of changes in the mix between permanent and temporary agricultural employment, as well as changes in total peak season employment and wage levels.

A study of agricultural wage labor markets in Pernambuco (Anderson) showed that an absolute and relative decline in permanent employment during the 1960s resulted largely from the introduction of severance pay legislation for rural labor. The legislation increased the relative cost of labor hired under permanent contracts and changed the nature of the permanent labor institution by eliminating employers' ability to use the threat of dismissal as inducement for permanent employee "subjection." In the 1970s the volume of temporary employment continued to grow. Permanent employment grew even faster, however, because as labor markets grew tighter, permanent contracts became increasingly attractive as means for guaranteeing the availability of harvest season labor. Despite the continuation of these forces into the mid-1980s, the ratio of permanent employment to total harvest season employment failed to increase, and even appears to have declined.

This paper argues that the great increase in interest rates on rural credit in the 1980s significantly reduced farmers' incentive to employ workers on a year-round basis, and in fact explains the relative decline in permanent employment during the period. The conceptual framework for the argument is described in the second section, and a more formal discussion of the model may be found in an appendix available from the author. The model incorporates economic rationales for the observation that slack season labor is hired under permanent contracts,

while harvest season labor requirements are filled by a mix of permanent and temporary employees. The model combines these institutional considerations with a detailed depiction of the technological possibilities constraining farmers' production and employment decisions in this region, identifies the range of exogenous factors that might induce changes in the equilibrium permanent employment share, and predicts the signs of their effects. An increase in the interest rate on short-term credit should increase the finance charge-inclusive cost of slack season labor and induce a reduction in the permanent employment share.

The central empirical argument for the importance of the interest rate effect is found in the third section, which describes changing economic circumstances in Pernambuco during the early- and mid-1980s, showing that, of all the determinants of rural labor market structure, only the interest rate changed in the direction predicted to reduce the permanent employment share. Many other changes were taking place, but all of them would be predicted to increase the permanent employment share. Thus, the interest rate effect must have been strong enough to counteract tendencies toward increased permanence and induce the observed decline. As discussed in the fourth section, econometric analysis of 1988–89 cross-section data corroborates several elements of the argument and, thus, is useful even though it allows for no direct estimate of the interest rate effect.

Determinants of the Mix between Permanent and Temporary Employment

Permanent agricultural workers in the region under consideration are those contracted to work year round, planting and weeding sugarcane during the interharvest season and cutting cane alongside temporary workers during the four- to six-month harvest season. Employers retain slack season workers under two-season or "permanent" contracts, thus securing their harvest labor in advance, since by so doing they may reduce labor costs in at least two ways. First, they avoid the high costs of having to recruit labor during the peak season (Bardhan 1979), which include both direct search and transport costs and the losses that occur when labor shortages prevent a sequence of agricultural tasks from being completed in a timely fashion. Second, if workers have no access to credit or insurance markets, then the discounted, expected cost of employing them for two seasons may be reduced by smoothing their wages across seasons and across states of nature. Thus, permanent contracts implicitly providing consumption credit and insurance may allow payment of harvest season wages that on average are lower than spot market wages (Bardhan 1983).[1]

The harvest cost savings associated with permanent contracts suggest that all slack season workers will be retained under permanent contracts, and that slack season labor will be hired beyond the point at which its marginal product equals its wage. Whether the cost savings stimulate farmers to offer year-round employment to many or few of their workers, however, depends on technological substitution possibilities and on the full configuration of prices and fixed factors conditioning production decisions.[2]

Farmers in this region have several technical options for varying the ratio of slack to peak season employment, while maintaining the volume of output. Semimechanization of the harvest—in which mechanical harvesters pick up loose, manually cut cane and load it into trucks—reduces harvest labor demand by making the bundling of cane unnecessary; so it allows increases in the permanent employment share. Herbicide use, on the other hand, reduces slack season labor requirements. Further, farmers may vary the relative importance of "extensive" and "intensive" cultivation practices. Extensive practices involve minimal replanting and weeding and consequent low productivity per acre, while more intensive practices involve replanting a greater proportion of the cane each year and weeding the standing cane several times, increasing per-acre slack season labor requirements. Though more intensive cultivation increases output, it also renders cane easier to cut, and seems to increase harvest labor requirements by less than slack season requirements.[3]

The ratio of slack to peak season labor re-

[1] Two other rationales for the existence of permanent contracts, related to incentives for unsupervised labor and to cost reduction through in-kind payments, are of historical but not current relevance here (see appendix).

[2] The properties of the region's sugarcane technology described in the following paragraphs should be regarded as assumptions underlying the proposition of the paper; they are based on casual observation and preliminary analysis of cross-section data, but they merit closer empirical examination.

[3] Fertilizer is applied in uniform per-acre quantities to most sugarcane land in this region. In a few cases, some of a farmer's worst sugarcane acreage is cultivated under a "very unintensive" strategy, in which no fertilizer is applied. Again, though this implies lower yields and lower harvest season labor requirements, it also implies less slack season labor use and is likely associated with lower ratios of slack to peak season labor.

quirements is also likely to rise as output expands over time on individual farms and to be greater on larger farms at any point in time. Output expansion on an individual farm requires extending either intensive or extensive practices on to land of lower quality. On steeper, poorer quality land, both slack and peak season tasks are more difficult to complete. The difficulty of slack season tasks may rise by more than the difficulty of cutting the cane, and the volume of output to be harvested also falls, making it likely that slack season per-acre labor requirements rise by more than peak season requirements. Larger farms appear more efficient in the use of labor, perhaps because of economies of scale achievable through the division of labor. The scale economies appear strongest in harvest season activities, so that the ratio of slack to peak season employment tends to rise with the scale of production.

If farmers select how much of their land to cultivate and which of these cultivation practices to employ on fields of varying quality, with the aim of maximizing end-of-year profits (while taking into account prices, wages, and the interest rate on short-term finance for slack season input payments), then the following predictions are possible. The ratio of slack to peak season labor demand, and thus the share of permanent contract offers in farmers' total labor demand, will rise when increased prices or reduced input costs stimulate expansion onto lower quality land. The permanent employment share should also rise as increases in the stock of harvest machinery reduce harvest season labor requirements, as increases in the effective price of chemical herbicides discourage their use, and as rising recruitment costs make permanent labor more attractive relative to temporary labor. An increase in the interest rate at which the slack season wage (and herbicide) bill is financed, however, will increase the finance charge-inclusive cost of slack season labor relative to the cost of peak season labor and will induce a reduction in the permanent employment share demanded.

If the net effect of exogenous changes on individual farmers' decisions is to increase total demand for harvest season labor, adjustments toward a new labor market equilibrium will provide two further reasons for the permanent employment share to rise. First, as labor markets tighten, recruitment costs rise, increasing the relative cost of temporary labor. Second, permanent wages should rise more slowly than temporary wages. If workers may be characterized as having diminishing marginal utility of income (in each season), then proportionate increases in permanent and temporary wages would produce a greater-than-proportionate increase in the utility workers derive from permanent contracts; thus, the share of workers seeking permanent employment would rise, tending to slow permanent wage growth.

The Case of Pernambuco in the Early- and Mid-1980s

Evidence of decline in the ratio of workers hired under permanent contracts to the total number of harvest season employees in the coastal zone of Pernambuco between 1978–79 and 1988–89 is derived from a farm-level sample survey administered in 1989.[4] The 1988–89 estimate of this share for the sugarcane-producing population in the sample region (based on 185 observations) is 56%. For a subsample responding to a retrospective section of the questionaires (165 farms), the share fell from 65% in 1978–79 to 57% in 1988–89. This represents a 23% increase in the share of sugarcane workers disemployed at the end of each harvest.

Several comments on the validity of the survey evidence are in order. Interviewers were identified as working with a researcher from a foreign university and were correctly perceived as having no connection with any Brazilian ministry for whom answers might be biased. Most interviews lasted from one to one-and-a-half hours, during which most interviewees were willing to provide careful answers. Some large employers had records allowing them to answer retrospective questions accurately, while smaller employers tended to be closely involved in hiring and administration and appeared to have little difficulty remembering.

The calculation of weights required for estimating both 1988–89 population shares and the sampling errors on those estimates are discussed in Anderson, where the sampling errors are found to be on the order of three percentage points. Constructing weights for the retrospective estimate required employing some ad hoc assumptions regarding land acquired and disposed of during the period by farmers in the sample, but the population estimate appears robust to vari-

[4] Average hours for both permanent and temporary workers probably fell during the period as the legal work week was shortened. Most permanent workers and many temporary workers work no more than this legal minimum, despite payment on a piece-rate basis and employers' experimentation with incentive schemes.

ation in these assumptions. The estimate also appears consistent with 1980 agricultural census calculations, which show a permanent employment share of 66% for the same group of municipalities. While some differences between census and survey shares at the municipality level suggest the margin of error is nontrivial, the conclusion that the permanent employment share declined over the period seems reasonable.

A number of economic changes over the ten-year period should have induced increases in the permanent employment share. Both area cultivated and the volume of sugarcane production experienced net expansion.[5] Though the administered price of sugarcane began to fall with respect to general price indices after 1982, the effective price of cane seemed to be rising for many growers in the region.[6] The great increase in the region's sugar refining and alcohol distilling capacity, stimulated by cheap investment finance in the 1970s, came on line in the early- and mid-1980s, generating intense competition between the mills for suppliers' cane. Farmers' certainty of selling their cane in a timely fashion increased. Some sugarmills began to offer free transport, input provision, and in some cases side payments. Expanding production brought with it rising wages and would be expected to bring an increase in the permanent employment share, as discussed above.[7]

Average non-wage benefits for temporary workers were rising relative to those for permanent workers during the period, as temporary workers increasingly sued for paid vacations, Christmas bonuses, severance pay, and other provisions of rural labor legislation, which had long been paid for most permanent workers. The expanded relevance of social security provisions for temporary workers is indicated by the observation that by 1988–89 around 40% of temporary workers were registered with the Ministry of Labor, though virtually none had been in 1978–79.

In addition, the costs of recruiting labor in the harvest season were rising. The distances employers had to go to find workers increased, and they began to provide transportation and temporary accommodations of increasing quality. Further, the timely execution of harvest season tasks increased in importance after 1983, when the price planters received for their cane began to depend on its sucrose content. This gave farmers an interest in reducing sucrose losses resulting from delays between preparatory burning and cutting or between cutting and loading for transport to the sugarmill, and thus increased the premium on having the labor of permanent employees prearranged.

The 1980s brought more mechanization of harvest tasks than did the years of cheap and abundant credit in the 1970s. The survey suggests that the share of sugarcane area harvested semimechanically rose from around 20% in 1978–79 to over 40% in 1988–89 (mostly on large farms), consistent with the observations of sector experts. Whether stimulated by rising wages and recruitment costs or by the new production of mechanical harvesters in, and appropriate for, the Northeast, this should have generated an increase in the permanent employment share.

An increase in the permanent employment share might also be expected to result from the concentration in operational landholding that occurred during the period, both through farmers (of all sizes) buying up other farms and through sugarmills reassuming direct administration of lands previously rented out. The association of larger-scale with higher permanent employment shares, discussed in the previous section, are corroborated in the cross-section results presented below.

Despite reports of increased herbicide prices relative to official daily wages, which would be expected to increase permanent employment and reduce herbicide use, a number of farmers began using herbicides during the period under study.[8] Even if the price reports are inaccurate and the relative price of herbicides declined, the decline in the permanent employment share on many farms where no herbicides were used would remain unexplained. If the relative price of herbicides rose as reported, the increase in herbicide use would appear anomalous but could in part be explained as a result of the interest rate increase. The increase in interest rates should have increased the discounted cost of slack season labor use proportionately more than it increased the discounted cost of herbicides. Fur-

[5] Hectares harvested and tons produced increased by 22% and 34%, respectively, between 1978 and 1987 (Instituto Brasileiro de Geografia e Estatística, *Produção Agrícola Municipal*).

[6] Deflated by Fundação Getulio Vargas "Index 2," the administered price fell 40% between 1981 and 1986.

[7] Average rural daily wages in Pernambuco rose at 3% per year relative to a general price index between 1976 and 1986 (Fundação Getulio Vargas).

[8] According to the records of a major producer in the region, the price of a litre of herbicide rose 182% relative to the price of a ton of cane and 110% relative to the official daily wage between 1982 and 1989.

ther, increased interest rates on credit made self-finance more attractive, at the same time that high and variable inflation may have made chemical herbicide stocks a more attractive form of saving for self-finance.

The only economic force generating a tendency for a widespread decline in the permanent employment share was the increase in the interest rate at which slack season labor was financed.[9] Through the 1970s farmers had access to increasing volumes of credit at increasingly negative real interest rates; interest rates on rural credit were fixed in nominal terms at between 12% and 18% per year, while inflation rates rose from around 20% per year in 1970 to over 75% in 1979. Rural credit interest rates began to rise in the early 1980s, though initially they remained fixed in nominal terms at 35% while inflation rose to 100% per year. Rural credit became subject to partial indexation in 1982, and to full indexation plus interest of 7% to 9% in 1987. Because rural credit was indexed to general price indices, while at the end of the period the price of sugarcane fell relative to such indices, *ex post* interest rates in units of the output became very high indeed. As late as 1988–89 a great majority of farmers represented in the sample (having at least 20 hectares) continued to borrow; and a number of those who did not use credit in that year commented that it was the first time they did not seek credit. They had received loans sized according to reasonably generous per-acre rules. Thus, the effect of rising interest rates was a widespread increase in the (shadow) cost of short-term finance. The effect on permanent employment of the resulting increase in the relative cost of permanent labor must have been strong enough to counteract the tendencies for increased permanence discussed above and induce the observed decline in the permanent employment share.

Lacking richer time-series data on permanent and temporary employment, the discussion has been confined to the analysis of net changes over a ten-year period in which developments were not uniform and could therefore be misleading. At the end of the period, farmers began to fear the elimination of sugarcane price subsidies as well as credit subsidies. Thus, for example, if the permanent employment share had risen or remained constant through much of the period, falling only at the very end, the importance of interest rate changes would be more difficult to judge. Such a scenario, in which sectoral crisis rather than sustained interest rate increases induced the change in employment structure, is implausible, however, precisely because it would require a sudden, large reduction in permanent employment. Well-enforced severance pay legislation makes such "dismissal without just cause" very costly. Comments by interviewees, and cross-section results (not presented) showing the permanent employment share to be higher on farms that experienced production declines, are consistent with permanent employment reductions being "slowed" to rates at or near the rate of attrition.

Econometric Analysis of 1988–89 Cross-Section Data

Econometric examination of the 1988–89 cross-section data corroborates some components of the above argument and thus contributes indirectly to an understanding of the relationship between interest rates and employment structure, even though it yields no direct estimate of rural credit's "farm level impact." Table I presents estimates of farm-level reduced-form equations, in which the permanent employment share is considered as a function of the technological and institutional factors varying in the sample. Approximately 10% of the sample is censored at permanent employment percentages of both zero and one hundred, so the reported coefficients are maximum likelihood "two-limit tobit" estimates.[10] Explanatory variables (including some not shown) were introduced both in absolute terms and interacted with the inverse of farm size to allow for scale differences. Interacted terms were multiplied by median farm size, so that the sum of coefficients on absolute and interacted terms yields the variable's total effect on a farm of median size. The specifications in table I restrict to zero the coefficients on variables for which the coefficients were found insignificant in unrestricted estimation.

The estimates in the first column of table I corroborate the arguments that the permanent employment share should have risen as operational landholdings were consolidated and as

[9] The discussion has focussed on labor demand side forces. It is also unlikely that supply side shifts toward temporary arrangements, such as might arise in response to increased nonagricultural short-term employment opportunities, induced the decline in permanence. Anderson cites evidence to this effect, but further research is merited.

[10] Permanent employment shares of zero arise only on small farms where family labor is important. The treatment of family labor is discussed in the appendix.

Table 1. Maximum Likelihood Two-Limit Tobit Estimates of Permanent Employment Share Equations

Variable	Specification 1	Specification 2	Mean:
Permanent employment share			46.6
Log (farm size in hectares)	6.3	6.2	5.7

[b] Median farm size is 297.5 hectares.

temporary labor recruitment costs rose. The permanent employment share rises significantly with (the log of) operational farm size, and this result is robust to reestimation within smaller farm size categories. Distance from the nearest sugarmill (usually located near an agglomeration of temporary workers) proxies for recruitment and transportation costs that increase the relative cost of temporary labor. It appears to increase the permanent employment share, though the effect is smaller for small farms. The indicator of temporary employee registration proxies for variation in nonwage temporary labor costs and is weakly associated with a higher permanent employment share. These results are consistent with the argument that recent increases in such costs should have increased the permanent employment share. They also make plausible an interest rate effect, which likewise acts through changes in slack season labor's relative cost.

Because official interest rates did not vary across farms, the interest rate effect itself cannot be estimated in a single cross section. If unobserved expectations regarding real interest rates varied somewhat across farms (despite indexation), and if farmers expecting lower real interest rates were both more likely to borrow and more likely to use more permanent labor as argued above, a positive correlation would arise between credit demand and the permanent employment share, even after controlling for variation in technological and institutional factors.[11] The second specification in the table includes an indicator of whether the farmer took out a loan (loan size reports being too noisy to be of interest), and the coefficient is found to be positive but statistically insignificant. The positive coefficient is consistent with the argument of this paper, but since a positive correlation could result from the existence of omitted variables other than the expected interest rate, even a significant correlation would constitute no proof of the interest rate effect. The correlation may fail to be significant simply because expected interest rates do not vary enough across farms, so the lack of significance allows no rejection of the interest rate effect.

Concluding Comments

Many costs of subsidized rural credit programs, such as described in Adams and Graham's general critique and in Araujo, Meyer, and Shiro-

[11] By farmers' reports, credit market participation was demand determined.

ta's discussion of the Brazilian experience, are well known; and many economists agree credit subsidies should be removed. Less has been said about the cost of adjustment to higher interest rates. This paper's analysis of historical circumstances over the early and mid-1980s in Pernambuco highlights a potential adjustment problem in regions where wage labor is important, finding that higher interest rates significantly increased the seasonality of agricultural employment. Even though such a shift in agricultural employment structure may eventually contribute to improved efficiency, it may be very costly for the most vulnerable of the rural population in the short and medium run, especially where workers released only seasonally from agriculture are not easily absorbed into nonagricultural production. The design of appropriate adjustment policies should therefore be given careful attention.

Access to Capital and Its Impact on Agrarian Structure and Productivity in Kenya

Michael R. Carter and Keith D. Wiebe

Access to capital and its distribution across agents can profoundly shape the structure and performance of an agrarian market economy.[1] It is conceptually useful to distinguish between *ex ante* and *ex post* capital access. *Ex ante* capital access denotes the ability of agents to finance production costs (e.g., labor and purchased inputs costs) which must be paid *ex ante,* that is, prior to the actual realization of production. *Ex post* capital access, that is access to capital after the realization of the production process, is of particular importance as an insurance substitute in low income agrarian economies where contingency markets are imperfect. Buoyant *ex post* capital access would permit an individual to stabilize consumption year to year even as production fluctuates annually.

A number of theoretical models have explored the static impacts of agrarian structure and differential capital access on resource allocation and productivity (see Feder, Eswaran and Kotwal, Carter and Kalfayan.[2] In addition to empirically exploring the impact of landownership structure on productivity in capital-rationed environments, this paper explores and motivates analysis of the evolution of landownership structure itself. In the contemporary context of market-oriented agricultural development strategies in general, and land market "activation" policies in particular, it is particularly important to understand the incentives for expansion and contraction of different classes of producers.

The authors are, respectively, an associate professor and a graduate research assistant, University of Wisconsin.

This work has been supported by the Land Tenure Center and the University of Wisconsin Graduate School.

The authors thank Richard Meyer for his thoughtful comments on an earlier draft.

[1] Access to capital means access to one's own wealth as well as to the intermediated wealth and savings of others.

[2] Whether or not skewed capital access is a feature of intrinsically imperfect rural markets, or whether it reflects lender response to interest rate regulation, is an important question of considerable importance and debate in the literature (see Adams and Graham, Carter).

The Non-Neutrality of Agrarian Structure: U-Shaped Farm Size–Productivity Relationships in Kenya

Kenya is unique among African countries for its commitment to market activation. Agriculture in Kenya's highlands has been highly commercialized since the colonial period. Agrarian structure today is variegated, with units ranging from a single acre to hundreds of acres in size. Blarel et al. analyze microeconomic data on 109 small and medium farms in the Njoro region of Kenya. Two patterns they observe are of particular interest here.

First, productivity varies strikingly with farm size, as illustrated by the fitted regression curves in figure 1. Output represents the per acre value of maize-beans, wheat, and livestock products at sample average prices. A statistically significant U-shape characterizes both output and family income (the latter is output less the value of all inputs except family labor). Profits (family income less the imputed value of family labor) increase monotonically with farm size. The intensity of family labor application on small farms is clear, driving profits down sharply on smaller farms. Profits even fall below zero for the smallest farms, suggesting that the market wage, at which the value of family labor is imputed, overstates the real opportunity cost of family labor to farm households.

A second size-related pattern of interest is the allocation of land to various activities, illustrated in figure 2. Two features are immediately apparent. Farms of all sizes allocate about the same amount of land to production of the staples maize and beans. And wheat, a purely commercial crop in Njoro, abruptly becomes the dominant activity on larger farms. The remaining sections of this paper explore the rationale and implications of this structural non-neutrality, with particular emphasis on the role of access to capital.

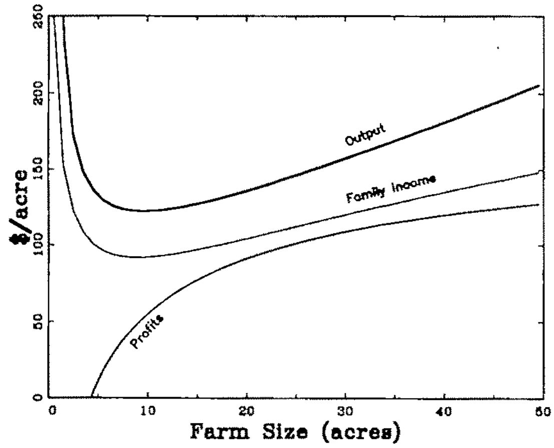

Figure 1. Output and net returns per acre

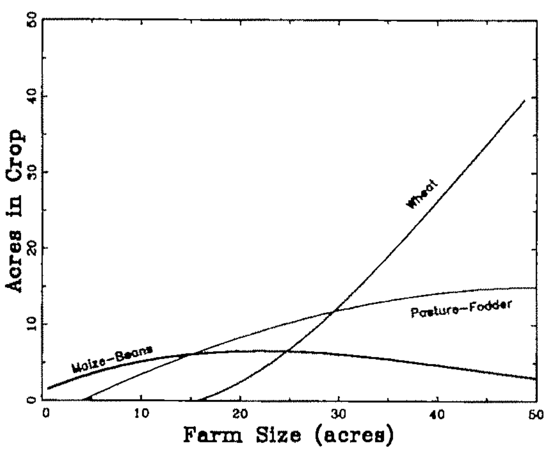

Figure 2. Area by crop activity

Ex Ante Capital Access and Farm Productivity

Rationed access to *ex ante* capital, interacting with an imperfect labor market, is one possible explanation for the striking farm size-farm productivity relationships displayed in figure 1.[3] The CGE model developed in Carter and Kalfayan can be used to explore this explanation. Agent behavior in their model is constrained by a capital constraint:

(1) $p_f F + wL_d + R_0 \leq w\Phi(L_s) + \beta(T)$,

where $\beta(T)$ is the amount of quantity rationed working capital available to an individual with land endowment T; F is fertilizer and other nonlabor purchased inputs; L_d is total quantity of hired labor in time units; R_0 is family subsistence needs less savings; $\Phi(L_s)$ is the number of days employed as a function of days supplied to the labor market, L_s, ($\Phi' > 0$ and $\Phi'' \leq 0$); and p_f and w are the market fertilizer price and wage per unit of labor time, respectively. Let μ denote the Lagrange multiplier or shadow price corresponding to constraint (1).

In addition, hired labor must be supervised so that the total units of effective labor (Tl) from L_h units of own and L_d of hired labor are

(2) $$Tl = L_h + \gamma(l_h)L_d,$$

where, assuming an informal family labor supervision technology, the effectiveness of supervision depends on the density of family labor per acre, l_h, and $\gamma < 1$ for all l_h and γ', $\gamma'' \geq 0$.

Maximization of household income subject to constraints (1) and (2) admits a variety of solution regimes depending on prices and the agent's land endowment. For a capital-constrained semiproletarian agent who supplies labor to the market ($\mu > 0$, $L_s > 0$ and $l_d = 0$), quantities of labor and fertilizer will be chosen to fulfill the following conditions:

(3a) $$q_l = (1 + \mu)w\Phi', \text{ and}$$

(3b) $$q_f = (1 + \mu)p_f.$$

For a capital-constrained labor-hiring farm ($\mu > 0$, $L_s = 0$ and $l_d > 0$), labor and fertilizer are chosen to fulfill

(4a) $$q_l = (1 + \mu)w/\gamma(l_h), \text{ and}$$

(4b) $$q_f = (1 + \mu)p_f.$$

Interpretation of (3) and (4) is straightforward. Inputs are used until marginal factor productivities are equated to real economic costs, defined as the direct opportunity cost marked up by the shadow price of working capital ($\mu > 0$). For the labor supplying agent (3a), the direct cost of labor is the market wage times the marginal employment probability. For the labor-hiring agent (4a), the direct cost of labor appears as an efficiency wage, the market wage paid per unit of effective labor input.

As indicated by first-order conditions (3) and (4), marginal factor products measure the severity of labor market imperfections and the shadow price of *ex ante* capital. All farmers in the Kenya sample devote some land to the pro-

[3] In the Kenya data, farms less than 3 acres in size borrow *ex ante* an average of 2 shillings per acre; large farms borrow 250 shillings per acre.

duction of a maize-bean intercrop. Fitting a standard Cobb-Douglas production function to the data on this fairly homogenous technology yields the following econometric results:

$$(5)\quad \ln Q = \underset{(5.36)}{3.64} + \underset{(8.05)}{0.45} \ln F + \underset{(2.74)}{0.23} \ln L + \underset{(2.72)}{0.26} \ln T \quad (R^2 = 0.78),$$

where all variables (except land) are converted to money units using sample average prices. With this monetary definition of inputs and outputs, marginal products represent the net increase in gross income realized from the application of an additional shilling's worth of any particular input. Exclusive of capital costs, profit-maximizing resource allocation at sample average prices would apply inputs to the point where each input's marginal product equals one.

For each observation i, the marginal product for factor X can be calculated as follows using the estimated parameters given in (5):

$$(6)\quad MPX_i = \partial Q_i/\partial X_i = (\partial \ln Q_i/\partial \ln X_i)Q_i/X_i = \beta_x Q_i/X_i,$$

where β_x is the estimated Cobb-Douglas regression coefficient for input X. In order to test for systematic size-sensitivity of markets, calculated marginal products were regressed on farm size:

$$(7)\quad MPL = \underset{(6.14)}{0.28} + \underset{(8.06)}{0.05T} - \underset{(-4.96)}{0.0001T^2} \quad (R^2 = 0.48)$$

$$(8)\quad MPF = \underset{(14.97)}{4.31} - \underset{(-2.78)}{0.10T} + \underset{(2.41)}{0.001T^2} \quad (R^2 = 0.07).$$

The estimated regression functions (7) and (8) are displayed in figure 3. The dashed horizontal line indicates the level to which marginal factor productivities would be driven assuming profit maximization and an interest rate of 20%.

On the (debatable) assumptions that purchased inputs are not quantity rationed and that their prices do not systematically vary with farm size, figure 3 shows that the shadow price of *ex ante* capital is very high on the smallest farms (300% for a 5-acre farm) and declines with farm size to about 100% for a 40-acre farm. The pattern for labor allocation is quite the opposite, as figure 3 shows. The smallest farms apply labor until its marginal product is only a fraction of the market wage, while the efficiency wage for larger farms (that is, the wage per-unit of effective labor effort) appears to be above the market wage.

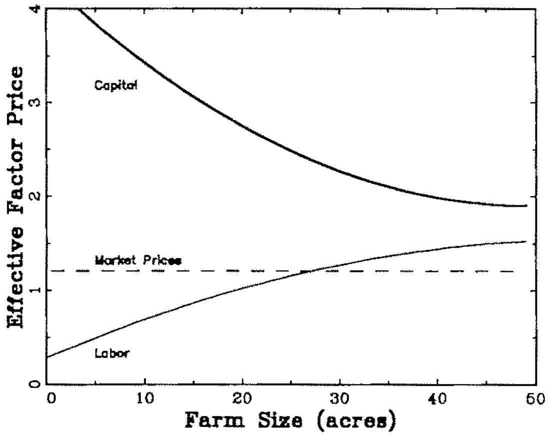

Figure 3. Effective factor prices

Unlike the conventional monotonic, inverse farm size–farm productivity relation, the U-shaped relation discussed above points to constraints which inhibit the productivity of smallholders. The analysis in this section suggests that, despite their access to cheap labor, the potential hyperproductivity of small farms is eventually overwhelmed by countervailing capital constraints.

Let $\pi(w, p_f, T)$ be the optimum value function defined by maximization of household income subject to constraints (1) and (2). For any given set of parameters, $\pi(w, p_f, T)$ can be used to explore the interacting impact of these various market failures on a given farm unit's incentives to change its scope of cultivation. For a farm of size T, the reservation price for land may be defined as

$$(9)\quad \rho(T) = \sum_{t=1}^{\infty} \Delta(T)/(1 + \mu(T + \epsilon))^t,$$

where $\rho(T)$ is the reservation price, $\Delta(T) = [\pi(w, p_f, T + \epsilon) - \pi(w, p_f, T)]/\epsilon$ is the per acre increment in income which could be optimally gained if ϵ additional hectares of land were owned by a farm of initial size T, and $\mu(T + \epsilon)$ is the discount rate calculated as the shadow price of capital specific to the size of the expanded farm unit.[4] Following the analysis of the impact of *ex*

[4] As written, (8) presumes that current prices will persist into the future. Also note that households, who by virtue of their small landholding supply much of their labor to the market, may have a high reservation price for land because landownership effectively permits them to earn a return on their labor by selling it to themselves.

post capital constraints on farm resource allocation and productivity, equation (9) will be estimated using the Kenya data.

Ex Post Capital Access and Agricultural Commercialization

Ex ante capital constraints shape production strategies by limiting small farmers' access to working capital. Production strategies may also be affected by capital constraints *ex post*, through their effect on household food security. In particular, constrained access to *ex post* capital as consumption insurance may contribute to Njoro farmers' decisions to produce maize-beans before allocating land to wheat, driving the patterns in figure 2.

A simple safety-first model (based on Wiebe) illustrates this point. Consider a household which may allocate land to the production of maize and wheat. Net returns to wheat production are on average twice as high in Njoro than are net returns to the production of maize. Nevertheless, specialization in wheat implies reliance on maize markets for consumption; despite state efforts to guarantee commodity prices, this remains an uncertain proposition.

If returns to wheat are both higher on average and more variable in real terms than are returns to maize, maximization of expected returns may periodically fail to secure consumption needs, here defined as a minimum maize requirement C for each of the household's N-resident adult equivalent members. In this case, the household faces a nontrivial problem in choosing, before yields and prices are known, the proportion q of its land to allocate to wheat.

Given q, average family income per farm acre can be expressed as a linear combination of family income to wheat (FI_w) and to maize (FI_m):

$$FI_q = qFI_w + (1 - q)FI_m.$$

The critical level d of family income per farm acre required to meet consumption needs is moderated by the household's access to *ex post* capital R:

$$d = (NC - R/p_m)/T,$$

and may be greater than, less than, or equal to zero accordingly. Because R is denominated in real terms, d is itself a random variable whenever $R \neq 0$.

Objective risk—the probability of a food deficit in any one year—depends on the distributions of net income $FI_q - d$ for all $q \in [0, 1]$. Given N, R, and T, objective risk depends in turn on the probability density functions of prices and yields of maize and wheat. Let these be described by cumulative distribution functions F_q of net income such that

$$F_q[0] = Pr[FI_q - d < 0].$$

Formally, the household's problem is then to

$$\max_q E[FI_q], \text{ subject to } F_q[0] \leq \alpha; \quad \text{otherwise, } \max_q F_q^{-1}[\alpha];$$

where α represents the highest level of objective risk acceptable to the household. The household chooses q to maximize expected income, but in so doing, it selects only from those crop combinations which offer acceptably low objective risk. When no choices of q satisfy the "chance constraint" the household must relax its decision making criteria and minimize its losses.

This model derives q^*, the optimal commercialization level, as a function of N, R, and T. Given N and T, three cases can be distinguished on the basis of access to capital *ex post*.

Case 1: $F_q[0] \leq \alpha$ for all q. If *ex post* capital access is sufficiently liberal (and hence d sufficiently low) that all choices of q satisfy the chance constraint, the household's problem reduces to the maximization of expected returns. This leads to a simple corner solution; since $E[FI_m] < E[FI_w]$, the household chooses $q^* = 1$.

Case 2: $F_q[0] \leq \alpha$ for $q \in [0, q' < 1]$, where $F_{q'}[0] = \alpha$. When capital access is less favorable, however, d is higher. In this case not all levels of q offer acceptably low risk; the chance constraint may be satisfied only for *some* q. Then the chance constraint is binding, and the household sacrifices some degree of expected income by choosing $q^* = q'$ in order to reduce objective risk to an acceptable level.

Case 3: $F_q[0] > \alpha$ for all q. When *ex post* access is tightly constrained, the income required of agriculture to meet basic needs becomes very high. If no choices of q satisfy the chance constraint the household must relax its decision-making criteria; choice of $q^* = 0$ minimizes losses in bad years.

Even if labor and *ex ante* capital markets are fluid, the same agricultural opportunities are technically available to all, and objective risk thresholds are identical, optimal strategies may vary across households according to their access to capital *ex post*. Specifically, case 1 households are sufficiently insulated from the risk of

a food deficit that they can afford to commercialize completely. Case 2 households are less well cushioned and produce food first before allocating land to wheat, while case 3 households are sufficiently vulnerable that they are forced to specialize in production of maize.

In general, household size N and farm size T are not constant but vary from farm to farm. If access to capital *ex post* mirrors the size-related pattern found in an earlier section with regard to access *ex ante* in Njoro, cases 1 and 2 would then characterize the sample's larger farms, while case 3 would better describe its smaller farms. These observations are consistent with the land allocation patterns illustrated in figure 2: larger farms commercialize to a greater degree than do smaller farms, and all farms appear to seek food security first before allocating land to wheat.

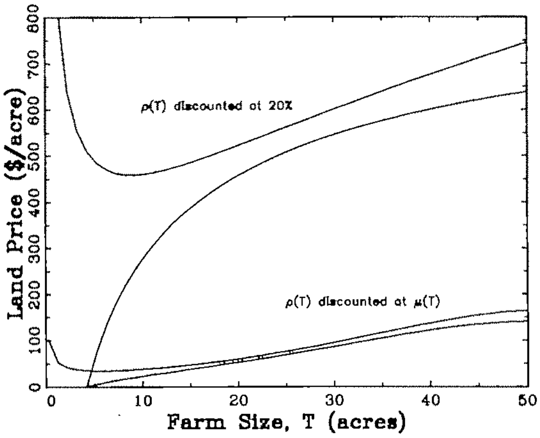

Figure 4. Imputed land price, $\rho(T)$

Willingness to Pay for Land and the Economics of Structural Evolution

The preceding two sections have shown how size-related patterns of access to capital generate size-related patterns of resource allocation and productivity in Kenya's smallholder sector. Agricultural performance is strongly influenced by agrarian structure, in keeping with the theoretical propositions of Eswaran and Kotwal. In addition, evidence of the non-neutrality of size suggests that agrarian structure is itself under pressure to evolve over time. The family income and profits measures discussed earlier in the paper offer simple reduced-form estimates for average returns to land reflecting smallholders' structure-sensitive choices. As such, these estimates can serve as crude approximations of a measure of the marginal returns to land needed to estimate the land reservation price $\rho(T)$ defined in equation (8).

Alternative estimates of the land reservation price are presented in figure 4. The first set of estimates assumes a constant rate of interest available to all farms, and simply scale up the net returns illustrated in figure 1. The second set uses as the discount rate the size-sensitive shadow price of capital which was estimated in equation (7). Capital market constraints are here seen to drive imputed reservation prices down for all farms, and for the smaller farms in particular.

Clearly, structure-sensitive capital market and resource allocation patterns interact in Njoro to generate incentives for land transactions which vary dramatically across the existing distribution of farm sizes. Specifically, as land markets become active, this suggests that large farms will enjoy a systematic capacity to outbid smaller farms for available land. Questions regarding the long-term path of agrarian structural evolution in a market context are thus a natural and important extension of conventional concerns about productivity in the short run. Access to capital, both *ex ante* and *ex post,* plays a critical role in shaping that path over time.

The Relationship between Credit and Productivity in Chinese Agriculture: A Microeconomic Model of Disequilibrium

Gershon Feder, Lawrence J. Lau, Justin Y. Lin, and Xiaopeng Luo

Credit is an important element in agricultural production systems. It allows producers to satisfy the cash needs induced by the production cycle which characterizes agriculture: preparation, planting, cultivation, and harvesting of the crops are typically done over a period of several months in which very little cash revenue is earned, while expenditures on materials, purchased inputs, and consumption must be made in cash. Cash income is received a short time after the harvest. In the absence of credit markets, farmers would have to maintain cash reserves so as to facilitate production and consumption in the next cycle. The availability of credit allows both greater consumption and greater purchased input use and thus increases welfare of the farmers.

If a producer faces an infinite supply of liquidity at a given price, the production decisions will be independent from consumption decisions, as has been shown in the household models of Singh, Squire, and Strauss. However, asymmetric information, and adverse selection typically prevail in credit markets, giving rise to credit rationing as an optimal behavior (Stiglitz and Weiss). Furthermore, government intervention in the form of interest rate ceilings or subsidized interest rates is common in many countries' agricultural sectors, necessitating rationing. When credit is rationed, some borrowers cannot obtain the amount of credit they desire at the prevailing interest rate, nor can they secure more credit by offering to pay a higher interest rate. In such circumstances, liquidity can become a binding constraint on many farmers' operations.

When liquidity is a binding constraint, the amounts and combinations of inputs used by a farmer deviate from their notional optimal levels (the levels that would have been utilized if liquidity were not a binding constraint). The marginal contribution of credit is therefore to bring input levels closer to the optimal levels, thereby increasing output and, because the quantity of land is fixed, yield. This potential gain in productivity is one motivation underlying many government programs seeking to provide more credit to the farm sector. An important issue in the context of agricultural credit policy is the magnitude of the expected productivity gain. If the marginal productivity effect of credit is small, then the resources may be more beneficially deployed elsewhere. Assessment of the expected productivity gain is not trivial because the effect of credit is likely to differ between liquidity-constrained and unconstrained farm households.

Some studies attempt to identify the effect of credit by estimating separate production functions or supply functions for borrowers and nonborrowers and then proceeding to compare the estimates (see review in David and Meyer, pp. 206–15). One major weakness of this approach is the implicit assumption that all borrowers and all nonborrowers are, respectively, homogenous with respect to their credit demand/supply situations. This assumption is often not valid, as many nonborrowers do not borrow because they actually have sufficient liquidity from their own resources and not because they cannot obtain credit, while some cannot borrow because they are not creditworthy. Similarly, the marginal effect of credit may actually be zero for borrowers for whom liquidity is not a binding constraint.

The same criticism applies to other studies in which all sampled observations are pooled to es-

timate production functions (or output supply functions) with credit as a production input or as a supply determinant. As will be argued in a subsequent section, the supply function is different (both in parameters and in variables) depending on whether liquidity is a binding constraint. Estimates which do not take account of these restrictions on the specification are therefore flawed.

The present study reports an econometric analysis of the effect of credit on output supply which avoids some of the aforementioned pitfalls. The central feature is the recognition that credit transactions are not necessarily in equilibrium at the household level. That is, the amount of credit desired and the amount offered are not necessarily equal, so that credit supply rationing (with unsatisfied demand) and nonborrowing (while supply is potentially available) are both possible. The analysis utilizes cross-sectional household-level data from a study area in northeast China, obtained in a recent farm survey designed by the authors. The plan for the paper is as follows: the next section provides background on the farm sector and the rural credit market in China and describes the specific study area and data utilized in the analysis. The formal model underlying the empirical analysis then is discussed. It is followed by a discussion of the econometric procedure and the empirical results. The last section discusses the implications of the results.

China's Farm Sector and Rural Credit Market

China introduced a smallholder agricultural production system in a series of reforms between the years 1979–84. The "household responsibility system" made individual households, rather than the communes to which they belonged, the decision makers and managers of their own farms. Individual families were allocated land by the communes on leases that run typically for fifteen years. The improved incentives brought about a significant increase in agricultural output and in rural income (Lin). While prior to the reforms there was only limited interaction between households and financial institutions, the emergence of smallholder agriculture implies that many households now need liquidity for seasonal production and consumption or longer-term credit to finance investment, construction, and ceremonial social events.

Most of agricultural households' transactions with the formal financial sector are done with the rural credit cooperatives (RCCs).[1] The interest rates for agricultural loans (as well as other loans) made by formal credit institutions are fixed by the government, with some variations according to loan categories. In 1987, the rates of interest for agricultural loans ranged between 7% and 14%. The degree of interest subsidy is believed to have been small.

There is evidence that, following the introduction of reforms, the volume of liquidity obtained from informal sources is substantial in China. Jiang asserts that noninstitutional sources contribute roughly half of the credit volume in rural areas. Feder et al. (1989) report non-institutional credit shares of between one-third and two-thirds in several study areas. The most common sources of informal credit in China are relatives and friends. Most of such loans carry no interest charges. Possible reasons for the absence of a substantial profit-motivated informal credit market in China are discussed in Feder et al. (1990b). They include unclear legal status, residual ideological resistance, and absence of collateral assets.[2]

The present study relies on data collected in December 1987 in Gongzhuling. Gongzhuling is located in Jilin province, within the corn belt of northeastern China where agroclimatic conditions dictate essentially one corn season a year. The original sample consists of 200 households selected at random from eight randomly selected townships. The information gathered covers inputs, outputs, financial assets, credit transactions, and household characteristics. Thirteen households are deleted after determining that their main activity was not agriculture or that their situation was unusual (e.g., a widow maintaining a home garden plot).

The data show that nearly three-quarters of the sample borrowed from formal sources (essentially the RCCs) during the study season. The frequency of informal credit transactions is much lower than that of formal transactions (about one fifth of the sample), and three-quarters of these loans were provided free of interest. Given the significant differential between the rates of interest on the two types of loans, this may be taken as evidence that informal credit is not a good substitute for formal credit due to limited fungibility (otherwise every borrower would ex-

[1] Greater detail on the credit market in rural China and in the study area is provided in Feder et al. 1989, 1990b.

[2] Land is on a fifteen-year lease and until recently use rights could not be transferred.

haust his or her informal credit first before going to the RCC). The share of formal credit in the total volume of new credit is 66.5%.

Table 1 presents the distribution of loans by purpose and by type of lender. It is readily apparent that the predominant stated purpose of formal loans (all of which are short-term) is for the financing of current production. Most of the informal credit is reported to have been obtained for purposes other than production, with construction and social expenditures appearing dominant. Informal loans contracted for these purposes, however, cannot be diverted easily to finance day-to-day consumption or production because the lenders, mostly relatives and friends, can easily monitor compliance. The bulk of the fungible credit, defined as credit which is not granted for easily monitored purposes, in the study area thus comes from the formal sector (87%).

Given the dominance of formal credit, a key issue for the present study is the extent to which its supply is a constraint on households' desired activities. The survey data collected permit an answer to this question. Borrowing households were asked if at the going rates of interest they would have liked more institutional credit than the amount they were actually granted. Households which did not borrow were asked the reason for not borrowing. The most common reason for not borrowing was availability of sufficient own resources. The borrowers who indicated a desire for more credit and the nonborrowers who responded that they could not obtain credit are classified as credit-constrained. As reported in table 2, about 37% of the farm households in Gongzhuling were constrained by credit according to this classification. The liquidity position of credit-constrained households as compared to nonconstrained households is compatible with intuitive expectations: They have significantly lower deposits in financial institutions, and overall, their liquid resources per unit of land are 12% below those of unconstrained households.

A Model of Farm Household Consumption, Production, and Investment

Suppose the household considers the allocation of resources at its disposal at the beginning of the production period between the following uses: (*a*) current consumption, (*b*) investment, (*c*) the purchase of variable inputs for current production (including labor and fertilizers). Variable inputs, in combination with land and existing capital, will produce this period's output. Investment will not mature by the time this period's output is produced, but its contribution to the household's welfare may be accounted for through a valuation function which summarizes the contribution of capital to the future consumption stream. The household's initial endowments of liquid resources, family labor, capital, and land (the latter two assumed not convertible to liquidity during the period) can be augmented by borrowing at the beginning of the period. Whether the household can borrow the entire desired amount or is constrained by a binding upper limit on the availability of credit is of considerable consequence because it determines whether production decisions are separable from the consumption decisions. The household is assumed to maximize a utility function defined over consumption per family member in the current and next period, plus the utility of future streams of consumption summarized by the valuation function of next period's capital, per family member. The optimization can be carried out under two scenarios: (*a*) The supply of credit is greater than or equal to the demand (i.e., credit constraint not binding), and (*b*) the supply of credit is less than the notional demand for credit (credit constraint binding).

The essence of the results of such a model[3] is that under case (*a*) above, the supply of output is not affected by the level of liquidity (includ-

[3] A rigorous derivation of model implications is available to interested readers from the authors.

Table 1. Distribution of Loan Purposes by Type of Lender (Percent)

Source of Loans	Sample Size (Number of Loans)	Purpose					
		Production	Farm Equipment	Construction	Consumption	Social (Wedding, Funeral, etc.)	Other
Formal	209	92.3	4.3	1.9	0	1.0	0.5
Informal	44	9.1	4.6	20.5	15.9	27.3	22.7

Category	Sample Size (Number of Households)	% Constrained
Borrowers	145	41.3
Nonborrowers	42	28.3
All	187	37.4

ing credit), the size of the household's own family labor force or the total size of the household. The parameters of the output supply function in this case are determined by the production function alone. Under case (*b*), however, output supply is positively affected by increases in liquidity (e.g., increased credit supply) and in the household's labor endowment, while the effect of total household size is indeterminate. Increases in the initial endowments of land and capital would have a positive effect on output supply in both cases (*a*) and (*b*), while they would have an indeterminate impact on input demands, depending on substitutability. The parameters of the output supply function under case (*b*) are determined by both the production function and the utility function.

Econometric Specification and Empirical Results

The econometric model most suitable for estimating the output supply function with the data available to us is the switching regression model with an endogenous criterion function described in Maddala (pp. 223–228). The model postulates for any observation i

$$Y_{1i} = \beta_1 X_{1i} + U_{1i} \quad \text{iff } \gamma Z_i + U_i \leq 0 \tag{1}$$

$$Y_{2i} = \beta_2 X_{2i} + U_{2i} \quad \text{iff } \gamma Z_i + U_i > 0 \tag{2}$$

where X_{1i}, X_{2i}, and Z_i are vectors of exogenous or predetermined variables; β_1, β_2, and γ are the corresponding vectors of parameters; and U_{1i}, U_{2i}, and U_i are random disturbances. Y_{1i} and Y_{2i} are two possible values of the dependent variable, only one of which is actually observed for any given household, depending on the value of the (unknown) criterion function $\gamma Z_i + U_i$. The random disturbances are assumed to have a trivariate normal distribution, identically and independently distributed across households. Applied to the particular issue at hand, equations (1) and (2) may be viewed as the output supply equations under a nonbinding and binding liquidity constraint, respectively. The criterion for whether liquidity is binding or not is whether the demand for credit exceeds credit supply, and the criterion function $\gamma Z + U$, in our case, is the excess credit demand function (i.e., demand minus supply). Excess credit demand is not directly observable. However, from the survey responses, we know whether a given household is constrained or unconstrained by liquidity. Using data on the dichotomous responses, the vector of parameters γ can be estimated up to a proportionality constant by a probit procedure. The estimated parameters are then used to generate Mills ratios, which are incorporated in the second-stage estimates where equations (1) and (2), with their Mills ratio corrections, are estimated by a linear regression. Under model assumptions, the estimated coefficients are consistent and asymptotically normal, and with appropriate corrections to their estimated variance-covariance matrix (because of the heteroscedasticity of the stochastic disturbance terms in the second-stage estimates) can be subjected to statistical tests based on normality.

The empirical specification of the variables which constitute the vector Z involves both determinants of credit demand and credit supply. Thus, in the case of variables which affect both demand and supply in the same direction, one cannot predict a priori the expected sign. These variables are (with the expected effect on the probability of being credit constrained indicated in parentheses for those with an unambiguous effect): (*a*) land; (*b*) capital; (*c*) number of adults (−); (*d*) number of dependents;[4] (*e*) education; (*f*) farm experience; (*g*) savings in financial institutions (−); (*h*) total initial liquid assets (−); (*i*) outstanding debt to financial institutions (+); (*j*) total outstanding debt (+); (*k*) last season's income (−); (*l*) previous loan default dummy (+). In addition, eight dummy variables for townships were introduced. The results of the probit estimates are presented in table 3.[5] Two estimated coefficients are statistically signifi-

[4] The number of dependents plus number of adults constitute household size. While the number of adults has an unambiguous effect, household size (and consequently the number of dependents) does not.

[5] The households with special large-scale ceremonial expenditures were not included in the econometric analysis, as their liquidity requirements and borrowing patterns could be quite different. This reduces the sample size for the econometric analysis to 156. However, including these households, with appropriate dummy variables and interaction terms, does not alter the nature of the results qualitatively.

No. of observations	156

[a] The equation also included eight township dummy variables. These are not reported.

cantly different from zero at the 5% level of significance and have the theoretically predicted sign: savings in financial institutions and last seasons's income. Eighty-two percent of the observations are properly classified as being credit constrained or unconstrained, implying a fairly good fit.

The reduced-form output supply equation for liquidity-constrained households, estimated with the double-log specification, involves the following variables (with the direction of the expected effect noted in parentheses): (*a*) total liquidity[6] (+); (*b*) number of adults (+); (*c*) number of dependents (?); (*d*) land (+); (*e*) capital (+); (*f*) education (+); (*g*) farm experience (+). The specification for the households not constrained by liquidity is similar except for the first three variables, which do not theoretically belong in the reduced form for output supply.[7] The estimated coefficients are reported in table 4.

In the output supply equation for constrained households, (column 1) the estimated coefficient of the total liquidity variable is positive and statistically significantly different from zero at the 5% level of significance, but the number of adults and the number of dependents do not have statistically significant estimated coefficients. The hypothesis that all three variables do not affect the supply of output for constrained households has a F-statistic of 2.96 and is rejected at the 5% level of significance, confirming the theoretical predictions of the model. The quantity of land is an important and statistically significant determinant of output supply for constrained and unconstrained households (the estimated coefficients of the output supply function for the latter group are reported in column 2). It is also worth noting that capital, education, and farm experience have statistically significant positive effects on output for the credit-unconstrained households but have statistically insignificant effects for the credit-constrained households. This finding suggests that capital, education, and experience are less likely to contribute to output if the farmer's choices are constrained by liquidity.

While under the assumptions of our model it is not appropriate to estimate the output supply equation for the unconstrained households with the inclusion of liquidity and household composition variables (liquidity is theoretically endogenous for such households, and the estimated coefficients would be subject to simultaneity bias), we experimented with the estimation of such a hypothetical counterfactual case on the assumption that the classification was wrong and therefore these households were liquidity-constrained. The results (column 3 in table 4) indicate that none of the estimated coefficients of the first three variables are statistically significantly different from zero (the hypothesis that all three are not significant has a F-statistic of 0.55 and cannot be rejected at any level of significance), implying that the counterfactual case is not borne out empirically. Another experiment was the estimation of the model using the whole sample without separation, that is, as

[6] This consists of cash value of product inventory, deposits in financial institutions, and fungible formal loans. Informal credit was assumed nonfungible as observed in the second section. Total liquidity differs from the total initial liquid assets in the probit equation, which do not include current fungible credit.

[7] The equations should have included output and input prices. However, because the data are derived from a cross-section within a confined geographical area, there is no price variation, and price variables are omitted.

Table 4. Estimated Coefficients of Second-Stage Switching Regression Model for Output Supply (Reduced-Form)

if all households were liquidity-constrained. The results show that the estimated coefficient of total liquidity in the output supply equation would have been about two-thirds of that in column 1. Predictions based on the wrong estimated coefficients would thus lead to significantly inaccurate assessments of the effect of credit on output supply.

Implications

Based on the estimated coefficients, if every credit-constrained household in the sample is given an additional credit of 17.82 yuan (equal to 1% of the average level of liquidity of the credit-constrained households), the total output of these households may be projected to increase by 201.08 yuan, or approximately 0.04% of the total output. Thus, on average, one additional yuan of liquidity (credit) would yield $201.08/(17.82 \times 48) = 0.235$ yuan of additional gross value of output. These results suggest that for the area of China covered in the present study, a significant proportion of the short-term credit provided by the rural credit cooperatives as "production credit" may actually be utilized for consumption and investment. Indeed, medium- and long-term formal credit is practically nil among the agricultural households in our study areas, and a similar picture is given by aggregate statistics. Rolled-over short-term credit is sometimes utilized to finance small-scale investments. A recent study by Feder et al. (1990a) finds that the diversion of short-term credit for farm investment is about 40% for an average household in the study area. This, in turn, implies that almost a third of the formal credit is utilized for consumption (whether of current goods or durables).

The results of the study highlight two important factors which should be considered when evaluating the likely impact of agricultural credit expansion: (*a*) Not all farmers, and sometimes only a minority, are constrained in their farming operations by inadequate credit; (*b*) expanded supplies of formal credit will be diverted in part to consumption, thus the likely output effect will be smaller than that which is expected when all funds are assumed to be used productively. These ideas have been propounded by the Ohio State school critics of credit supply-led development schemes. The present paper thus provides empirical verification of these views.

Analyzing the Farm-Level Impact of Agricultural Credit: Discussion

Richard L. Meyer

In the 1960s and 1970s, many studies were conducted to evaluate and measure the demand for agricultural credit in developing countries and the impact of many subsidized credit programs then in effect, especially those designed to increase small farmer access to loans. The 1973 AID spring review of small farmer credit, a comprehensive review of programs in several developing countries, represented the first major occasion when serious doubts were raised about the real impact of such programs.[1] Our critical review of research conducted up to the late 1970s led us to question the basic methodology of many impact studies and, therefore, their empirical results (David and Meyer). One fundamental problem was that much of the research failed to account for the wide range of production, consumption, and investment activities undertaken by a rural household. Given the fungibility of farm-household cash flow management, it is difficult to identify the true impact of loans supposedly given for farm production. Production loans from financial institutions may not contribute much additionality to farm input use and output if, because of fungibility, they simply substitute for own savings or other sources of loans.

A second shortcoming concerned the well-known attribution problem. Many studies tried to measure credit impact by observing differences between borrowers and nonborrowers or before and after borrowing. But loans were often granted as part of multipurpose agricultural programs which provided subsidized inputs and intensive extension services in addition to credit. Often the authors simply attributed to credit any positive differences found between borrower and nonborrower groups, thereby ignoring the possible impact of these inputs and extension.

A third problem arose because of the concessionary loan interest rates employed in most programs. Low interest led to excess demand for loans and the nonprice rationing that occurred often resulted in large loans to farmers with greater factor endowments, access to better inputs and technical information, and better management. Therefore, borrowing could be the result rather than the cause of differences observed between borrowers and nonborrowers.

The interesting studies presented in this session employ new theoretical and quantitative approaches to explore more contemporary credit impact issues in three widely different developing countries. In the first paper, Anderson analyzes the possible link between changes in farm labor contracts and the large increases during the past decade in real interest rates on rural loans for sugarcane farmers in northeast Brazil. This research is particularly interesting because no developing country matches Brazil in the magnitude of credit subsidies used to stimulate agricultural growth during the past couple of decades. Anderson notes that during the cheap credit period of the 1970s, permanent employment grew faster than temporary (volante) employment because permanent contracts became an increasingly attractive way to guarantee the availability of harvest season labor. During the 1980s, however, the permanent labor share reportedly declined. On her sample farms, the decline was from 65% in 1978–79 to 57% in 1988–89. Her review of empirical data leads her to discount the role of rising wage rates and cane prices, extended social security benefits, mechanization, and herbicide use in explaining increased reliance on temporary harvest labor. Rather, she believes it is the result of the sharp increase in interest rates, from a negative 60% or 70% real rate in the early 1980s to a positive 7% to 9% by 1987, that raised the cost of slack season labor. Her arguments are plausible and well presented, but she lacks robust time-series data to rigorously test them and her cross-sectional model does not contribute strong evidence. No infor-

[1] This review was the last of the large-scale reviews conducted by AID of specific development issues. The results of this ambitious undertaking are summarized in Donald.

mation is provided to show if the borrowing patterns of sugarcane farmers actually changed over time in response to the interest rate changes. We should expect that a long regime of subsidized rural lending, such as existed in Brazil, would have distorted resource allocation. Shifting to positive interest rates should encourage adjustments which, among other impacts, could alter labor relations. If the huge credit subsidies led to a build-up of mechanization on farms and in sugarcane mills, their abrupt removal could prompt a reduction in aggregate employment in the entire sugar sector. Under such circumstances, interest rate reform would likely have broad consequences.

In the second paper, Carter and Wiebe model how differential farm access to production and consumption credit can influence productivity and agricultural structure in the Kenyan highlands. Without describing the characteristics of the sample, they analyze patterns of output, net returns, family income, and profits per acre for 109 farms. They find the typical result that small farms produce relatively fewer commercial crops and earn lower income and profits than larger farms. They model a household that must finance subsistence, purchased labor, and fertilizer out of wage earnings and borrowed funds. They assume, without providing evidence, that credit is a function of land endowment, so it is not surprising that small farmers face binding working capital constraints because of limited family labor and borrowing capacity. This helps explain the pattern of land allocation and related farm profits and suggests that large farms will be able to outbid small farms when land markets become active.[2]

In a sense this paper takes us back more than twenty years because it is precisely the concern about differential access to credit that prompted the subsidized small farmer credit programs of the 1960s and 1970s. But evidence subsequently showed that targeted lending is not effective in resolving equity problems (Adams and Meyer). What we can hope for is that financial institutions will become increasingly sophisticated over time so that, if Kenyan lenders currently ration loans exclusively on land size, they will increasingly look at broader debt repayment capacity criteria in their future lending. It would have been interesting to have learned the authors' views about credit supply problems and their possible reform, in addition to the traditional warning about productivity and structure problems.

In the final paper, Feder et al. explore how credit constraints may affect farm efficiency following the adoption of the household responsibility system in northeast China. The strength of this research is in the careful analysis of survey data described in this and their other referenced papers. These papers really need to be read as a collection to appreciate fully their analysis. This particular paper reports on the data analyzed from a sample of 187 households in the corn belt of northeastern China. The other papers analyze data collected in other regions.

The authors are concerned that Chinese farmers face binding liquidity constraints leading to suboptimal use of production inputs. Unlike other countries with well-developed informal lenders, they argue that noninstitutional credit in this region is mostly provided interest free by relatives and friends for purposes other than production in circumstances that can be effectively monitored. Thus, the bulk of fungible credit comes from institutional sources.

Farmers who borrowed institutional credit but indicated a desire to borrow more at current rates of interest and nonborrowers who responded that they could not obtain such credit were classified as credit-constrained. This group, representing 37% of the farmers, also reported significantly lower deposits in financial institutions and had 12% less liquid resources per unit of land. In an earlier paper (1989), Feder et al. show that credit-constrained farmers had lower levels of input use and lower output than nonconstrained farmers in the sample. Their econometric results suggest that a doubling of formal loans would lead to an output gain of 3.8%. An additional dollar of liquidity in short-term funds would yield about 23¢ of additional value, but the long-term effect would depend on the return generated from funds diverted to investment.

Intriguing credit issues remain in this research. What explains the reported unsatisfied demand for credit? Relatively few farmers report input supply constraints. No strong evidence is presented of rapid mechanization or enterprise changes. Land cannot be easily transferred, so presumably farm size is fairly constant. In addition to the new production possibilities, the Chinese reforms seem to have unleashed a strong demand for housing investment, consumption, and ceremonial expenditures. Many of these expenditures are fairly large rel-

[2] The potential that larger farmers with higher profits and more favorable loan terms have for offering higher land bid prices is well established in the literature concerning U.S. agriculture. One well-known model for evaluating land prices is presented in Lee and Rask.

ative to the typical size of production loans and are not normally authorized uses of institutional credit. These circumstances give rise to the observed pattern and uses of noninstitutional loans and to a desire to divert production loans and household savings to these uses. Interest rates of 7% to 14% may be a small price to pay for fungible institutional loans if it helps the borrower escape scrutiny and monitoring of the friends and relatives who grant consumption and investment loans. However, there are always potential risks of discovery when diverting institutional loans. An even larger demand for such loans would likely emerge if the constraints on their use were relaxed.

What can we learn from these papers that contributes to the long-standing debate over the nature of rural financial markets in developing countries and the appropriate strategy to use in improving them? The China example reminds us that, if there are serious constraints in production inputs, there will be little demand for production loans. But if there are liquidity demands for consumption and investment, there will be a strong demand to divert fungible loans to these purposes. The greater the fungibility of institutional loans and the lower their interest rates relative to alternative sources, the more valuable they will be and the more likely will be the diversion of funds. Low interest rates lead to excess demand and nonprice rationing. This gives larger, more powerful farmers a reason to use their influence to get a larger share of the pie. It also gives rent-seeking loan officers an opportunity to extract bribes and other considerations from rationed borrowers. Borrowers who "buy" loans see little reason to repay them, so loan recovery is compromised along with the viability of financial institutions.

There is no question that getting an advantage in the credit market by obtaining a larger loan or better loan terms can translate into advantages in other markets. Access to loans and loan size are usually correlated with land ownership, particularly in underdeveloped formal financial systems. Therefore, inequalities in land are often at once the cause and the effect of credit market inequalities, as implied by Carter and Wiebe. This fact prompts policy makers to try to regulate financial markets so that certain groups, such as small farmers, gain greater access. But experience shows that this has been an ineffective policy, so equity concerns must be addressed more directly through interventions in other markets, especially land. The most that can be expected from the financial markets is that, through experience, lenders will learn to assess risks and returns correctly so that agricultural loans become part of their efficient portfolios.

It is also clear that regulation-induced distortions in financial markets, when a large volume of credit is involved, as was the case in Brazil, will greatly exacerbate existing inequalities and create distortions in resource allocation. There will be gainers and losers in the painful adjustment process following removal of such regulations. The cost of adjustment should be, but is not likely to be, part of the evaluation process when such regulations are considered in the first place.

Rural Poverty among Racial and Ethnic Minorities

Joyce E. Allen and Alton Thompson

Historically, rural minorities in the United States have been economically and socially disadvantaged.[1] Their disadvantaged status has its origins in institutional racism, human capital deficits, and geographical concentration in persistently poor areas with a low tax base and consequently minimal capital to invest in improving their socioeconomic conditions (Bedics, Durant and Knowlton, Kuvlesky et al., Moland, Tienda). Over the past twenty-five years, their plight has improved largely because of dismantling of *de jure* segregation; higher educational attainment; growth in the national economy; and expansion of education, training, and public transfer programs (Durant and Knowlton, Moland, Rodgers and Weiher). Nevertheless, rural minorities continue to be disadvantaged relative to minorities in urban areas and to whites in rural areas (Jensen 1990, Lichter, Lyson). In this paper, we examine recent trends and patterns in the economic status of rural minorities. Our focus is on the two largest rural minority populations, blacks and Hispanics. Further, we analyze the effect of race on poverty status and the determinants of poverty among rural minorities. Last, we address the policy implications of these findings.

Measure of Poverty

Prior to analyzing poverty trends, it is useful to examine poverty in a conceptual framework. As Davis (p. 11) has pointed out, "the word poverty has assumed a multiplicity of meanings at different times and places." While it is generally agreed that poverty refers to the inability to obtain basic necessities required to sustain a minimally adequate standard of living, it is difficult to operationalize the concept. Measurement of poverty is important for two reasons: (*a*) to determine who is economically deprived in order to target assistance to those persons and (*b*) to monitor progress over time in alleviating economic deprivation. There are many ways of measuring poverty, none of which is perfect. Moreover, estimates of the poverty population and the characteristics of that population are sensitive to the measurement tool. The official poverty level, as defined by the federal government, is an absolute standard as opposed to a relative one. In 1988, a family of four was considered to be in poverty if its annual money income was below $12,092 (U.S. Bureau of the Census).

The current measure of poverty was officially adopted by the federal government in the 1960s during the midst of the "War on Poverty." It is based on food needs of households of varying sizes and composition. The 1955 Survey of Food Consumption conducted by the U.S. Department of Agriculture (USDA) revealed that families of three or more persons spent, on average, approximately one-third of their money income on food. Thus, analysts at the Social Security Administration multiplied the cost of the Economy Food Plan (the least costly of four food plans developed by USDA) by three to derive poverty thresholds. The thresholds have been updated annually for inflation. Although some revisions occurred in 1969 and 1981, the original measure of poverty has remained basically constant over time.[2]

The deficiencies in the current measure of poverty have been well documented (e.g., Davis, Morris and Williamson). The nucleus of the

This research was funded, in part, by the Joint Center from a grant provided by the Ford Foundation and the Rural Economic Policy Program of the Aspen Institute.

[1] The terms rural and nonmetropolitan (nonmetro) are used interchangeably throughout this paper to refer to localities outside Metropolitan Statistical Areas (MSAs), as defined by the Office of Management and Budget.

[2] The following changes were made in 1969: (*a*) poverty thresholds were indexed to the Consumer Price Index in lieu of the economy food plan, (*b*) threshold for farm families was raised from 70% to 85% of the corresponding threshold for nonfarm families. The 1969 changes resulted in an additional 1.6 million persons being classified as poor in 1967. The separate thresholds for farm families were eliminated in 1981.

original poverty threshold was the Economy Food Plan, a plan designed for short-term emergency use. Morris and Williamson (p. 18) report that "a family could not expect to maintain a nutritionally adequate diet by following this diet on a long-term basis." Further, when the poverty thresholds were developed, in-kind benefits were not a major proportion of total income packages. However, over the years they have grown in importance. Indeed, food stamp benefits and Medicaid payments totaled $43.4 billion in fiscal 1988 (Office of the President). Annual food stamp benefits averaged about $600 per participant in fiscal 1988 (U.S. Department of Agriculture). Yet, in-kind benefits are excluded when determining poverty figures because countable income includes money income only. Another problem is that the definition of income refers to pretax income and thus ignores mandatory payroll taxes which reduce the amount of earned income available for consumption. In addition, researchers (e.g., Morris and Williamson) suggest that income is underreported in some government surveys, which results in inflated estimates of the poverty population.

Two other weaknesses in the measure of poverty are noteworthy. Consumption patterns have changed over time, but the current measure of poverty is based on data that are thirty-five years old, even though more recent data are available. In particular, the average proportion of income spent on food has declined from about 33% to less than 20%, which indicates that a multiplier higher than three could be justified, thus raising the poverty thresholds. Another dimension of the measurement problem is that the poverty thresholds do not vary by residence, implying that the same amount of money is needed in urban and rural areas to avoid economic deprivation. Despite these and other limitations, the official definition of poverty is an appropriate measure when examining poverty trends, largely because it has not changed over time and alternative measures have not gained widespread acceptance.

Rural Poverty Trends and Patterns

Data from the U.S. Bureau of the Census show that progress was made from 1970 to 1980 in reducing poverty among persons living in nonmetropolitan areas (table 1). This holds true across race and ethnicity. However, the decline was greatest among blacks. In fact, the rate for blacks declined by 26% compared to 18.3% for Hispanics and 3.7% for whites. Nonetheless, a disproportionate number of rural blacks remained impoverished. From 1980 to 1985, rural poverty rates increased largely because of national and global economic changes which adversely affected rural-based industries (e.g., farming, timber, oil, gas, mining) (O'Hare).[3] The percent increase was largest for Hispanics (33.3%), followed by whites (22.8%), and blacks (9.3%). From 1985 to 1988, rural poverty rates ranged from 2.9 to 0.6 percentage points above the 1980 level, despite the robust economic recovery which followed the 1981–82 recession. In 1988, 40.3% of rural blacks, 34.9% of rural Hispanics, and 13.1%, of rural whites were poor. The relatively high poverty rates during the economic recovery (especially among minorities in rural areas) appear to raise questions about the adage that "a rising tide lifts all boats." Indeed, Danziger and Gottschalk argue that demographic factors and changes in the shape of the income distribution limit the effectiveness of macroeconomic conditions in reducing poverty.

While poverty rates have been incessantly high among rural minorities, some population subgroups have been affected more than others. Specifically, persons in families with a female householder (no husband present) have substantially high poverty rates relative to the rates for all persons in families (table 2). Moreover, the majority of dependent children (under age 18)

Table 1. Poverty Rates for Nonmetro Persons by Race and Ethnicity, 1970–88

[3] Metro poverty rates also increased during this period. However, the increase was larger in nonmetro areas. For example, the nonmetro rate increased by 6.7% compared to 18.8% in metro areas. Further, by 1988, the metro poverty rate was only 2.5% above the rate reported for 1980. In contrast, the nonmetro rate was 3.9% above the corresponding rate for 1980.

in female-headed families are poor. In 1987, three-fourths of rural black children and two-thirds of rural Hispanic children in female-headed families were poor. The corresponding figure for rural white children was 51.4%. The data show that poverty rates are highest for young children (under age 6).

A number of negative outcomes are associated with growing up in a female-headed family. Garfinkel and McLanahan observe: "About half of them [female-headed families] are poor and dependent on welfare. The mothers and children in such families also have poorer than average mental health and use a disproportionate share of community mental health services. Most important, perhaps, compared with children who grow up in two-parent (husband-wife) families, the children from mother-only families are less successful on average when they become adults. They are more likely to drop out of school, to give birth out of wedlock, to divorce or separate, and to become dependent on welfare."

Table 3. Educational Attainment of Poor Nonmetro Householders by Race, 1987

Median years	12.1	10.4

Source: U.S. Bureau of the Census, Current Population Reports, Series P-60, No. 163, *Poverty in the United States: 1987*. Washington DC, 1989.

The literature also indicates that children from female-headed families are less likely than their counterparts in two-parent families to graduate from high school and are at increased risk of having low earnings and living in poverty. Further, several researchers have concluded that many of the negative outcomes are related to the extreme economic deprivation that exists in many female-headed families (Allen and Joshi).

Because stock of human capital of the householder is correlated with the household's poverty status, we examined data on one indicator of poor rural householders' human capital, their highest level of education (table 3).[4] Not surprisingly, a sizable proportion of poor rural householders have not completed high school, a finding which emphasizes their human capital deficiencies. Moreover, a substantially higher segment of blacks (63.2%) than whites (43.9%) were in this category. The data reveal that only a small proportion (5.5%) of poor rural black householders had at least one year of college. Some of the observed deficiencies in the human capital of rural blacks are probably the legacies of segregated schools in the South combined with a historic pattern of inadequate school financing. For example, Lyson has found that rural blacks and Hispanics are concentrated in counties with lower school expenditures compared to the expenditures in rural counties with low concentrations of minorities. He estimates that school expenditures were 17.8% less in rural counties with large concentrations (30%, or more) of

[4] Comparable data were not available from the Bureau of the Census on the educational attainment, work experience, and occupation of poor nonmetro Hispanic householders for 1987.

blacks and 12.2% less in those counties with large concentrations of Hispanics.

Human capital skills can influence employment opportunities and, thus, poverty status. Data from the U.S. Census Bureau show that a sizable proportion of poor rural householders are employed (table 4). For example, 42.9% of poor black rural householders were employed in 1987, but only 17.5% of them worked year-round (50–52 weeks). The proportion falls to 13.3% for those who worked full-time (35 hours or more per week) year-round. The dominant reasons that poor black rural householders did not work were illness or disability, keeping house, or inability to find work. Many of those who were keeping house likely were female householders with dependent children. For persons in this category, child care costs combined with limited human capital could mean that if they were employed, their earnings would not be sufficiently high to ensure improvement in their economic status.

Table 4. Work Experience and Occupation of Poor Nonmetro Householders by Race, 1987

Note: Poverty status and work experience in 1987. Families as of March 1988.

[a] The Census Bureau includes members of the armed forces in the aggregate data on which work experience of householders is based but it does not report data on them separately. Thus, the percentages for worked and did not work do not total 100.

[b] Includes clerical.

Poor black rural householders who were employed were heavily concentrated in the following low-wage occupational groups: services and operators, fabricators, and laborers. Moreover, they held a narrower set of occupations compared to their white counterparts. This finding could reflect the nature of the job market in counties where rural blacks are heavily concentrated. For example, Lyson and Falk indicate that Black Belt counties are dominated by industries that are either slow growing, stagnating, or declining. Further, Bellamy and Parks found that Black Belt counties gained few or lost more manufacturing plants compared to non-Black Belt counties and tended to have more routine (i.e., low-wage) manufacturing.

Determinants of Rural Poverty

We used data from the March demographic file of the 1988 Current Population Survey, conducted by the Bureau of the Census, to examine determinants of rural poverty. The unit of analysis is nonmetropolitan families headed by a civilian. Table 5 presents a summary of the operational definitions of the variables used in the empirical model. Past studies (e.g., Thompson, Traub, and White) have found that several of these variables are important predictors of poverty. Based on previous empirical studies, we hypothesized that the following rural subpopulations will have a greater propensity to be in poverty: blacks, families headed by older per-

Table 5. Operational Definitions of Variables

Variables	Coding
Dependent variable:	
Poverty	0 = income at or above poverty threshold
	1 = income below poverty threshold
Independent variables:	
Race	1 = black; 0 = white
Age	Age (in years) of family head
Family type	1 = female head; 0 = other[a]
Family size	Number of persons in family
Region	1 = South; 0 = non-South
Education	Years of schooling of family head
Earners	Number of earners in family
Weeks worked	Annual number of weeks worked by head
Industry	1 = secondary; 0 = primary

[a] Other refers to families headed by a married couple or male householder with no spouse present.

sons, female householders, large families, Southerners, families headed by persons with low levels of education, families who have only one earner, families headed by persons who work a limited number of weeks during the year, and families headed by persons who are employed in the secondary sector.

Poverty status, the dichotomous dependent variable, is based on the federal thresholds. Most of the independent variables presented in table 5 are straightforward and require little explanation. One exception, however, is industrial structure. According to the dual labor market theory, some of the observed earnings and/or income differentials are related to the structure of the job market. Proponents of this theory (e.g., Averitt, Hodson, Tigges) argue that jobs can be divided roughly into two sectors, primary (monopolistic) and secondary (competitive). Firms in the primary sector tend to be large, diversified, capital intensive, and to offer high wages and opportunities along clearly defined career ladders. Conversely, firms in the secondary sector tend to be smaller, more labor intensive, more vulnerable to the vagaries of the labor market, and to offer low wages and limited opportunities for career mobility. Based on Hodson's industrial typology, we classified the following industries as constituting the primary sector: durable manufacturing; construction; transportation, communication, and public utilities; wholesale trade; finance, insurance, and real estate; public administration; and professional and related services. The secondary sector, in the model specification, consisted of nondurable manufacturing; retail trade; business and repair services; personal services (including private household); entertainment and recreation services; mining; and agriculture, forestry, and fisheries.

The logistic regression estimation procedure that we employed enabled us to assess the probability (or odds) of a person being in poverty as a function of a set of explanatory variables. The model is of the form:

$$\log(P(pov)/1 - P(pov)) = \alpha + \Sigma\, \beta_i X_i,$$

where α is the intercept term and β_i is the set of coefficients for the explanatory variables, X_i.

Equations (1)–(4) in table 6 contain the effects of the log-odds and odds for selected variables that we hypothesized would affect the probability that families in rural areas would be poor. The signs on the independent variables were as expected, with the exception of age of head

Table 6. Logistic Regression Models of Poverty Status: Nonmetropolitan United States

	Estimates For Models			
Independent Variables	Total Sample (1)	White Respondents (2)	Black Respondents (3)	Hispanic Respondents (4)
(Intercept)	5.81	5.08	7.00	4.22
Race	0.65			
	1.91**[a]			
Age	−0.04	−0.04	−0.04	−0.03
	1.04**	1.04**	1.04**	1.03
Family type	1.19	1.14	1.47	0.93
	3.28**	3.13**	4.35**	2.53**
Family size	0.46	0.45	0.66	0.53
	0.63**	0.63**	0.52**	0.58
Region	−0.07	−0.07	−0.09	0.59
	0.93	0.93	0.91	1.80
Education	−0.18	−0.18	−0.22	−0.09
	1.20**	1.20**	1.25**	1.09
Earners	−0.99	−0.89	−2.00	−1.11
	2.69**	2.44**	7.39**	3.03
Weeks worked	−0.05	−0.06	−0.05	−0.05
	1.05**	1.06**	1.05**	1.05
Industry	0.76	0.77	0.80	0.67
structure	2.14**	2.16**	2.23**	1.95*
Model X^2	1515.91	1216.80	210.78	93.17
R^2	0.29	0.26	0.37	0.22

Note: For each independent variable, two estimates are shown. The first value is the effects on the log odds, and the second value is the effects on the odds.

[a] Double asterisk indicates $p \leq .001$; single asterisk indicates $p \leq .05$.

and region.[5] To aid in interpretation, we transformed the log-odds to the odds by exponentiating the log-odds regression coefficients. Thus, we can determine the magnitude and relative importance of selected variables, including race, in accounting for poverty among families in rural areas. In the sections below, we focus primarily on the substantive magnitude of the odds coefficients. Variables described as significant were statistically significant at the 0.001 level, unless otherwise noted.

The results from equation (1) show that the most important variable in accounting for poverty among persons in rural families is family type. That is, persons in female-headed families are significantly more likely to be in poverty than persons in families headed by a married-couple or a male householder. The odds of persons in female-headed families being poor is 3.28 times higher than for other family types.

Number of earners, industrial structure, and race follow next in importance. As expected, poverty was a decreasing function of the number of family members who had earned income. The model results show that each additional earner in the family reduces the odds of being in poverty 2.69 times. Converting the odds coefficient to a proportional effect reveals that each additional worker decreases the probability of a rural family being in poverty by 6%. Another finding pertaining to the labor market indicates that families headed by persons employed in the secondary sector have a greater likelihood to be in poverty than those headed by a person employed in the primary sector. Specifically, the former group is more than twice as likely to be in poverty than the latter. Similarly, black rural families were nearly twice as likely to be in poverty compared to their white counterparts.[6]

Education of the householder, a proxy for the stock of human capital, had a modest, but significant, effect on the odds of a rural family being in poverty. Converting the odds coefficient to a proportional effect, each additional year of education decreased the probability of being in poverty by 1.5%.

Age of the householder and the number of weeks that he or she worked had meager effects on the probability that rural families were poor. The odds coefficients for these variables were almost 1:1 (even odds). The direction of the relationship shows that the probability of being poor decreased modestly with age and the number of weeks worked. Family size and region had the smallest effects on the odds that rural families were poor. Specifically, the probability of a rural family being in poverty increased with family size; each additional family member increased the odds of being in poverty by 0.63, holding other factors constant. Further, rural families in the South did not exhibit a greater likelihood of being impoverished than their counterparts in other regions of the country.

As shown above, the race differential in the probability of being in poverty was relatively substantial. Equations (2) and (3) provide information on the nature of these differences as reflected by the magnitudes of the coefficients. In addition, equation (4) provides comparable information for persons of Hispanic origin. Without exception, the coefficients for white families mirror those for all families. A salient finding for the black respondents, however, is that the number of earners in the family contributed substantially to the likelihood of being in poverty. Holding other factors constant, each additional family member who had earned income was estimated to reduce the odds of being poor by 7.39 times. This odds coefficient has, by far, the largest magnitude of all the variables in the four equations. Moreover, it was three times larger than the corresponding odds coefficient for the white respondents (2.44) and nearly two and one-half times larger than the odds coefficient for Hispanics (3.03). A second salient finding for the black respondents is the importance of family type. The odds of a rural family headed by a female being poor is 4.35 times greater than for families headed by a married couple or male householder. The corresponding odds coefficients for the white and Hispanic families were 3.13 and 2.53, respectively.

The number of earners and family type were the two variables that contributed most appreciably to the probability that rural Hispanic families were poor. This was the same pattern observed for whites and blacks. However, there were some ethnic differences in the nature and magnitude of the odds coefficient for region. Rural Hispanics living in the South were 1.80 times more likely to be in poverty than their counterparts in other regions. This finding was significant at the 0.10 level.

[5] In some preliminary models, age of family head was specified as a quadratic variable. However, it was not statistically significant in these models.

[6] Because of the small number of Hispanics relative to non-Hispanics, the ethnicity variable was dropped from the model. Inclusion of that variable would have resulted in an unreliable log-odds coefficient for ethnicity. In fact, SAS LOGIST procedure would not generate the coefficient.

The substantial similarity of the odds coefficients for the remaining five variables—age, family size, education, weeks worked, and industry structure—show that the racial and ethnic differentials were minimal. Although, the magnitudes of the coefficients were different for blacks and Hispanics, the rank order of importance for the variables included in the model were identical.

Policy Implications

The findings in this study have implications for public policies that are designed to ameliorate poverty among rural minorities. As shown above, family type is an important determinant of rural poverty. Because many female householders with dependent children are not employed, they rely heavily on Aid to Families with Dependent Children (AFDC) benefits for income. In the South, where rural minorities are concentrated, AFDC benefits are typically low. For example, the maximum monthly benefit in Mississippi for a poor family of three was $120 in 1989 (U.S. House of Representatives). Thus, policies that would be beneficial to poor rural minority female-headed families include (*a*) raising the level of AFDC benefits and (*b*) assisting female householders to enter the labor force. For many of these householders, affordable, reliable, quality child care would be a necessity. Expansion of the Child Care Tax Credit could assist female householders because it would provide additional financial assistance for work-related child care expenditures. Because Congress has passed legislation this year to expand child care tax credits and the Bush administration has also proposed legislation in this area, it appears likely that some expansion will occur in the near future. However, given the current budget deficit, the tax credits are unlikely to be expanded sufficiently to have a large effect on rural poverty among female-headed families with dependent children.

The results from the model show that regardless of human capital, industrial structure has a substantially significant effect on rural poverty. This finding has implications for job creation strategies. If rural poverty is to be reduced, *ceteris paribus,* then the bulk of jobs needs to be created in the primary rather than the secondary sector. Otherwise, a large proportion of rural persons would be among the working poor because their earnings would not be sufficient to lift themselves and their families out of poverty. However, rural areas are at a competitive disadvantage when seeking primary industries, in part the result of deficiencies in the human capital of their population.

Although improvements are needed in the human capital skills of rural minorities, the fact that they are heavily concentrated in economically disadvantaged areas implies that local resources may not be available to support needed improvements in the quality of education. Thus, school financing issues are critical. It is important that state governments address inequities in school financing. Recent lawsuits in Texas and Kentucky have focused attention on the effects of linking school financing primarily to local resources in those jurisdictions where poverty is pervasive. School financing, based on the wealth of the entire state, could help upgrade the human capital of rural minorities.

The logistic model revealed that race is an important determinant of rural poverty. Based on this finding, we suggest that equal employment policies combined with enforcement of civil rights laws are critical strategies for alleviating poverty among rural blacks. These efforts should also be beneficial to rural Hispanics.

In conclusion, the policies cited above are vital to help ameliorate poverty among rural minorities. Some (e.g., human capital development, job creation) could be important elements of a comprehensive rural development program. Rasmussen contends that the first rural development efforts (e.g., improving physical characteristics of rural areas—roads, electricity, et cetera) met with quick and quantifiable success but that unemployment, persistent poverty, and inadequate housing may be more intractable. Indeed, these conditions which disproportionately affect rural minorities are the challenges that policy makers face in the 1990s.

The Impacts of Structural Change and Public Policy on the Rural Disadvantaged

Ralph D. Christy and Enrique E. Figueroa

The social and economic consequences of technological and institutional change in U.S. agriculture have untold and largely unrecorded impacts on economically disadvantaged ethnic minorities in rural America. Over the past few decades, we have witnessed rapid economic transformation in agriculture and in rural communities. One of the most important characteristics of rural America during the 1980s has been the upward trend in the poverty rate. Census Bureau data from 1987 indicate that 16.9% of people living in nonmetropolitan areas had incomes below the poverty level, up from 12.6% in 1970. The national poverty rate was 12.5% in 1970 and 13.5% in 1987. Poverty rates were especially high among racial and ethnic minorities. For example, the poverty rate was 44.1% among blacks and 35.6% among Hispanics residing in nonmetropolitan areas (U.S. Census 1987).

Put succinctly, the argument does not favor the use of technologies and institutions to retain a larger-than-necessary segment of our population in agriculture. At best, multiplier effects from agriculture are much lower than other economic activities that are industrial or manufacturing based. As a result, agriculture's major contribution to an economy is to "free-up" labor and resources to advance urban, industrial, and service-based economic development. Our concern with the transformation that occurred in agriculture, however, is that the disadvantaged—particularly ethnic minorities—who were spun out of agriculture were not adequately re-equipped to contribute to a changing economy for a number of reasons, including lack of equal opportunity and premarket and labor market discrimination. This situation now meets us head on; for, if the national statistics are correct, by the year 2000, three-out-of-five new entrants in the work force will be nonwhite. This projection spells potential problems for a country finding itself drawn closer to a global economy where efficiency, comparative advantage, and competitiveness rule the day, and that, for several reasons, has not invested sufficiently and wisely in its human resources. Therefore, for the first time in the nation's history, a situation exists where what is good for the country coincides directly with the interest of minorities (Wharton).

The objective of this paper is to focus on the relationships between technological and institutional change and the human capital needs of minorities in rural America. Specifically, this paper seeks to (*a*) review human capital theory in the context of a framework for analyzing economic change in agricultural and rural societies, (*b*) provide examples of the minority experience under structural adjustments in agriculture, and (*c*) offer some policy prescriptions for professional considerations. This paper is organized in sequential order under these three headings.

Theory of Change and the Role of Human Capital: An Evolutionary Approach

Institutional or evolutionary economics offers a framework which seeks to explain change. It alleges that a useful classification of the fundamental forces which influence the economic process consists of technology, institutions, resources, and people. These separate influences, and the interaction between them, provide a useful conceptual framework to study the impacts of technological and institutional changes on minorities in rural areas. Neoclassical economics has come under attack as a useful framework in policy analysis and social change because the theory purports to seek equilibrium as

The authors are an associate professor and an assistant professor, Departments of Agricultural Economics, Louisiana State University and Cornell University, respectively.

Comments of Alvin Schupp and Gary Thompson on earlier drafts of this paper are much appreciated by the authors.

opposed to explain change; the assumptions are unrealistic and too easily violated (Hirshman), and policy analysis of social and economic problems requires multidisciplines (Bonnen).

The Theory of Change

The theory of change operationalizes the four driving forces as follows: according to Gordon and Adams, technology refers to the capabilities that people possess for improving their material welfare and for performing tasks in ways that involve less effort or are more effective. Technology is central to the basic tenets of institutional and neoclassical economic theory. To an institutionalist, the economy is influenced by an ongoing, cumulative, dynamic technological change as opposed to the view that an economy is driven by a desire of individuals for monetary gain (invisible hand). Institutional economics treats profit-seeking conduct as one of several institutionalized behaviors, not the only influencing force in society. Institutions represent the constellation of rights and duties that determine domains of choice for individual members of society. Humans, with their evolving biology, are the actors who manage the technology and the participants who form institutions that are subject to the constraint imposed by resources. And the final ingredient in influencing economic change is resources. In broad terms, resources include the whole physical and energy content of the universe (Gordon and Adams).

The theory of change is expressed as the interaction between changes in technology, institutions, humans, and resources. The institutional theory of change views technology as a primary and dynamic element in an economic process. Gordon and Adams write: "Monitoring all these interrelations are individuals, who are what they are in terms of physique and behavior as a result of their evolving biology and the impact of the evolving interaction of knowledge, institutions, and resources upon them. Also, the institutions of society are monitoring the individuals and constraining their behavior. Technology and resources, and individual biology, are evolving and interacting and conditioning individual attitudes and behavior. All this involves an ongoing, mixed-up process."

For example, a change in technology requires individual and institutional change. Likewise, change in institutions influences the behavior of humans and informs organizational performance.

Human Capital Development

The economics of human capital was introduced by T. W. Shultz with the publication "Investing in Human Beings" (Blaug). Later, Becker, in *Human Capital*, put forth a new theory by viewing improvements in humans as an investment (i.e., capital investment) in contrast to a consumption activity, particularly as it relates to post-secondary education. This research coincided with the early developments of the "War on Poverty" and, as such, much of the thinking of that time was incorporated into the policies and programs directed toward human capital development of the poor. Therefore, research was directed toward answering the question: Does the program make a difference? This research focused little on the interaction between technology, institutions, resources, and human capital.

In pursuing this question, the neoclassical debates of economics drew researchers to the examination of the relationships between educational inputs and dimensions of expected outputs. Thus, educational production functions took the form

$$Y = f(x_1, x_2, x_3 \ldots x_n),$$

where Y is test scores, earnings, or economic development; and X_1, X_n are vectors of inputs to include expenditures, teacher quality, physical plants, etc.

As a result, we have a body of economic research that uses alternative measures of outputs and different measures of inputs in an effort to identify and understand the factors contributing to improved educational results.

Now, before drawing out some of the major findings, it is important to understand some shortcomings that are inherent to the framework (i.e., production function) and to the nature of the problem being addressed (data, measurement and operational). Nevertheless, by drawing on several review articles and key research, insight is provided on the relationship between educational inputs and test scores, earnings, and economic development.

Test Scores

Much of the initial work applying the educational production function approach to the explanation of test scores was directed to the gap between the scores of minority students and white students. The use of test scores as a dependent

variable was an attempt to evaluate schools' performance. This approach, despite its limitations, has provided some consistent findings important to educational policy makers (Hanusheck). (*a*) Differences in family socioeconomic background lead to significant achievement differences. (*b*) Differences among schools and teachers are important in explaining differences in achievement. (*c*) Differences by race (family background) interacting with school resources influence achievement. Hanusheck points to a number of uncertainties. Given the contradictory results of the studies and measurement problems, the effect of school quality, peer compositions, and dynamics of the educational process of achievement are not clearly understood.

The policy implications of studies evaluating achievements, particularly as they relate to minorities, centers around the effectiveness of compensatory education (i.e., Head Start) aimed at preparing preschool students for school (Title I of the Elementary and Secondary Education Act of 1965) and improving the achievement of disadvantaged children in elementary schools (measured by standardized test scores). Mullin and Summers concluded that the programs have a positive, though small, effect on the achievement of disadvantaged students. Sawhill summarized the results of this research as: (*a*) I.Q. gains are large in the immediate post-program period but vanish over time. (*b*) Some measures of school success, such as normal grade progression and not being required to attend special education classes, remain positive throughout the follow-up period. (*c*) The evidence for other indicators of scholastic achievement is mixed. (*d*) Three studies found lower high school dropout rates among participants.

Earnings (Income)

A fundamental assumption for investment in education, influenced by the human capital literature, is the existence of a positive relationship between educational levels and earnings. In the aggregate, the positive relationship between expenditures on human capital and earnings should reduce poverty rates among targeted groups.

What does the evidence suggest? According to Sawhill, the ability of human capital programs to increase productivity and earnings has been varied, primarily because of research design problems. Little is known as to why specific programs work. Do education and training actually increase productivity, or do they simply give people credentials or access to mainstream labor markets that helps them to land jobs? Drawing on survey literature, Bassi and Ashenfelter conclude that employment and training programs have been neither an overwhelming success nor a complete failure in terms of their ability to increase the long-term employment and earnings of disadvantaged workers. Major results of training programs are: (*a*) Positive results for adult women linked to job search skills that aid women entering the labor market. (*b*) No consistent findings of a significant effect among adult men. (*c*) Youth programs (i.e., Job Corps) are effective in enhancing incomes.

Research that focuses directly on educational and training programs in rural areas is limited. Huffman concluded that the lower productivity of black farmers is undoubtedly one of the factors contributing to the exodus of black farmers from southern agriculture at double the rate of white farmers during tthe 1950s and 1960s when agricultural technology was changing rapidly. This study highlighted the differences in educational levels between black and white farmers and the influence of extension service and research programs of land grand universities (1862 and 1890), given the historical discrimination practices of the region.

Economic Growth and Development

The empirical or statistical evidence supporting the relationship between human capital and economic development is not as robust as the case linking education to test scores and individual incomes. Economic development is an ongoing process and a more complex concept than the relationship between test scores and income. Economic development encompasses the process which an economy undergoes in transforming itself from a rural, agricultural based economy to an urban industrial-service-based economy. Schultz (1961) made this observation in attempting to link education to economic growth. "The connection, however, between education and economic growth is exceedingly complex. It is far from easy to identify those fruits of education that consist of improvements in the capabilities of a people that are useful in economic endeavor. It takes years as a rule to develop these capabilities and then it requires more years for these capabilities to prove their worth in production. It is not as simple as adopting hybrid seed corn or applying a few bags of

fertilizer in the spring and garnering the crop in the fall" (p. 47).

A region of the United States where questions of human capital and economic development are frequently posed is the rural south (Swanson). Education reform is seen as a strategy to obtain economic development within the region (Deaton and Deaton). Skees and Swanson conclude that the single most important factor associated with the well-being of rural communities is the level of education among the adult population. They note a striking consistency among the counties in Kentucky with low levels of adult education and median family income; these counties have the highest unemployment and underemployment and poverty. Generally, research suggests that human capital development is a necessary but not sufficient requisite for economic development.

Institutional Implications of Human Capital Development

Much human capital research has involved the application of neoclassical economics with the appropriate statistical and production function methods. Institutional research in the human capital development literature is not as well developed. However, a parallel exists between production economics and institutional economics, which has a focus on prescribing and predicting outcomes derived from alternative institutional arrangements (Schmid). Schmid draws this parallel by suggesting that one may seek to explore the effect of alternative institutions for human behavior in a similar way production economics attempts to explore the effect of alternative inputs on different levels of output. This type of inquiry is concerned with the question: Do alternative institutions make a difference?

Research using the so-called education production functions have attempted to link selected inputs to levels of output measured in terms of test scores, income, or economic development. The institutional approach seeks a link between alternative institutional arrangements (i.e., teacher training, capital improvements, administration) and the behavior of the individuals seeking human development. For example, institutional research may want to analyze the relationship between the organizational structure of school and learning attitudes, value of knowledge, and peer influences. Note two fundamental problems from this approach: because they are often case studies, the research focuses upon given attributes of schools and the learning process; and, second, they consider the relationship between a particular attribute and student outcomes to the exclusion of the possibility of interactions of inputs and exclusion of other attributes. Nevertheless, the production function approach provides policy relevance to the research efforts by drawing attention to the effects of inputs—student characteristics, teacher and school inputs—on the performance of the school system.

The broader question—How to capture the interrelationships between technology, institutions, resources, and human capital?—has particular implications for minorities in agriculture and rural society. The examples of the impacts of structural change and public policy on selected rural disadvantaged groups will provide insight into how changes in technology and institutions bear major consequences that are often detrimental. These relationships have in the past been largely outside the policy and research debates of our profession.

Structural Change and the African American Farmer and Rural Resident

Since, the early years of our nation, the role of the African American in the agricultural economy has been influenced by a series of institutional and technological changes that have transformed society profoundly, frequently placing this minority group in a precarious position. (This section draws on Johnson et al.) Both institutional and technological changes have played major roles in the transformation of agriculture and rural society; however, the consequences of these changes for the African American have been little understood (or understood perhaps too late) and up to now have received a low priority on social science research and public policy agendas. Several factors may account for the lack of information on the African American in rural society: (*a*) research programs, because of recent federal legislation, are relatively new to 1890 institutions, (*b*) ill-conceived and conflicting public policies, and (*c*) disparity in economic growth across regions in the United States.

The total number of nonwhite farms declined by 91% from 481,601 in 1954 to 44,640 in 1987. White farms declined by 48% from 4,301,420 to 2,240,976 during the same time period. Thus, nonwhite farms disappeared at almost double the rate of white farms. Nonwhite farms declined by 94% compared to a 56% decline for white

farms between 1954 and 1987 in the South, a region where the majority of African American farmers exist. Further, nonwhite farms in 1954 accounted for almost 20% of all farms but by 1987 they accounted for only 3.0% of all southern farms.

Since 1910 the amount of land owned by African American farmers has steadily decreased, with the exception of the period from 1940 to 1950. During that decade, under the prosperous conditions of the war and immediate postwar period, there was a growth in both the number of African American farmers who owned land and the amount of land owned. Hall reports that the peak period for minority-owned land was in 1920 when 13,949,000 acres were controlled by African Americans. By 1987, 22,954 African American owned farms held 2,636,896 acres of land, representing a new loss of 11.3 million acres of land. The amount of land owned by African American farmers continued to be proportionately less than land operated by white farmers. Several factors contributed to the decline of African-American-owned U.S. farmland, including credit policy, rural education, and intergenerational transfers.

The analysis of the impact of the fundamental changes occurring in rural America on the African American must consider demographic realities. Over 90% of U.S. African Americans resided in the South at the turn of the century and, despite the tremendous outflow of African Americans from the rural south, the southern region of this country contains more than half of the U.S. African American population (Lichter and Hester). More important, Lichter and Hester further observed that well over 90% of all nonmetropolitan blacks resided in the South. Therefore, an analysis of the social and economic well being of the rural African American should focus on the development of the rural South.

Increments in the poverty rate have been a major concern. In some counties—particularly in the South—poverty persists. A county with persistent poverty has had per capita income in the lowest quintile, i.e., the lowest 20% in terms of per capita incomes among counties in the United States for at least three decades (Bellamy and Ghelfi). These counties are characterized by low educational levels, poor health (physical disabilities), and a high percentage of African Americans in their population. Bellamy and Ghelfi note that poor counties have lower per capita income than those counties which improved between 1979 and 1984. Understanding the evolving characteristics of these counties may suggest policy alternatives for enhancing the socioeconomic conditions of their residents.

Institutions and technology are fundamental forces giving rise to the changing structure of agriculture and the status of rural communities. Understanding how these changes have influenced the economic well-being of African Americans is a challenge for policy makers and professional economists. This paper argues that institutional and technological forces have demonstrably placed African Americans, partly because of the lack of human capital development, in a precarious position. African Americans, as a group, still earn lower incomes (Smith and Welch), are three to four times more likely to experience poverty in rural areas, and have exited agriculture at twice the rate as their white counterparts. The decade of the 1980s has also witnessed deterioration in the educational progress of African American youth at the high school (Jaynes and Williams, p. 334) and the college levels (Carter and Wilson). This knowledge becomes more alarming when one considers the fact that the economy is in the midst of another major transformation—information-service age (Eitzen and Zinn). Given the growing importance of the minority population within this country, much is needed to further develop our understanding of the impacts of the forces in this new economic environment and putting in place the appropriate research, outreach, and policy responses.

Immigration Policy and Hispanic Labor Issues

The passage of the Immigration Reform and Control Act of 1986 (IRCA) brought a new set of policy and institutionally related issues with particular importance to Hispanics in the United States. Included are the following issues: the impact of employer sanctions on discriminatory employment practices against Hispanics; impact on the wage rate of native and newly legalized Hispanics (a significant number of IRCA-legalized individuals are Hispanics, as are native individuals vying for the same jobs as the newly legalized); impact on the viability of industries that historically have utilized illegal workers (agriculture being one); regional impacts of labor availability which may place perishable agriculture commodity production at high risk; impact of an expanded H2-A program on native and IRCA legalized Hispanics; and the eco-

nomic impact on communities with high concentrations of native Hispanics and IRCA-legalized individuals. Though the consideration and passage of IRCA as well as the IRCA mandates generated a number of research papers, a clear concensus on the policy implications has yet to surface. Given that Hispanics—native, IRCA-legalized, and undocumented workers—comprise a significant percentage of the labor pool for seasonal agricultural labor, the policy issues have particular relevance for the perishable products sector of agriculture. In the remainder of this section, the above issues are expanded and examples of past relevant research are presented.

Rochin and de la Torre identify a broader set of issues pertinent to Hispanics in rural America as well as relevant demographics. By the turn of the century, Hispanics will number nearly 29 million and reside predominantly in California, Texas, New York, and Florida. Rochin, Santiago, and Dickey present an historical analysis of the contribution of individuals of Mexican decent on Michigan agriculture. Their conclusions indicate that farm mechanization has not removed the need for seasonal labor, that labor-intensive production enterprise is increasing, and that a need exists for addressing the problems specific to the Hispanic component of the labor force in Michigan.

Employer Sanctions and Employment Discrimination

Employer sanctions require that employers verify the legal status of all employees. If an employer employs undocumented workers, then he/she will be warned, fined, and can eventually be incarcerated if violations continue. To preclude possible discriminatory (against "foreign-looking" individuals) practices by employers, IRCA mandated an analysis of the impact of employer sanctions on discriminatory hiring practices. The General Accounting Office (GAO 1990) found that widespread discrimination did exist and some of the discrimination was a result of IRCA; however, the component of total discrimination attributed to IRCA was difficult to quantify. The need exists for broader and more rigorous analysis of the economic impact of discrimination, particularly on Hispanics. Also, if employer sanctions are repealed because of adverse discriminatory effects, what impacts will this outcome have on the availability of illegal workers in agriculture, on wage rates, on rural communities with high concentrations of Hispanics, and on the viability of agricultural producing regions?

Wage Rate Effects

How will IRCA affect the U.S. agricultural labor market, particularly supply response? Few studies exist that can provide a basis for answering the question. Emerson found that both demand and supply of local harvest labor are inelastic, that migratory labor supply is more elastic, and that labor markets are linked across seasons. Also, free trade would lead to increased/decreased migration from Mexico to the United States during the winter/summer, and guest worker programs lead to losses for domestically owned factors of production. In short, migratory labor has not fared as well as domestic labor, and guest workers adversely affect domestic workers. Torok and Huffman found the elasticity of U.S. demand for apprehension of undocumented workers with respect to the Florida agricultural wage rate was −2.05; the elasticity of U.S. demand for apprehension of undocumented workers with respect to the real price of Florida tomatoes was +.05; and the elasticity of U.S. demand for apprehension of undocumented workers with respect to the U.S. unemployment rate was −0.47. The U.S. demand for apprehensions of undocumented workers decreases as the Florida wage rate increases and, therefore, relatively more undocumented workers enter the labor force, which in turn exerts downward pressure on wages. As Florida tomato prices increase, the demand for apprehensions increases, which in turn serves to decrease the supply of harvest labor. This outcome may curtail tomato supply and therefore contribute to high tomato prices. Emerson, Walker, and Andrew found a domestic citrus-harvest labor-supply elasticity of 6.45; an elastic effect of income opportunities outside the citrus industry on the supply of citrus harvest labor of +1.09; the importation of harvest workers negatively affects the wage rate of harvest labor; off-shore (H-2) workers reduce the employment opportunities of domestic workers; and government policies have not represented the best interests of domestic labor. The large supply elasticity of citrus labor is inconsistent with the inelastic supply cited at the beginning of this paragraph; but the inconsistency is because the former concerns itself with local labor, whereas the latter is for migrants. If one argues that IRCA has diminished mig-

rancy, then this outcome will exert upward pressure on wages if labor supply decreases. Last, the 1988 GAO study found that illegal workers in agriculture do exert downward pressure on wages received by domestic workers and that seasonal agricultural services crops (SAS) have not suffered production declines because of their historical reliance on illegal workers.

Domestic citrus pickers, many of whom are Hispanics, would receive higher wages if the IRCA were successful at stopping the hiring of illegals. However, if preventing the hiring of illegals includes discriminatory hiring practices against Hispanics, then the net result is ambiguous. The apprehension of illegals by the Immigration and Naturalization Service has acted to sustain higher prices for Florida tomatoes, alleviated excess demand for harvest labor, and exacerbated unemployment. These outcomes require careful attention and analysis.

Regional Impacts of Labor Availability

Most of the seasonal agricultural workers (SAWs) legalized under IRCA were from California, roughly 70%. The IRCA-mandated quota for replenishment of agricultural workers (RAWs) for fiscal year 1990 was zero. RAW's are workers that can be admitted into the United States if they work at least ninety days in SAS crops. After three years, RAWs can then apply for permanent residency. The zero quota for RAWs is difficult to analyze. It has a positive effect on domestic and IRCA legalized Hispanics because fewer individuals will compete for jobs; however, for this to be true, one must assume that H2-A workers will not be imported and employer sanctions will be strictly enforced. A priority preference for RAWs was afforded to family members of SAWs. Therefore, the potential for families to be unified was diminished by the zero quota.

Related to this topic is how regions in Mexico have been impacted by IRCA. Ranney and Kosesoudji provide an assessment of remittancs by Mexican residents who worked in the United States—$55.00 per week—whether they paid taxes (50% did) and Social Security (67%) and found that 50% worked in California and 33% worked in Texas. Warren and Passel provide a regional distribution of illegals in the United States, and White, Bean, and Espenshade present an analysis of undocumented migration in the United States. Much remains to be done about regional "push-pull" factors, the differential impacts of national policy on communities with clusters of Hispanics, and analysis of the economic gains/losses of future distributions of RAW quotas.

Expanded H2-A Program

In 1986, 21,177 workers were certified by the U.S. Department of Labor (DOL) as H-2s—47.5% worked in Florida in the sugarcane industry, 30.1% in the apple industry (13% in New York, 7% in Maine, and 7% in Virginia), and the rest in various other agriculture industries. A critical component of the program is the wage rate that H2-A workers will receive. GAO (1988) found serious flaws in how DOL determines the appropriate wage rate and concluded that the estimates were highly imprecise. It found that the presence of foreign workers depresses wage rates and that the prevailing wage rate, when estimated in areas where foreign workers are or have been, does not provide an accurate reflection of the prevailing wage rate. The H-2A program impacts on Hispanic workers by depressing agricultural wages and by curtailing the demand for domestic agricultural workers. As recommended by GAO, it is imperative that new methodologies and procedures be developed for ascertaining the adverse wage effect and its effect on the availability of domestic labor. Without these efforts, Hispanic agricultural workers will continue to face adverse economic conditions.

Economic Impact on Communities

IRCA's impact on communities with high concentrations of Hispanics—principally in California, Texas, and other southwestern states—is an important and virgin research arena. From an income perspective, Sehgal's work provides illuminating evidence on the impact on a community. In her sample of foreign-born individuals, she found 7% of Hispanic households, 30% of Asian, 17% of white, and 30% of African American households had annual incomes greater than $35,000. The comparable figures for native born individuals were: Asians (26%), whites (20.5%), African Americans (17%), and Hispanics (11%). The level of education of both foreign and native born individuals appears to be responsible for the income differentials. One can surmise that establishing citizenship for Hispanics increases the potential for their educa-

tion, particularly for their offspring. Similarly, Rochin found that a number of Chicano farm worker cooperatives did not succeed because of the poor training of individuals managing the cooperatives.

Several communities have high concentrations of Hispanics. Presley points out that currently 6.6 million Latinos live in California and, by 2030, 14.8 million Latinos are expected to reside there. The following quote from Presley succinctly addresses the challenges ahead for individuals interested in public policy issues pertinent to Hispanics. "Studies are needed of the implications of immigration, particularly in light of IRCA, for health, education and other public services: the social organization of the immigrant communities in California and the impacts of emigration upon the foreign sending communities; the effects of IRCA on jobs and the restructuring of the labor market, especially in the agricultural sector, and ways to help California firms adjust to these changes and to comply with the law."

Conclusions

For a society that has transformed from a rural to an industrial-service based economy, the drive to maintain some comparative advantage in food production is reasonable. But this economic development process also requires the need for helping individuals make the transition. Thurow states that "the failure to aid in this transition is the central failure of current agricultural institutions and arrangements" (forthcoming). Many argue that our profession is unwilling to tackle the broader socioeconomic policy issues of our time. Bromley writes, "The focus seems to remain—for the most part—on tinkering with different support programs to ameliorate the strong production incentives that they create" (forthcoming). The problems of concern in this paper require a broader perspective than economic adjustments within the agricultural sector alone. As the divergence between agriculture and rural communities becomes more apparent, so will the linkages between some contemporary urban problems and challenges to rural communities.

Many segments of rural America are responsive to major sectorial shifts and macroeconomic changes which act much as a tide—when the tide waters are high they lift all boats and vice versa. However, there is growing evidence that a persistent group, the disadvantaged, is a visible component of our society; and this subset, for the most part, seems to be immune to aggregate social and economic forces. Wilson defines the underclass as "that heterogeneous grouping of families and individuals who are outside the mainstream of the American occupational system. Included . . . are individuals who lack training and skills and either experience long-term unemployment . . . and families that experience long-term spells of poverty and/or welfare dependency" (p. 8). To date, little is known about the complex causal links among economic conditions, family structure, and individual or group values.

Conversely, it is commonly recognized, that individuals experiencing poverty are generally less educated and exhibit unstable employment histories. Future policy directives important to disadvantaged minorities in rural America must be given priority if the United States is to remain competitive. Several elements of a public policy agenda that can meet the needs of the disadvantaged are offered and they need to be specific so as to redress this situation.

Public policies in agriculture and rural areas have had differential impacts on ethnic minorities. Some of these impacts have been very detrimental, principally because of the lower levels of human capital. Policies directed toward helping minorities make the transition were slack, and many families have remained in poverty for several generations in both rural and urban areas. Specific policies are needed to redress this situation.

Programs associated with agricultural policies were operated in a manner that has further widened the gap between disadvantaged groups and the rest of the population of rural America. This occurred for several reasons, including the fact that program administrators discriminated against ethnic minorities, the lack of political influence by the rural disadvantaged, and the unavailability of clear and simple information about program objectives and procedures. Programs must consider alternatives that will take into consideration these shortcomings.

Human capital development has the effect of increasing not only individual incomes; but, in a rapidly changing economy, it also increases individual mobility. Education has historically been a state and local government responsibility. Because the U.S. economy is rapidly transforming, additional federal support should be given to human capital development programs to meet the demands of a rapidly changing economy.

Finally, the large unemployment rates among

the disadvantaged and ethnic minorities calls for an expanded role of government in the creation of jobs, particularly in the public service arena. Evidence from previous human capital development programs suggests that employment opportunities along with training will lead to the desired level of participation in the economy by disadvantaged individuals. As the economic organization and public policy environment change, rural development policies must adapt to the changing economic and social conditions to encourage an economic development that will reach disadvantaged groups.

Human Capital, Economic Development, and the Rural Poor: Discussion

Refugio I. Rochin

It is a pleasure for me to comment on the two papers presented: one by Allen and Thompson ("Rural Poverty Among Racial and Ethnic Minorities") and the other by Christy and Figueroa ("The Impacts of Structural Change and Public Policy on the Economic Well Being of the Rural Disadvantaged"). Both papers complement each other nicely by focusing on the often neglected disadvantaged populations in rural America and the possible correlates or "determinants" of rural poverty. They also bring to light much needed information on rural African-Americans and Hispanics. These two groups, with the possible exception of Native Americans, face the highest incidences of rural poverty in the United States today, and their situation is worsening. The papers are also timely and important, especially with regard to emerging national demographic trends. The major trends affecting our rural economy have been reported regularly in the *Monthly Labor Review*. According to the Department of Labor, by the year 2000 we will have several challenges related to matching the supply of labor with the demand for labor. Of note: (*a*) There will be relatively fewer new workers from the traditional labor pool of white males. (*b*) White male workers will be relatively older and probably in the top positions, with few in the lower rungs of industry. (*c*) There will be more women, more minorities, and more immigrants entering the labor force, and their resumés will be vastly different from those of white males. They will have problems of child care and schooling. (*d*) Most new jobs will be in service and information industries, and all new labor force entrants will face fewer jobs in manufacturing and retail trade. (*e*) New jobs will require higher skills but not necessarily higher education.

The challenges for employers will be immense. They will have to adjust to the fact that women and minorities are going to reshape the American workforce, that new minority and immigrant entrants to the labor market will outnumber new white entrants by three to two, and that one in every three U.S. residents will be nonwhite by the year 2000. Rural America's future will not be immune to these trends. Both farmers and rural employers will have to be increasingly concerned about competing for more minorities and women. Employers will be indirectly involved in issues of the disadvantaged, in recruiting and accommodating more persons of diverse backgrounds into their workforce.

I would like to comment now on the paper by Christy and Figueroa because they give us clues as to how these demographic trends are affecting rural America and how we should study these trends. To begin with, Christy and Figueroa remind us that rural workers have been traditionally mobile workers who eventually leave agriculture for urban areas and until now have been historically displaced in line with general changes in farm size and structure. They also point out their concern with the rural disadvantaged, particularly ethnic minorities, "who were spun out of agriculture and were not adequately re-equipped to contribute to a changing economy for a number of reasons—including lack of equal opportunity and pre-market and labor market discrimination." I agree with that concern, but I believe that the new demographics portend a situation that will result in a need for rural institutions and rural employers to become more wary of unchecked local labor displacement. That is, if the demographic forecast unfolds, then the rural economy may be left without an adequate supply of rural workers. Rural job seekers will find themselves in demand in many nonfarm sectors. The result will be that the best and the brightest will leave for employment in urban areas. Labor-intensive farm states like California, Florida, and Michigan may find themselves short of seasonal and temporary workers unless,

Refugio I. Rochin is director of Chicano Studies and an associate professor of Agricultural Economics, University of California, Davis.

of course, new immigrants are brought into the United States. At this time, I do not believe that enough attention is being paid to this plausible phenomenon.

The continuation of off-farm migration of workers suggests that the farm sector will be increasingly affected by labor shortages of possibly serious magnitudes. How do we remedy this situation? Will society pay to generate seasonal pools of workers? Should we offer more year-round employment to existing farm labor and rural workers to keep them in the rural economy? Should we continue our immigration policies? These are issues we cannot ignore. Yet, few people are researching them today. Related to these questions, however, Christy and Figueroa ask us to be more knowledgeable of the Immigration Reform and Control Act of 1986 and other immigration policies. The issues they raise are very important for both rural employers and workers of the future.

Christy and Figueroa give considerable attention to the way we study change and the role of human capital. They advocate a "theory of change" which, according to them, is an institutional theory that looks at the interrelationships between technology, institutions, humans, and resources. I encourage such a perspective. Most contemporary problems of rural America are more social and institutional than technical in nature. The fact is, the economic well-being of most rural citizens does not depend on the prosperity of the farm sector. The future challenges are not merely ones of farm production but new challenges facing entire rural communities and people. In arguing for a "theory of change" Christy and Figueroa rightly note that "a change in technology requires individual and institutional change. Likewise, change in institutions influences the behavior of humans and informs organizational performance." However, I would criticize Christy and Figueroa in one minor way. The "theory of change" they propose is more a paradigm than a theory. It is an outline of the key components our research should address. But, if we are going to accept this design or paradigm or framework of research, then we must also ask how we are going to train and educate social scientists to work in this framework. How will we get our research institutions to contribute support to such research, more than likely interdisciplinary? Would we have to discard the neoclassical economic approach to study the changes they envision? I doubt it. But their plea to broaden the research focus is a good one.

Now I would like to comment on the paper by Allen and Thompson. They have gone beyond the usual review of literature by attempting to determine the causes of rural poverty. They have also focused their attention on the "rural" poor and have selected a very interesting set of independent variables to correlate with poverty. I am particularly pleased with their analysis of poverty according to race and ethnicity. It is evident that the poor in rural America differ by race. The number one problem of the white poor is poverty of female-headed households. Whereas the number one problem of the Black and Hispanic poor, according to the regressions, appears to be the relatively low number of household earners. Without this analysis I would have probably reversed the ranking of these factors for each racial group. I was also intrigued by the variable "industry structure." By dividing industries into two types, "secondary" and "primary," we have a typology which suggests that the rural poor are overrepresented in the "secondary sector," composed of (*a*) nondurable manufacturing; (*b*) retail trade; (*c*) business and repair services; (*d*) personal services; (*e*) entertainment and recreation services; (*f*) mining; and (*g*) agriculture, forestry, and fisheries. It is interesting to note however, that three of the industries included in this group (nos. *c*, *d*, and *e*) are going to grow, according to the projection of the Department of Labor. Allen and Thompson recommend greater job creation in the primary sector as a way to address rural poverty. I do not believe that form of job creation will absorb enough low-income wage workers. Instead of depending on more jobs in the primary sector, the policies also should be to change the conditions in the secondary sector—raise minimum wage, provide fringe benefits and child care, stablilize employment, and develop more opportunities for women and minorities to be the leaders in these industries.

The absence of absolute numbers regarding the magnitude of rural poverty concerns me. While Allen and Thompson refer to the rates and percentages of rural poor, they do not tell us how many are poor. I would like to fill in this gap by data I produced with my colleagues Ed Dolber-Smith and Douglas Gwynn from the 1988 CPS tapes. Table 1 corroborates the high incidences of poverty faced by the black and Hispanic populations in nonmetropolitan areas in 1988. But also evident is the high absolute number of non-Hispanic white poor. Moreover, it is apparent that poverty in nonmetropolitan America is disproportionately high given that nonmetropolitan areas contain only 23% of the na-

Table 1. Total U.S. and Nonmetropolitan Poverty by Race and Ethnicity, 1988

	Total Poor in America	Nonmetropolitan Poor	Percent Nonmetro Poor of Total Poor
Total population	32,506,826	8,979,687	27.6
Poverty rate (%)	13.5	17.0	
Non-Hispanic white	16,161,515	5,895,702	36.5
Poverty rate (%)	8.7	13.1

tion's people and 27.6% of the poor.

Allen and Thompson must rely on data for nonmetropolitan areas to serve as a proxy for rural areas because the annual CPS Public Use Files have no data on "rural" people. They do not point out, however, that a serious problem in rural social science research is the lack of a clear and precise definition for the "rural sector" and its people. Rural definitions for U.S. populations and places have been generally treated as residuals, as any population living in an area not designated as urban. This approach is rooted in criteria used by the U.S. Census Bureau. Referring to the Bureau's *1980 Census Users' Guide*, we find, for example, that "the urban population comprises all persons living in urbanized areas (UA's) and in places of 2,500 or more inhabitants outside UA's. The rural population consists of everyone else."

An interesting problem about this criterion is that a rural classification need not imply farm residence or a sparsely settled area because a small city or town is rural as long as it is outside a UA and has fewer than 2,500 inhabitants. Moreover, this "residual" criterion also leaves the problem that a "rural" area and population can exist within a Metropolitan Statistical Area (MSA). Again, according to the Census Bureau, an MSA is "a geographic area consisting of a large population nucleus—a census defined urbanized area—together with adjacent communities that have a high degree of economic and social integration with that nucleus."

With this definition for the MSA, we have the possibility that many MSAs contain "rural" people. As such, nonmetro data cannot and should not be used synonymously for rural data. One may ask if this causes a serious problem. Is not the nonmetropolitan concept a significant and meaningful synonym for rural? Does it make a difference in our research to ignore the rural population of MSAs?

My reserach with Kawamura, Gwynn, and Dolber-Smith found a large numerical difference in the count of rural poor when the rural people within MSAs were considered. We conducted a comparative analysis of the California poor, using 1980 census data, of both urban and rural populations within both MSAs and non-MSAs. It turns out that a large number of California's poorest rural people are subsumed in the metropolitan areas of Sacramento, Fresno, and Bakersfield. These rural, metropolitan poor are also different in some respects from the nonmetropolitan poor. They are largely Hispanic and white, with employment in agriculture and agribusiness. The nonmetropolitan poor in California are white and Native American (Kawamura et al).

I commend both presentations for addressing key demographic and social issues of rural America. I urge rural social scientists to continue research along the lines recommended by the authors.

Human Capital, Economic Development, and the Rural Poor: Discussion

Claudia Parliament

Poverty is perceived by many as primarily an urban problem. Inner city poverty is concentrated and visible, but as long as the United States has gathered poverty statistics, a disproportionate share of the poor have been found to live in rural areas. If characteristics or causes of poverty are unique to rural areas, then policies can be designed to alleviate rural poverty. Unfortunately, the analyses provided in the two invited papers do not address the unique aspects of the rural poor. Neither paper justifies the need or proscribes policies to specifically target rural poverty.

Allen and Thompson begin with a review of the many deficiencies of the current measure of poverty. Their criticisms do not point out, however, that the current measure of poverty does not discriminate between poverty related to age or disability and poverty caused by lack of employment opportunity or adequate education. Allen and Thompson would strengthen their analysis of poverty among rural minorities if they focused on factors affecting the nonelderly and nondisabled persistently poor.

The disproportionate share of poverty among African Americans and Hispanics in nonmetro counties of the United States is well documented by Allen and Thompson. To underscore a need for policies directed to rural minorities, however, the unique differences between rural and urban poverty must be reviewed. The authors err by omitting a reference to the high incidence of poverty among Native Americans. A discussion of rural poverty among racial and ethnic minorities must at least acknowledge the incidence of poverty among the minority with one of the highest rates of rural residence and poverty.

With respect to the analysis of the determinants of poverty, Allen and Thompson should reconsider the use and interpretation of two of their explanatory variables. The industrial variable is more likely a proxy for wage differences due to skill levels than a measure of the size and dominance of firms, and the assumed monotonic effect of age on poverty disregards the higher incidence of poverty during child-bearing years and old age.

The lack of significance of southern residence on poverty may reflect the deterioration of jobs associated with agriculture, mining, and forestry in areas outside the South during the 1980s. The decline in natural resource-based industries during the decade significantly increased the incidence of poverty in resource-based rural counties in the West and Midwest. These relatively recent pockets of poverty have been referred to as the new rural poor (Stinson).

In the discussion of the policy implications of their results, Allen and Thompson first call for increasing Aid to Families with Dependent Children benefits, assisting females to enter the labor force, and providing adequate day care. These changes are needed for all single parent households living in poverty. The authors could strengthen the case of the rural poor if they underscored the difficulties of providing employment and day care in areas with sparse populations and vast distances between trade centers.

Allen and Thompson's discussion of the need to subsidize education should emphasize that, on average, rural schools have fewer resources, less adequate facilities, and less experienced teachers than urban areas (Ross and Rosenfeld). Many rural poor reside in school districts with the most limited resources.

The authors indicate that the existing civil rights and equal employment laws must be enforced to overcome the racism associated with poverty. They did not emphasize, however, that many small, rural firms may not be covered by federal equal employment laws.

In the second paper, Christy and Figueroa intend to show the detrimental effect of structural and institutional changes on ethnic minorities in

Claudia Parliament is a faculty member, Department of Agricultural and Applied Economics, University of Minnesota.

rural America. They discuss the decline of nonwhite farming and the recent change in immigration policy with the passage of the 1986 Immigration Reform and Control Act (IRCA). Although the case studies are in themselves interesting, the theoretical connections between structural change and public policy, and the human capital needs of rural ethnic minorities are not made.

The authors imply that the African American exodus out of farming increased poverty, but no evidence is provided. Christy and Figueroa attribute the decline in landownership by nonwhites to credit policies, education, and intergenerational land transfers. The authors could have directly addressed the role of U.S. farm policy in the decline of nonwhite farmers. Farm policy promotes efficiency rather than equity, and the bias toward large, commercial farms promoted the massive dislocation of small minority farmers. The decline of nonwhite farmers is one of the unmeasured social costs of our farm policy. They also could have cited evidence that the Cooperative Extension Service devoted many of its resources to assisting large farms rather than small, minority farmers in the South (Baldwen), in support of their discrimination claims.

The effect of the change in immigration on Hispanics is the second change analyzed in the paper. To address the effects on rural ethnic minorities, however, the authors need to indicate the specific effects of IRCA on rural residents and migrant farm workers. They only note that IRCA may have the ambiguous effects of increasing both wages and discrimination among Hispanics.

The authors state that rural poverty must not be equated with farm poverty, and that rural poverty will not be solved by manipulating existing farm policy. This rationale may be appropriate given that only 8.5% of rural poor were farm residents in 1986 (Woods, Ross and Fisher). However, among rural households the highest incidence of poverty exists among small farmers and migrant farm workers, and thus farm policy may be the most appropriate vehicle to address their poverty.

The authors could expand their discussion of the need for human capital among rural minorities with an analysis of the structural decline of rural manufacturing. Rural areas successfully attracted new manufacturing jobs during the 1960s and 1970s, partially the result of lower labor costs. This growth of manufacturing made possible the rise from poverty of many rural households, particularly in the rural South where most of the manufacturing-dependent counties are now located. Since 1979, however, manufacturing employment has declined, and rural manufacturing industries may not be able to adapt to technological change and competition because of the relatively unskilled rural labor force. The authors' call for increased human capital investments in rural ethnic minorities continues to be a crucial rural development tool.

Both papers indicate the need to move toward a broader definition of poverty in recognition that disadvantage is a multifaceted phenomenon that is not adequately described solely by income. A better indicator of poverty may include measures of illiteracy, crime, substance abuse, and labor force attachment. These characteristics have been used to describe the "underclass"—those socially isolated and in persistent poverty (Wilson, Ruggles and Marton). Although the development of policies directed at the underclass are currently dominated by urban analysts, the characteristics also apply to the persistently poor in rural areas, and rural analysts should participate in the development of future poverty policies.

Transactions Costs and Efficiency in Western Water Allocation

Bonnie G. Colby

Controversy over the appropriate balance between market and regulatory approaches to allocation makes resource economics a fascinating and dynamic area of inquiry. Over the last twenty years, the tension between market forces and broader social values has become increasingly evident in state water transfer policies. Through the 1950s, water transfers out of agriculture were uncommon and were discouraged by some western states. However, the American West's economic transition from ranching, irrigated farming, and mining to urban growth, services, tourism, and industry brings strong incentives to transfer some water out of agriculture.

Economists argue that market forces should play a greater role in water allocation—emphasizing the inefficiency of allocating water to grow low value and surplus crops, while nonagricultural water users struggle to develop expensive new supplies. Agriculture accounts for 85%–95% of water use in many western states, and the cost of reducing irrigated acreage so that water can be available for other uses is generally far less than the cost of developing new water supplies (Young). Moreover, transfer of only a small portion of water used in agriculture would be sufficient to satisfy foreseeable nonagricultural water demands, so disruption of western U.S. agricultural production would be negligible (Tregarthen, Young).

Over the last decade, market transfers have become a more common means to reallocate water, though nowhere could such voluntary transactions be characterized as a "free market" (Saliba and Bush). Every western state imposes conditions on water transfers. Such policies generate uncertainties and costs for transferors and have been described as inefficient and unnecessary impositions on the market (Tregarthen, Anderson and Johnson). Should public policy seek to minimize the cost of transferring water, or can transactions costs actually facilitate efficient reallocation by accounting for social costs of transfers?

Transactions costs are generally characterized as factors that prevent markets from operating efficiently or as factors that prevent markets from forming altogether (Coase, Demsetz, Cheung, Tregarthen, Crouter). In western U.S. water markets, transactions costs are incurred in searching for trading partners, ascertaining the characteristics of water commodities, negotiating price and other terms of transfer, and obtaining legal approval for the proposed change in water use (Colby et al.). This paper addresses the latter category of transactions costs, termed policy-induced transactions costs (PITC) in this discussion. Transferors incur PITC as they seek to obtain state approval to transfer a water right to a new place and purpose of use. PITC may include attorneys' fees, engineering and hydrologic studies, court costs, and fees paid to state agencies. PITC specifically exclude the price paid for the water right and the costs of implementing a transfer once it has been approved because these costs are not specifically attributable to state policies.

This paper evaluates PITC generated by state water transfer policies and argues that PITC force consideration of externalities that would otherwise be ignored by water buyers and sellers negotiating in their own best interests, concluding that PITC have a legitimate role in promoting efficient water allocation. Data from several western states with active water markets are used to analyze the economic incentives and distributional impacts of transactions costs imposed by state water transfer policies.

The Institutional Framework—Water Transfers and State Policies

Western cities pioneered the era of western water reallocation by purchasing irrigated land, some-

The author appreciates input on earlier drafts from Dick Gardner, Chuck Howe, Dan Tarlock, Henry Vaux, and Gary Woodard without implicating them for the contents of this article.

times entire irrigation districts, to acquire water rights for urban development (Saliba and Bush). While city growth is still the driving force behind water markets, in the late 1980s new forces for reallocation emerged. Water transfers to support wildlife, fisheries, and recreation have become more common as the role of water in supporting environmental amenities and tourism is increasingly recognized (Colby 1990). Cities and environmental interests, alarmed by the droughts of the 1980s, now selectively seek water supplies that will be reliable even during dry years and so place a premium on rights with the highest priorities. Since irrigators' rights are typically senior and are most likely to be reliable during drought, they are a valuable commodity in many areas. While water transfers routinely occur among neighboring farmers in many areas of the West, this article focuses upon transfers from agricultural to nonagricultural water use. These transfers, which often involve moving water from one basin to another and from rural to urban areas, generate considerable controversy and demand for changes in public policies governing water transfers.

Market exchanges promote flexibility, allowing water allocations to adapt to changing economic conditions and new social values. Water transfers can also generate externalities. While transfers can create positive externalities in the area to which water is being moved, this paper focuses on negative impacts because these lie at the heart of controversies over water transfer policy. Negative externalities include reduced water supplies for other water right holders, diminished economic activity in communities from which water is taken, lower river flows, and degradation of water quality, fish and wildlife habitat, and recreation opportunities (Saliba and Bush, Kapaloski). Local direct and secondary economic losses from reduced irrigated acreage are typically small relative to the benefits created by new uses of the water (Howe, Lazo, and Weber, this issue; Young). The most significant externalities are probably those associated with recreational and environmental water values and with water quality. Benefits generated by water instream are often classic public goods not conducive to well-defined property rights and characterized by nonrivalry, nonexcludability and misallocation in private market exchanges. A number of studies indicate that leaving water instream can create economic benefits that exceed the benefits from transfers and diversions for offstream uses (Daubert and Young, Loomis, Ward). Moreover, streamflows and wetlands will become more highly valued as growing urban populations demand opportunities to recreate on free-flowing waters and view wildlife, and as water providers and waste water dischargers rely on the assimilative capacity of rivers and marshes to meet more stringent water quality standards. These public good aspects of water allocation are generally neglected when private water transfer agreements are negotiated.

Policy makers are struggling to balance these externalities with the economic benefits and flexibility that transfers can provide. Western states require prior evaluation of transfer proposals before approval is granted for changes in the purpose and place of use of a water right (Colby, McGinnis, and Rait). However, different types of third-party impacts are accorded markedly different degrees of importance in western water law. Foremost among the externalities considered is reduced water supplies for other water right holders. Other impacts are addressed in only a few states.

Those seeking to transfer a water right to a new use must file an application with the state water agency. Applicants often hire attorneys and engineers to help prepare the application. The scarcity of water supplies relative to demand and the degree of controversy surrounding water transfers affects applicants' need to hire experts. For example, there are no remaining unclaimed water supplies in eastern Colorado, Colorado transfers require judicial proceedings, transfers are typically heavily contested, and consultants are typically retained at an early stage. In contrast, the transfer approval process in Idaho and Wyoming is much less formal, partly because there has been less pressure for water transfers in these states. In areas where there is less competition for existing water sources, procedures are simpler, water transfers generate less conflict, and PITC are lower.

Filing a protest is the primary means for parties who object to the proposed transfer to influence the state agency review process, though not everyone who believes they may be adversely affected can legally file a protest. The earliest, and still the most common, legal basis for protesting a transfer is impairment of existing water rights. Western state laws historically emphasized protection of existing water rights so that water users would have secure incentives to make the investments necessary to develop the West. However, water right holders do not represent the multiple interests that benefit from water resources and that experience losses as a result of water transfers. Most states limit ac-

cess to water rights for instream uses. Only two of the thirteen western states allow private parties to acquire water rights for maintaining streamflows (MacDonnell 1989).

Recreationists, farm equipment dealers, streamside homeowners, rafting outfitters, and bait shops all have an economic interest in maintaining streamflows but generally cannot obtain water rights to protect their interests. Further, water quality is poorly integrated into most states' water laws. Waste treatment facilities are designed based on historic streamflow levels and rely on the dilution provided by flows to assure compliance with discharge standards. However, in most western states water rights cannot be acquired for protecting water quality, and impairment of water quality is not a valid basis for protesting a water transfer (Kapaloski). State policies which limit who may hold water rights, which disallow protests by those who do not hold water rights, and which limit the reasons for which a protest may be filed, constrain the externalities which are considered when a transfer proposal is evaluated.

When legally valid protests are filed, transfer approval is significantly delayed as the applicant and protestants argue over the magnitude of transfer impacts and the extent of mitigation or compensation. If the parties can agree, their negotiated modifications of the transfer proposal are submitted to the state agency and transfer approval normally follows. If the applicant and protestants cannot come to an agreement, the state agency will hold hearings and make a ruling on the transfer application. The ruling may approve the transfer as requested by the applicant, grant conditional approval with modifications to satisfy protestants' concerns, or deny the transfer altogether. Parties dissatisfied with the state's decision may appeal to state courts. The threat of a costly, protracted hearing followed by an unpredictable ruling on the transfer application is a powerful incentive for the parties to negotiate a settlement.

Transactions Costs and Efficient Water Transfers

The ability to impose transactions costs on those proposing to transfer water, an ability conferred by state laws governing who may hold water rights and file protests, represents bargaining power in the water allocation process. Market transactions are undertaken for economic gain, based on the perception that water supplies will generate higher returns in their new use than in their former use. The power to erode this expected gain through imposing transactions costs gives third parties leverage with transfer proponents and a role in water reallocation decisions.

"Optimal" Transactions Costs

For PITC to facilitate efficient water allocation, they would have to provide incentives such that water reallocation occurs if and only if the social benefits of transferring water exceed the social costs. Social welfare is maximized when water transfers occur to the point where the marginal social benefits of transferring one more acre-foot equal the marginal social costs. Given the public good nature of many water uses and pervasive externalities associated with water transfer, private marginal costs of water transfers are likely to diverge from the social marginal costs. Transactions costs could promote efficient allocation if they behave as a Pigouvian tax, causing private decision makers to account for social costs by "taxing" transferors through PITC.

Figure 1a illustrates how PITC could, in theory, enhance efficiency. WTP_1 represents the original market demand for water in urban use, and WTP_2 represents a new higher level of demand, prompted by urban growth. *PMC*, private marginal costs, is the supply curve for cities seeking to transfer water out of agriculture and is based on irrigators' willingness to sell water. *PMC* measures farmers' foregone net benefits when water is removed from agricultural use. At the original equilibrium allocation, Q_1 units of water are used by cities, and the remainder of regional supplies are in agricultural use. The new market allocation would be at Q_2, and $Q_2 - Q_1$ units of water would be transferred from agriculture to the new urban use. Suppose, however, that the social marginal costs of water transfers exceed *PMC* by an amount represented graphically by the wedge between *SMC* and *PMC*. This divergence between *PMC* and *SMC* reflects those negative impacts of transferring water out of agriculture that are not already incorporated into *PMC*, the sellers' own foregone net benefits. The socially optimal transfer is $Q^* - Q_1$, a smaller amount of water than would be transferred if only private costs and benefits were considered. If PITC reduce the transferors' net willingness to pay to WTP_3 (where WTP_3 is WTP_2 minus *PITC*), then the privately negotiated quantity transferred will approximate the opti-

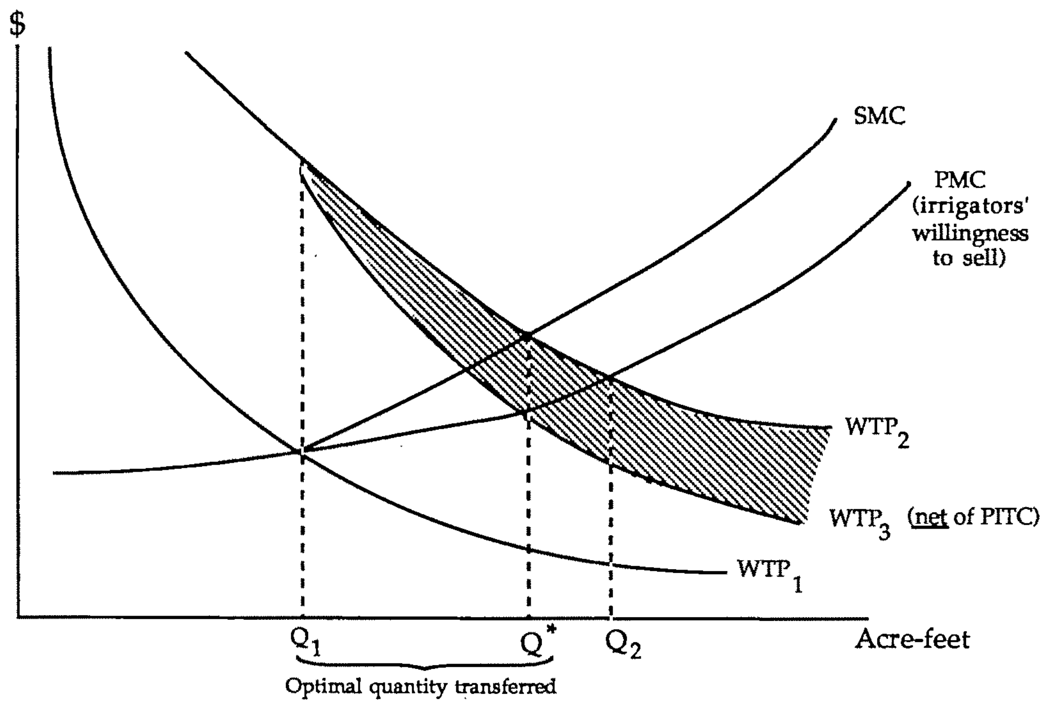

Figure 1a. Optimal PITC

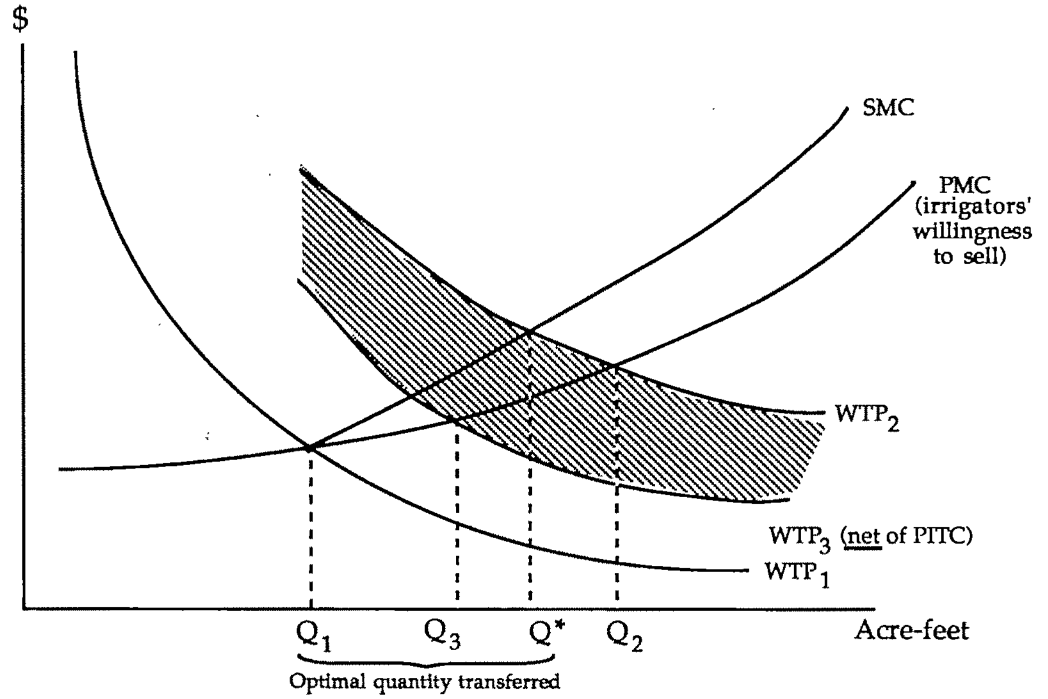

Figure 1b. Overregulation; PITC are too high

mal transfer quantity, $Q^* - Q_1$. "Optimal" PITC, represented by the vertical height of the shaded area between WTP_2 and WTP_3, equal the difference between *PMC* and *SMC* for each quantity of water transferred and cause transferors to account for social costs when making a market transaction.

In principle, PITC that reduce willingness to pay for water transfers could promote economic efficiency. The shaded area in figure 1a is not a net loss to society but is rather an income redistribution (like a Pigouvian tax) from transfer applicants to those who provide services in the transfer approval process. Transactions costs are not "money down a rathole," they are expended to clarify, protect and transfer property rights (Randall). Rights to use water are extremely heterogenous, sometimes poorly defined, and involve pervasive interdependencies. It is not costless to identify the nature and magnitude of third party impacts related to water transfers and PITC are part of the "price" of developing transferable private property rights in a resource which has extensive public good attributes.

"Overregulation" of transfers, such that private and social gains from transfers are eroded by high PITC, is also possible. This is shown in figure 1b. In the absence of any PITC, a larger than optimal amount of water ($Q_2 - Q_1$) would be transferred. With high PITC, indicated as the shaded area, WTP_3 represents urban willingness-to-pay for water transferred net of PITC. For any quantity of water transferred, PITC exceeds the difference between social and private marginal costs. Costs of complying with state regulations are so high that a less-than-optimal quantity, $Q_3 - Q_1$, is transferred to urban use and social net benefits are reduced compared to the optimal transfer, $Q^* - Q_1$. Given that either "overregulation" (PITC too high) or "underregulation" (PITC too low) is possible, in theory, what do we know about actual PITC in the western states?

PITC in Western States Water Transfers

Several recent studies examine the cost of obtaining state approval to transfer water rights from agriculture to other uses in selected western states. The data do not permit rigorous testing of an overregulation or underregulation hypothesis but they provide some indications on the magnitude and distribution of PITC. Colby et al. analyzed applicant, protestant, and state agency costs for water transfers in several states with active water markets. Data on applicants' and protestants' PITC were collected for transfers initiated in the 1980s. This study sampled professionals involved in water transfers who expressed a willingness to participate in the study. While this permitted the collection of detailed information on PITC, the results are not based on a random sample of all transfers and, therefore, are not necessarily representative. However, the results are similar to those produced by another study (MacDonnell 1990) that analyzed characteristics of all transfer applications filed in Colorado, New Mexico, and Utah over a ten-year period.

Colby et al. found that applicants' PITC averaged \$91 per acre-foot of water transferred with considerable variation among states. Applicants' PITC in Colorado averaged \$187 per acre-foot, \$54 in New Mexico, and \$66 in Utah. Another measure of PITC involves the opportunity costs to transfer applicants of time delays while waiting for state agency approval of a transfer proposal. This period is measured in months from the time a transfer application is filed to the date of the state agency decision. Time delays varied considerably by state; 29 months in Colorado, 4.3 in New Mexico, and 5 in Utah.

Applicant costs per acre-foot transferred vary with the market value of water in the areas studied by Colby et al. Applicant costs were higher on a unit basis in the front range of Colorado, where water rights often sell for \$4,000 or more per acre-foot, and were significantly lower in the middle Rio Grande Valley of New Mexico, where water rights sell for under \$1,000 per acre-foot. This study found that applicant costs per acre-foot averaged 6% of the price paid by the applicant for water rights to transfer.

Statistical analysis of the Colby et al. data revealed that larger transfers have lower PITC per acre-foot transferred, indicating some economies of scale. Protests have a significant and positive impact on applicant cost per acre-foot. Time delay, a measure of applicants' opportunity costs, is also significantly and positively related to whether or not protests were filed. In Colorado, transfers involving water rights in the most "water scarce" areas of the state had significantly higher applicant unit costs and time delays than elsewhere. These results suggest that PITC are higher where the economic values that may be affected by the proposed transfer are higher—in areas where water is more scarce and water rights sell for a higher price.

Colby et al. also collected data on costs incurred by those protesting transfer applications in Colorado. The number of protests filed per

transfer application ranged from zero to 15. Those filing protests spent between $750 and $24,400 apiece, with an average cost per protest filed of $7,052, indicating that parties protesting a transfer to protect their own water rights can incur significant costs.

MacDonnell (1990) compared characteristics of water transfers in several western states and found variation among states similar to Colby et al. In Colorado, 80% of transfer applications were eventually approved over the ten-year study period (1975–84), while 90% were approved in Utah and 95% in New Mexico. (Approval does not imply that the applicant obtained permission to transfer as much water as originally requested because many approvals are conditioned on modifying the original transfer proposal to satisfy objectors.) MacDonnell found that 60% of all transfers were protested in Colorado over the period 1975 to 1984, and that it took an average of 21 months to obtain state approval. In sharp contrast, only 5% of transfer applications were protested in New Mexico over this same period, and the average time to obtain approval was 5.8 months. In Utah, about 15% of change applications were protested and the average time to obtain approval was 9 months.

One explanation for the variation among states in time delays, approval rates, and frequency of protests lies in the different types of transfers occurring in each state. Transfers out of agriculture are generally more controversial than transfers among farmers. Transfers out of agriculture account for 80% of transfers in Colorado and only 30%–40% of the transfers that have occurred in New Mexico and Utah over the last ten years (MacDonnell 1990).

The MacDonnell data indicate interesting variations in transactions costs and time delays within individual states. In Colorado, 84% of transfer proposals in the most populous and "water scarce" basin in Colorado were protested, compared to only 40% in the least competitive basins in the state. In New Mexico, larger transfers took much longer to win state approval—the average volume of New Mexico transfers approved in less than three months was 79 AF compared to an average volume of 312 AF for transfers taking more than four years to approve. In Utah, one basin accounts for a disproportionately large number of all protests filed in the state. In this basin, which is experiencing high growth rates and has no remaining unclaimed water supplies, approval time delays are twice as long as typical elsewhere in Utah. These intrastate comparisons indicate that PITC are higher in areas where water is more scarce and more valuable, transfers are more controversial, and the externalities of water transfers are more likely to be significant.

Policy Implications

Consider the following hypothesis: The transactions costs generated by state regulation of water transfers out of agriculture are lower than would be socially optimal. This runs counter to the view that government regulation of water transfers is excessive and prevents markets from efficiently allocating western water. While the overregulation view may apply to impediments to transferring water out of federally subsidized irrigation projects (barriers which do not originate in state water law), state policies make transfers less expensive than they should be, by failing to account for externalities associated with transfers. This argument rests on the following points:

(*a*) State laws specifically exclude some parties who may experience significant externalities from filing protests and from influencing the conditions of transfer approval. In general, only neighboring water right holders can force their concerns to be accounted for. Wastewater treatment managers, recreationists, environmental interests, and persons who live along streams or make their living in recreation or agriculturally linked economic sectors typically have no role in the evaluation process. Current levels of transactions costs reflect only one of the many types of externalities that are associated with water transfers and neglect the public good aspects of water resources.

(*b*) Current PITC related to impacts on other water right holders do not appear to be excessive, given water values in the areas studied. Those who do have legal basis to protest a transfer, other water right holders, act in their own self-interest to protect the benefits they receive from their water right. It can be costly to file a protest, and one must assume protestants consider their expected net payoff before entering the fray. Payoffs to protestants take the form of modifications in the transfer proposal to eliminate impairment of protestants' water supplies and sometimes monetary compensation for accepting impairments. The costs of protesting serve to inhibit (though probably not eliminate) frivolous protests filed purely to obtain payoffs from transfer applicants. The costs incurred by applicants and protestants appear to reflect the

economic values at stake. PITC are significantly higher in areas where existing water supplies are fully appropriated, importation or development of new supplies is expensive, and demand for water is increasing. In these areas, the value of water is high, and high PITC seem appropriate, not an indication of inefficiency and overregulation.

While the hypothesis that PITC are lower than optimal cannot be empirically proven, there is also no convincing evidence for presuming, as much of the literature on water allocation does, that western states overregulate water transfers and that public policy should make transfers cheaper and faster. Water transfers occur regularly in the three states for which PITC data was collected, with an average of 70, 100, and 350 water transfers approved each year over the period 1975–84 in Colorado, New Mexico and Utah, respectively. With PITC averaging only a small fraction (6%) of the prices paid for water rights, current state policies do not appear to overly burden market reallocation (Colby et al).

It would be farfetched to argue that the optimal PITC illustrated in figure 1a portray the actual situation and that current PITC accurately represent the social costs of transfers. Market imperfections have been amply documented for western water transfers (Anderson and Johnson, Saliba and Bush). Further, given the lack of consideration for any externalities other than those experienced by water right holders, PITC probably underrepresent social costs. However, the preliminary data available indicate that PITC are "well-behaved," not inconsistent with the incentives that would be created by a Pigouvian tax on water transfers. The higher the value of water, the greater the economic impacts on other water right holders and the higher the "tax" on transfers in the form of PITC.

Why not tax water transfers directly to account for external impacts? Determining the optimal rate for such a tax would require complete centralized information on all parties' marginal costs and benefits. Existing information regarding externalities is dispersed among affected parties, hydrologic and economic studies to identify the magnitude and distribution of impacts are costly and few would argue that state agencies should be assigned the task of collecting the information needed to impose a credible Pigouvian tax. The current institutional framework relies on autonomous, self-interested transfer applicants and protestants to incur costs to the point where it is no longer worthwhile to do so. The benefits and external impacts of transfers are considered as each party determines the expenses they will incur to pursue or oppose a particular water transfer and the "deals" they are willing to make to reach a settlement. However, to the extent that state laws exclude those who have real economic interests from participating in the process, some social costs are being ignored.

Improvements in the Current Institutional Framework

Having argued that PITC have a legitimate role in the water reallocation process, given public goods and externalities associated with transfers, there are indications that some state policies exaggerate PITC beyond the social costs they should reflect. Colorado has much higher PITC and longer time delays for approval than other western states. Part of these differences result from higher water values in Colorado, as evidenced by significantly higher market prices than are typical in other states (Saliba and Bush). However, Colorado PITC are out of proportion with water prices, compared to other states. Colby et al. found that, while PITC average 6% of water rights prices for all states studied, they average 12% for Colorado. One might hypothesize that PITC are higher in Colorado because a broader range of values are protected when transfer proposals are evaluated in that state, but Colorado water law actually lags behind other states in considering instream and public interest values (Colby 1988).

In Colorado, changes in water use are evaluated in the state water court system in formal judicial proceedings. Fully one-third of all U.S. attorneys specializing in water law are members of the Colorado Bar, and attorneys fees account for the bulk of PITC, leading one to suspect rent-seeking behavior. There are probably rents created by barriers to entry in the Colorado legal profession (state bar exams) and there are rents to be captured as water is reallocated from lower-valued to higher-valued uses. The Colorado water bar seems to be a primary beneficiary of the state's court-based approach to governing water transfers, as over half of PITC go to the attorneys representing applicants and protestants. A smaller proportion go for engineering and hydrologic studies to measure impacts and for compensation to injured third parties. While current PITC do reflect externalities imposed on water right holders and play a role in promoting efficiency, they also redistribute the rents from

water transfers in a manner that raises equity concerns. Where taxation and redistribution of profits from water transfers have been contemplated, the intended beneficiaries have been rural counties, wildlife preserves and state stream protection programs, not lawyers (Colby 1990).

One goal of policy changes should be to generate information on the externalities that accompany water transfers in a least-cost manner. Most disputes between applicants and protestants involve the quantity of water that should be transferable. States should establish a transferable quantity per irrigated acre. New Mexico, with the lowest PITC of the states studied, sets a standard quantity of water that may be transferred per unit of irrigated land retired. Parties who disagree with this quantity bear the costs of proving some other amount is appropriate. In contrast, the Colorado system invites all parties to provide evidence on transferable quantity, with considerably higher PITC incurred for engineering and legal studies. As a second recommendation, judicial proceedings should not be the first forum for evaluating a transfer proposal as in Colorado. The adversarial nature of court proceedings prompts "overinvestment" in attorneys and other experts. Third, data developed for previous transfers (river basin and groundwater models, engineering reports, crop consumptive use studies, etc.) should be publicly available and used to build up a cumulative information base for evaluating transfer impacts, with the goal of reducing information costs.

A second goal of policy should be to broaden the types of externalities that are considered. Water rights should be accessible for instream uses, through transferring an existing right or appropriating unclaimed water, just as they are for offstream uses. The ability to acquire water rights for maintaining streamflows would allow water quality managers, recreationists, and environmental interests to become right holders and give them a legal basis for protesting proposed transfers. Some states' laws allow "public interest" factors to be considered when a transfer proposal is evaluated, but public interest provisions are rarely used to contest a proposed transfer because the concept is new and ill-defined and few specific criteria exist. States need to define the public goods attributes of water that they wish to protect and to incorporate these into their transfer policies. Some are already doing so (Colby, McGinnis, and Rait). These changes will undoubtedly raise PITC, but will also permit a broader range of social costs to be accounted for as water is reallocated.

Summary

Western states' water laws evolved to protect those who diverted water for offstream uses such as mining and agriculture, granting property rights in water for these early uses. Historically, the primary concern in evaluating proposed water transfers has been protection of water right holders. Western state economies have changed and so have the values that the West's water institutions must serve. Broader access to property rights in water and to the transfer approval process can allow a wider array of externalities to be considered and will make water transfers more expensive than previously. Given that important values can be affected by transfers, is there a sound economic rationale for making water transfers as inexpensive as possible? High PITC reflect the substantial and multiple economic benefits associated with water in various uses, benefits which can be impaired by a transfer. PITC are high in areas where new water supplies are locally unavailable and expensive to import, demand for water is increasing and water rights are valuable property. PITC are lower in states and in river basins where unclaimed water is still available, there is less pressure for transfers and water rights are lower in value. Transactions costs generated by state policies are a reasonable means to account for social costs of water transfers, given the immense centralized information requirements for an optimal tax on transfers. The present institutional structure gives affected parties, each weighing their own costs and benefits, an incentive to generate information on transfer impacts and to negotiate transfer conditions and mitigation of externalities. State water transfer criteria are not arbitrary hindrances imposed upon the marketplace. These policies protect existing investments by water right holders and, as they are broadened to include other interests, they can reflect public good values affected by water use and transfer.

Socioeconomic Impacts of Water Farming on Rural Areas of Origin in Arizona

Alberta H. Charney and Gary C. Woodard

A land rush of sorts has occurred in parts of rural Arizona during the last six years. Municipalities, developers, speculators, and the federal government all have purchased or acquired leases to over one-half million acres of land, with half the acquisitions made by private parties, 30% by municipalities and 20% by the federal government (Woodard and McCarthy). Some of the land is irrigated agricultural land, some is rangeland, and some is raw desert. The purchasers have acquired the land not for the value of the land or its crops or any structures but for its associated water rights. This phenomenon, known as "water farming," has been occurring in other parts of the West for decades (Colby, this issue). Its emergence in Arizona was triggered by certain provisions of the state's 1980 Groundwater Management Act (Checchio, Woodard et al.).

Municipal areas located in designated Active Management Areas that plan to grow beyond the year 2001 must convince the Arizona Department of Water Resources that they have a 100 years assured water supply for new development. Historically, Arizona municipalities have relied on a mix of surface and groundwater to meet growing urban demand. However, there is little or no unappropriated surface water in the state, and the Safe Yield provision of the Groundwater Management Act severely limits future groundwater pumpage from aquifers underlying urban lands (Woodard and Checchio). As a result, municipal water providers plan to transfer water to urban areas, eliminating much of the irrigated agriculture in the areas of origin.

Arizona's water transfer "market" can be distinguished from that of Colorado, New Mexico, Utah, Nevada, and most other western states in the following ways:

The authors are research specialists in the Division of Economic and Business Research, College of Business and Public Administration, University of Arizona.

This research was funded by a grant from the Ford Foundation's Rural Poverty and Resources Program.

(*a*) Acquisitions are driven by legal requirements to secure "paper" water rights more than any perceived need for the water. If the quantity of water secured or being negotiated for transfer all was put to municipal and industrial uses at 140 gallons per capita per day (the targeted consumption rate of ADWR), then enough water for an additional 3.2 million persons is involved. Current state population is just under 3.7 million.

(*b*) The transactions are very few in number but very large in terms of acres, acre-feet, and dollars. The "typical" water farm in Arizona consists of 10,000 acres of deeded land plus 20,000 acres of leased land, has a price of $15 million, and can supply 15,000 acre-feet per year, based on a 100-year pumping regime for groundwater.

(*c*) The focus is on unquantified groundwater rights, not quantified surface water rights. Of eighteen water farms, ten are groundwater only, four involve both surface and groundwater, and four involve surface water only (three of which are federal acquisitions of Colorado River water to satisfy various claims). Of the roughly half-million acre-feet of potential annual supply, over three-quarters is groundwater.

Water Farm Characteristics

Certain characteristics distinguish a good potential water farm. Access to a large, high-quality source of surface or groundwater is one element. Being able to purchase large, contiguous tracts of land at reasonable prices also is important when acquiring access to unquantified groundwater rights. And a reliable, low-cost means of transporting the water from area of origin to area of use is essential, as the cost of infrastructure to transport the water can greatly exceed the cost of the water farm itself. West-central Arizona, with its high-quality groundwater aquifers underlying farms and ranches de-

preciated by the depressed agricultural economy and bisected by the Central Arizona Project aqueduct, has all these characteristics. The CAP aqueduct, which will bring Colorado River water to the Phoenix and Tucson metropolitan areas, offers such an attractive means of transporting other waters to the state's urban areas that nearly all water farming activity to date is concentrated in La Paz and western Maricopa Counties (Checchio, Woodard and McCarthy). Of the eighteen actual and proposed transactions, seven involve land lying wholly within La Paz County and four involve land partly within La Paz. As a result, the impacts of water farming also are concentrated. This has caused considerable concern in La Paz County, which is 95% public land and lacks a diverse economic base.

Economic theory suggests that the first water to move from agricultural uses will be from the least productive, or marginal, irrigated land. This pattern is observed in the purchase and retirement of the thirty-three cotton farms in the Avra Valley near Tucson over a sixteen-year period because those farms with the lowest per-acre yields sold out first and the more productive farms remained in operation another ten years. However, if location relative to existing aqueducts or seniority of rights is important to municipal purchasers (Howe, Lazo, and Weber, this issue), then more productive land with higher-valued crops may be purchased first. Also, when groundwater is involved, there is no "use it or lose it" incentive to continue cultivating the land until the water is transported so as to maintain the rights and produce incidental profits from the farming activity. In fact, because most groundwater pumped in Arizona is mined groundwater, there is an incentive to retire the land to preserve the water. For principally political reasons, a number of short-term lease-backs have been negotiated in Arizona. However, most irrigated agriculture on water farms likely will be retired in the near future.

Economic Impacts

Assessing the economic impact of water transfers on La Paz County involves estimating in economic measures the difference between what would occur with and without the water transfers. The following analysis determines the economic impact of retiring a hypothetical "typical" 1,000 acres of farmland in La Paz County. The results are then used to discuss tax revenue impacts for local governments.

Several different types of "impacts" typically are distinguished. "Direct" impacts are those employment and income impacts that are immediate and explicitly related to agriculture. In the case of assessing the employment impact of reduced agricultural acreage in La Paz County, the direct impacts include the change in employment at all establishments (farms, orchards, etc.) primarily engaged in the production of cotton, alfalfa, vegetables, fruits, nuts, and other crops.

Indirect impacts are determined by forward and backward inter-industry linkages, or the extent that agricultural products either are used in the production of other locally produced products (e.g., alfalfa cubes, ginned cotton) or that agricultural products utilize raw materials or intermediate products or services that also are provided locally. These technically linked sectors may be support activities, such as crop and soil services, farm management services, and legal services, as well as intermediate manufactured goods (e.g., seed and fertilizer).

Induced impacts occur through changes in local income flows and population changes. Proprietors and employees of the agricultural sector and of the technically linked sector earn income. This income and the consumption habits of these proprietors and employees determine the level of activity of the remaining (nonbasic) sectors. Person A, working on farms or in related industries, earns money which is spent buying goods and services. In doing so, she provides employment for person B in one of the local market-oriented sectors. In turn, B spends his income and provides employment for person C, also working in the local-oriented sectors, and so on.

Another induced impact occurs through changes in population. When employment falls, the change must be reflected in either an increase in the unemployment rate, a drop in the labor force participation rate as discouraged job seekers drop out of the labor market, or an outmigration of people seeking employment elsewhere. Typically, a reduction in employment results in all three of these changes occurring to one degree or another. If the decline in employment results in increased unemployment or discouraged workers, then the induced income impact described above accurately controls for these changes. However, when outmigration occurs, there are additional induced impacts because vacant housing results in declines in construction and construction-related employment.

A combination of methods is used to compute

the economic impacts resulting from constraints imposed by data limitations. The primary constraint was lack of time-series data on La Paz County, which split off from neighboring Yuma County in 1983. Consequently, employment and income data exist only since 1983, and traditional econometric approaches cannot be used. The present analysis utilizes a survey of growers to determine farm budgets, a survey of agriculture-related businesses to determine the nature of the services provided in La Paz County, and a telephone survey of a variety of other businesses in La Paz County. These surveys, combined with detailed employment data for La Paz County, permit all employment by sector that is directly or indirectly related to agriculture to be identified (Charney and Woodard).

Income- and population-induced impacts are determined using a large-scale econometric model of Arizona and its three major subcomponent areas: Maricopa County, Pima County, and the nonurban balance of state. This econometric model, while designed for impact analysis, lacks sufficient detail in the agricultural and related sectors to be useful in assessing the direct and indirect impacts. However, its structure easily is adapted to generate income- and population-induced effects (Charney and Taylor).

Table 1a presents direct plus indirect, induced, and total impacts of retiring 1,000 acres of agricultural land. For each 1,000 acres retired, La Paz employment falls by approximately seventeen employees. Of these seventeen employees, 10.5 are direct or indirect impacts and 6.5 are income or population induced. Of the 10.5 direct and indirect jobs, 65% are in farming and 16% are in agricultural services (see table 1b). There are additional indirect impacts in construction; manufacturing (e.g., production of animal feed and cottonseed oil); trade (particularly farm machinery and equipment and automobiles and parts); services; and small amounts in transportation, communications, public utilities; and finance, insurance, and real estate. The sectoral mix of the induced impacts is very different from the direct and indirect impacts, with income-induced impacts concentrated in the trade and service sectors, while the population-induced impacts primarily are in the construction and real estate sectors. The personal income impact of retiring 1,000 acres of farmland is approximately $363,000. Of this, $271,000 is the direct and indirect impact, and $92,000 results from induced effects. The direct and indirect income per employee impact (the income impact divided by the employment impact in table 1a) is large relative to the induced income per employee impact for two reasons. First, income per sector includes both labor and proprietors' income, which results in relatively high income per employee figures for the farm sector. Second, the induced impacts are concentrated in low-wage sectors, such as trade and services.

The estimated per acre impact of water transfers is larger than that of some other studies for several reasons. First, this analysis assesses the impact of retiring 1,000 acres of farmland. Other studies deal with the retirement of a combination of farmland, rangeland, and unimproved land. The land purchased for water transfers in Arizona also is a mix of farmland, rangeland, and raw desert; however, the impact analysis is based on 1,000 acres of the most productive, i.e., farmland. Second, less than half the farmland slated for water farms in La Paz County is in comparatively low-valued crops, such as alfalfa; the remainder is in higher-valued crops, such as cotton, grains, fruits, vegetables, and nuts. Third, the method used to generate these numbers, a method that combines input-output concepts with survey data and the simulation re-

Table 1a. Estimated Economic Impacts of Retiring 1,000 Acres of Agricultural Land

	Direct and Indirect	Population and Income Induced	Total
Employment (jobs)	10.5	6.5	17.0
Personal income ($1987)	271,000	92,000	363,000

Table 1b. Distribution of Employment Effects among Economic Sectors

Economic Sector	Direct and Indirect	Population and Income Induced	Total
	(%)		
Farm	65	0	40
Nonfarm			
Agricultural services	16	0	10
Construction	2	10	5
Manufacturing	2	5	3
Transportation, Communication & Public Utilities	1	3	1
Trade	7	26	15
Finance, Insurance & Real estate	1	10	4
Services	6	31	16
Government	0	15	6
	100	100	100

sults of an econometric model, explicitly includes the economic impacts of outmigration. An area with a small economic base, such as La Paz County, cannot absorb the labor force released from the agricultural industry as a larger economic area could. Thus, the number of outmigrants (relative to the number of agricultural jobs lost) is substantial. This outmigration generates additional economic impacts, particularly in the construction and real estate industries. All but the most sophisticated input-output models do not explicitly account for economic impacts of outmigration.

Fiscal Impacts

Table 2 presents estimates of revenue impacts for the City of Parker, for La Paz County government, and for other local governments in La Paz County. Estimated revenue impacts for Parker are $2,564 for each 1,000 acres of retired farmland. Half of this impact is attributable to the decline in sales (Parker has a 2% local sales tax rate). "Other" revenues to Parker include miscellaneous revenue items, such as business license taxes, licenses and permits, fines and forfeits, etc. There is no local property tax in Parker.

La Paz County government is impacted primarily through reductions in property taxes and state-shared sales taxes. Other revenues for La Paz County government include the auto lieu tax, licenses and permits, charges for services, fines and forfeits, etc. The "direct" property tax effect is the potential property tax lost to local communities in La Paz County if land (or a land leasehold) is purchased by another municipality because, according to the Arizona constitution, one municipality cannot be required to pay taxes to another. However, this impact may be zero if farmland is purchased by private parties or if the purchasing municipalities make voluntary payments in lieu of property taxes to local governments in La Paz County.

Over 100,000 acres of deeded land and 300,000 acres of leased land have been earmarked for water farms on properties entirely or partially within La Paz County (table 3a). Much of this land is grazing or raw desert land rather than irrigated farmland. However, nearly 50,000 acres of irrigated farmland is involved, land which currently grows an assortment of low and high-valued crops (table 3b). While it is not clear how long farming will continue on the irrigated acreage because water will not be physically transported from many water farms for decades, most land will be retired within a few years.

To put the present analysis into context, we assume that the roughly 40,000 acres of irrigated farmland lying entirely within La Paz County are retired at some point in the future. Retiring 40,000 acres of farmland causes 340 jobs to be lost, which represents 13.6% of La Paz County's 1987 employment. The personal income loss represents 9% of La Paz County's 1987 income.

The estimated revenue impacts imply that the City of Parker will lose approximately 5% of their non-utility revenues if 40,000 acres are retired. The county government of La Paz will lose approximately 6.4% of its revenues if the direct property tax effect is included. Without that direct effect (assuming nonmunicipal purchasers or in-lieu taxes), the county government is estimated to lose approximately 5.4% of its rev-

Table 2. Estimated Revenue Impacts (1987 Dollars per 1,000 Acres of Retired Farmland)

	City of Parker	La Paz County	Other Local Governments	Total Governments
Direct property tax		1,824[a]	5,383[a]	7,207
Indirect & induced property tax		3,279	9,686	12,965
Sales tax	1,255			1,225
State shared sales tax	166	2,320		2,468
Highway user revenue fund	238	553		791
Lottery funds	26	0		26
Other	879	3,541	[b]	4,420
Total	2,564	11,517	15,069	29,150

[a] This category applies only to the degree that municipalities purchase land and refuse to make voluntary in lieu payments to the local governments in La Paz County.
[b] Impacts on other revenue categories for other local governments were not considered, e.g., the reduction in state aid to schools associated with reduced enrollment.

Table 3a. Pre-Purchase Land Uses for Water Farms within La Paz County

Water Farm	Land Uses
Birmingham	5,618 acres of mostly raw desert
BJ Ranch	191,180 acres are grazed; the remaining 2,963 acres are farmed, with 1,737 acres in cotton
Cibola Valley Immigration District	4,600 acres irrigated agriculture
Crowder-Weiser Ranch	Use of 7,670 acres unknown; 2,388 acres irrigated, 1,117 acres undeveloped, 2,746 acres grazed
Five landowners	1,300 acres of mostly irrigated farmland crops
Fullmer Ranch	2,751 acres of irrigated agriculture, 1,210 acres raw desert, 138,544 acres used for grazing
Harquahala Valley Immigration District	24,000 acres of irrigated agriculture
Lincoln Ranch	800 acres irrigated crops including sod, cotton, fruits, and vegetables; 240 acres are grazed
McMullen Valley	1,200 acres of pecan and pistachio orchards and an additional 3,725 acres of cotton
Planet Ranch	2,400 acres of alfalfa
Ranegras Plain	22,950 acres of raw desert, 2,000 acres of cotton, 10,550 acres grazed

Table 3b. La Paz County Water Farm Acreage by Land Use

Land Use	Acreage	Percent
Irrigated agriculture	48,127	10.7
Unirrigated grazing land	343,260	76.3
Raw desert/abandoned farmland	50,970	11.3
Unknown land uses	7,670	1.7
Total water farm acreage	450,027	100.0

enues. The other jurisdictions will lose 12.8% with the direct property tax effect and 8% without it.

Several important points should be made about the estimated impacts presented in this article. First, all impacts do not occur immediately. It may take five or more years for impacts to work their way through the local economy after a farm is retired. For example, property values tend not to fall immediately when demand for housing falls. Rather, property owners tend to hold onto the property, unable to sell it, until the "real" value erodes via inflation. Thus, the indirect property tax impacts occur through reductions in real property values over time.

Second, the impacts do not occur evenly throughout La Paz County. The impacts, relative to the size the local economy, will be much larger in the eastern part of the county, which is almost completely dependent on agriculture. Although agriculture is important throughout the county, the economic base of the western part of the county includes tourism and sales to residents of the Colorado River Indian Reservation.

Third, we have not analyzed any positive aspects of water transfers, specifically impacts of spending associated with farm purchases and construction of transport infrastructure and impacts on areas of import. It is assumed that, once bought out, little or none of the purchase money will be respent in La Paz County. In addition, we are not viewing rural-to-urban water transfers as a zero-sum game for the state as a whole. The focus of this study is limited to the impacts in the areas of origin only.

Impacts on Future Development

The estimated impacts described above do not take into account the potential foregone growth that may be associated with either water transfers or the purchasing of water farms in La Paz County. For example, land that is used solely for water farming may be unavailable for development. The scarcity of deeded land in La Paz County and the fact that water farms located near the CAP canal also are located near the interstate highway and railroad make availability of developable land a concern.

In addition, there is an unquantifiable water "image" that is important for attracting business. Maintaining an image of having adequate water supplies has prompted Arizona businesses to advertise that "urban Arizona has no water shortage," a claim now being backed up by purchases of water farms. Residents of both rural and urban communities tend to view as desirable those community attributes that describe

where they live (Nunn and Urban). Therefore, one identified cost associated with rural-to-urban water transfers is that transfers threaten valued rural cultures and lifestyles (Nunn and Ingram). However, residents of La Paz County appear to be more concerned about lost opportunities for growth and development than about threats to their current lifestyle. Lack of safeguards or requirements to reserve water for use on the purchased land may make La Paz County a very unattractive location for development. Any economic growth that would have occurred but for the water farming activity represents additional, unquantified losses.

A survey of 317 community leaders in twelve water-importing and exporting areas of Arizona, New Mexico, and Texas was designed and administered in an attempt to better understand concerns about various nonpecuniary threats to rural areas of origin (Ingram). The survey contained eleven multipart questions that solicited views on who are the winners and losers in water transfers, which types of losses are most serious, and the degree to which these losses can be mitigated or compensated. One principal finding was that 93% of the respondents in La Paz County agreed with the statement, "The losses to the community associated with the transfer of water are of such a nature that they cannot be compensated," as did a majority of respondents in the Phoenix and Tucson areas (Oggins).

Additional findings of the survey include perceptions that certain groups, including government officials, attorneys, water utilities, and various water experts tend to gain when water is transferred, while private well owners, indigenous groups, future generations, and small farms tend to lose. The degree to which respondents believe that market solutions generally increase public welfare depends upon the occupation and role of the respondent, with city officials and members of the Chamber of Commerce most confident in market solutions and farmers, agriculture-related businessmen, and members of school boards and PTAs least confident.

There also were differences in the degree to which various types of respondents believe that urban water conservation is a viable alternative to water transfers and the effectiveness of various potential compensation schemes. In general, mitigation/augmentation approaches that put authority over water transfers or up-front money in the hands of local government were preferred over other approaches that involved other entities, payments to individuals, or payments only at time of physical transport of the water.

Conclusions

Impacts of rural-to-urban water transfers that result in loss of irrigated agriculture do not result in significant economic impacts when viewed from a statewide perspective. When viewed from a county level, such impacts are substantial but not devastating. Similarly, fiscal impacts are real but not catastrophic. However, the impacts tend to be highly concentrated because the factors which make particular parcels suitable water farms can result in geographic clustering of purchases. Therefore, if water transfers result in the levels of economic gain claimed for them, strong arguments can be made for mitigation and compensation. However, some of the more important potential losses associated with transfers, including loss of autonomy and reduced options for future development, can be neither estimated nor compensated.

The Economic Impacts of Agriculture-to-Urban Water Transfers on the Area of Origin: A Case Study of the Arkansas River Valley in Colorado

Charles W. Howe, Jeffrey K. Lazo, and Kenneth R. Weber

The development of new water supplies has grown increasingly costly, both in financial and environmental terms. Public values related to instream flows, preservation of natural areas, and wildlife have increased sharply relative to the values of traditional water uses. In such a setting, reallocation of existing supplies becomes increasingly attractive, and water transfers have been hailed as the solution to western U.S. water shortages (e.g., Anderson, Saliba and Bush, Howe et al).

A major U.S. Geological Survey-funded study (MacDonnell et al) has found frequent water transfers in several western states (Colorado, New Mexico, and Utah) but infrequent transfers in other states (e.g., California and Wyoming), the frequency being strongly affected by the institutional structure for effecting transfers and the pressure on water supplies. A glance at water use data (U.S. Geological Survey) shows that 80% of all water diversions and nearly 90% of all water consumption in the western United States occur in irrigated agriculture, strongly suggesting that small percentage reallocations from agricultural to nonagricultural uses could satisfy growing nonagricultural water demands for decades.

Some economic studies suggest that economic impacts of rational transfers from agriculture will be minimal. Popular perceptions are more pessimistic and foreboding: "draining the lifeblood of farms" or "tantamount to agricultural suicide" (*Rocky Mountain News*). Some resolution of these contradictory facts and perceptions is called for.

The Benefits and Costs of Water Transfers

The buyer and seller of water in a market transaction presumably gain from the transfer, but other parties can be affected positively or negatively. The most obvious are those experiencing externalities from the transfer, i.e., positive or negative physical impacts on their production or consumption activities that are not compensated through the market. Negative externalities from transfers include reductions in water quality, in water available because of reduced return flows, and in instream values such as recreation and aesthetics. Positive externalities can occur downstream from the new use because of better water quality or increased return flows.

Protection of third parties from negative externalities of transfers is at least partly provided by the laws and institutions governing transfers in the western United States. For example, downstream parties are protected from reduced return flows by regulations that limit the transfer to the prior consumptive use (in contrast to the amount diverted). Transfers from a particular stream may be limited if water quality deterioration causes harm to remaining users. However, recreation, wildlife, and aesthetic uses typically are not protected. As Hartman and Seastone pointed out in 1970, positive externalities are not accounted for in western U.S. water administration, creating a bias against transfers. In sum, important positive and nega-

The authors are, respectively, a professor of economics and director of the Research Program on Environment and Behavior; a doctoral candidate in economics; and a research anthropologist, Research Program on Environment and Behavior, University of Colorado.

The research has been carried out under grants from the Rural Poverty and Resources Program of the Ford Foundation and the General Service Foundation.

tive externalities are not taken into account in water transfer processes.

Parties indirectly linked through the market to the sale or purchase of water also gain or lose in ways that are validly included in national economic efficiency calculations (e.g., MacDonnell and Howe). For example, there may be transitory or permanent income losses to factors of production in sectors with backward or forward linkages to irrigated agriculture. In the presence of persistently depressed rural conditions, factors of production left unemployed in agriculture, in agricultural supplying activities, and in agricultural processing activities can be idled for long periods, leading to real national efficiency losses. Substantial economic and psychological costs are incurred even by those factors that successfully move to new occupations. Such costs typically are ignored in comparative statics analyses, often erroneously being labelled "pecuniary" gains or losses.

Naturally, the apparent importance of these indirectly incurred costs depends on the "accounting stance" employed by the analyst. In the area of origin, indirect employment and income losses can be persistent and of great importance. At the state level, both direct and indirect losses of income and employment in the area of origin may be offset by gains in the importing areas. At the national level where the agricultural losses easily can be made up by expanded production in other states, the losses in the area of origin may appear totally inconsequential.

The state laws and institutions governing water transfers typically overlook the indirect economic costs imposed on the area of origin. Microeconomic and regional analyses suggest that the severity of economic impacts on the area of origin will differ according to (*a*) whether or not the new use is inside or outside the economic area encompassing the area of origin, (*b*) the economic vitality of the area of origin, (*c*) whether or not the water sales proceeds are reinvested in the area of origin, and (*d*) the strength of the backward and forward linkages between irrigated agriculture and supplying and processing sectors.

Description of This Study

This is a case study of a seven-county reach of the Arkansas River in southeastern Colorado, an area from which a large amount of agricultural water already has been transferred to urban uses and for which there is the prospect of even larger future transfers. The study is not a complete evaluation of these transfers, but only of the negative economic impacts caused directly and indirectly by the reductions in irrigated agriculture. The negative impacts are measured in terms of employment, personal income, value added, and population for the area of origin and for the State of Colorado.

The Arkansas River Valley of southeastern Colorado was chosen as an area where the impacts of transfers could be severe because it has (*a*) a dry, highly variable climate with mean precipitation of only eleven inches; (*b*) little opportunity for agriculture in the absence of irrigation; (*c*) geographic isolation from other farming areas, making the substitution of imported supplies for local production costly; (*d*) clear backward and forward linkages to suppliers and processors for a significant portion of irrigated outputs; (*e*) a historically marginal, depressed economy; and (*f*) heavy agricultural indebtedness. Table 1 provides an outline of the region's land, farming, irrigated areas, and cropping patterns.

Roughly 30% of all crops are irrigated, but only 2.4% of irrigated crops are vegetables, fruits, or other specialty crops that typically require further processing. The Arkansas Valley is famous for its Rocky Ford melons, which are crated and shipped across the country. Some melons also are grown for highly valued seed. Other specialty crops that receive extensive processing in the valley are onions, tomatoes, and flower seeds. These crops have strong forward linkages to processing. The irrigated feed grain and hay crops support the feedlot industry of the region.

Table 1. The Arkansas Valley Study Area: Baca, Bent, Crowley, Kiowa, Otero, Prowers, and Pueblo Counties

	Acres
Total land:	7,661,440
Land in farms:	5,934,856
Land in farms with irrigation:	349,815
Farms with groundwater sources:	121,068
Farms with direct flow irrigation:	228,747
Nonirrigated field crops	749,357
Irrigated field crops	300,709
Vegetables	6,902
Fruits and specialties	536
Total crops	1,057,504
Total irrigated crops	308,147

Historical Transfers and Their Impacts

A water transfer does not just happen at an instant of time with its full effects experienced instantaneously. Water sales and subsequent transfers may be negotiated over several years. Once a farmer or a ditch company decides to sell, cropping patterns, land maintenance, and productivity begin to change. Water may be held on the land by court decree for revegetation or may be partially left on the land because the buyer does not yet need it. There is no such thing as a clean-cut water transfer. Subject to such caveats, table 2 presents the significant historical agriculture-to-urban transfers.

Vegetable and specialty crop acreages remained quite steady over time for the valley as a whole. Most of these crops were grown under contract to shippers and processors, and there was always a waiting line of growers wanting contracts. Thus, over the historical period analyzed, the high value, forward-linked horticultural crops always were "bumped" onto new lands as old lands were dried up. Thus, historically there were no vegetable/specialty phase-outs and no forward linkages due to those crops. There is no evidence that the phase-outs of feed grains, hay, and the irrigated pasture held back the expansion of feed lots over the historical period from 1955 (Otero Ditch sale) to 1985 (Colorado Canal sale). Thus, forward linkages were judged to be absent in this historical period.

It was our intent to use the combination econometric/input-output Colorado Forecasting and Simulation Model (COFS) of the Center for Economic Analysis, University of Colorado, Boulder, to analyze the temporal pattern of impacts of both the historical and the potential future transfers. COFS is a REMI model that has been elaborated over nearly a decade to include a demographic submodel and analyses for substate regions of which the Arkansas Valley is one. Unfortunately, it was not possible to recalibrate COFS for the earlier period, so a statewide input-output approach was used for the historical analysis, an IMPLAN model based on the 1977 BEA I-O model, updated to 1982 dollars. The results of the analysis are presented in table 3.

The loss of state net income of $53 per acre-foot certainly was more than offset by cost-savings to the cities buying the water because the cost of developing new water has risen to more than $2,000 per acre-foot. Again, however, the incidence of the income losses will be largely in the area of origin, while the cost saving (and consequent increase in expenditure on other goods and services) will be in the buying cities. The same can be concluded regarding the incidence of losses and gains of government revenues.

In sum, the statewide direct and indirect employment and income losses stemming from historical agriculture-to-urban transfers appear to have been small relative to the costs of alter-

Table 2. Historical and Potential Transfers

Table 3. Statewide Negative Direct and Indirect Impacts of Historical Arkansas Valley Transfers (1982 dollars)

Reductions in:
Employment = 157 = 1 job per 308 acres
State net income = $5,290,000 = $53 per A.F. Cons.
Local/state government revenues = $506,350 = $5 per A.F. Cons.

native ways of getting water for the urban areas. However, the incidence of the costs is upon the rural areas, while the benefits accrue largely to the urban buyers.

Table 4. Future Transfers: Percent Reduction from Baseline Projection in Year 2020

	Arkansas Valley		State	
Scenario	3	5	3	5
Farm employment	10.1	21.0	1.2	2.5
Total employment	0.8	1.6	0.0	0.1
Population	0.2	0.3	0.0	0.0
Value added—farm	10.0	21.1	1.2	2.5
Value added—total	1.4	2.5	0.0	0.1
Personal income—total	1.1	1.6	0.0	0.1

Note: 0.0. Indicates negligible differential (<0.5%).

Potential Future Transfers and Their Estimated Impacts

Information regarding future transfers was obtained from transfer applications already filed and from discussions with water users and ditch company officials (see table 2). The occurrence and timing of future transfers is highly speculative. Most water users and water officials agreed that the potential transfers listed in table 2 are likely.

Several scenarios were run through the COFS model for these future transfers, each differing in the canals phased out and the extent of assumed forward linkages. Scenario 3 reported below assumed all the potential transfers indicated in table 2, including the vegetable and specialty acreages when the last two canals are phased out (all vegetable and specialty crops were assumed to be "bumped" onto the lands of the last two canals). Scenario 5 reported below is the most severe scenario and assumes all those transfers plus partial forward linkages of vegetables and specialty crops to food processing (based on percentages sold fresh and percentages sold under contract for processing) plus an 80% phase-out of feedlots in response to increased costs of importing feed grains and hay. The results are reported in table 4 in terms of percentage decreases from the baseline COFS projections (no water transfers) to the year 2020.

These results show that farm employment and value added in the Arkansas Valley are severely impacted under both scenarios 3 and 5, the latter producing 21% reductions from the projection without transfers. The percentage decreases in total employment and value added, however, are much smaller. At the state level, these changes and the changes in personal income sink to insignificance.

The temporal pattern of negative impacts (not shown here) remains negligible for the Arkansas Valley until the Fort Lyon Ditch is phased out in 2003 (see table 2). The Bessemer and Catlin transfers result in very large local employment and income impacts because they have been assumed to carry all the vegetable and specialty crops.

Conclusions

Judged at the state level, none of the water transfer scenarios analyzed results in significant losses to the state agricultural or general economy. Historical transfers appear to have imposed total costs in terms of employment and personal income that would easily have been offset by cost savings and alternative expenditures in the importing urban areas. The same conclusions hold for the prospective transfers.

However, the incidence of the costs is always on the area of origin, while the benefits accrue to the area of new use. If water is transferred from agriculture to expanding uses in the same economic region, then many of the negative effects are offset locally. Most of the time, however, transfers are to uses outside the agricultural economic area. In such cases, significant uncompensated costs are imposed on the local economy. These effects are exacerbated by the use of sales proceeds to repay heavy farm debt and the absence of local investment opportunities for these funds.

The results thus imply that states should not fear water transfers: transfers will not wreck ba-

sins of origin nor state economies. The results do imply, however, that transitional assistance is warranted to help those parties suffering uncompensated externalities and indirect displacement by transfers. Areas of origin warrant assistance.

The Impacts and Efficiency of Agriculture-to-Urban Water Transfer: Discussion

Norman K. Whittlesey

The paper by Colby is well written, thoughtful, and provocative. She reviews the record of water exchanges in the West, focusing on the policy-induced transactions costs (PITC) necessary to obtain state approval of proposed water rights exchanges. These costs result from considering externalities that otherwise would be ignored by water buyers and sellers negotiating in their own best interests. But I have a concern that we recognize only the economic activity that is capable of self-representation in this process. By defining competition in this manner, we may fail to recognize significant social uses and values of water, particularly those associated with nonappropriated uses on many flowing streams. Colby states that the "public interest" is rarely used to contest a proposed transfer.

Colby correctly demonstrates the optimal PITC as exactly equivalent to a Pigouvian tax representing the externality costs associated with a water right exchange. However, the *WTP* curve, as derived, will not include the externality benefits associated with the alternative uses of water. This curve should be shifted upward to reflect these benefits and to indicate an optimum level of water transfer. Alternatively, there is no reason to expect the *SMC* curve always to lie above the *PMC* curve if it reflects both positive and negative externalities of the exchange. In any case, a water transfer should take a balanced position toward the externality benefits and externality costs of the exchange.

Colby's major conclusion is that transactions costs generated by state regulation of water transfers out of agriculture may be lower than socially optimal. My response is that if a major portion of transactions costs goes to engineers, hydrologists, lawyers, and economists to define water rights on a case-by-case basis, there must be great inefficiency and potential inequity in the process. In the interest of efficiency, we must be able to define the transferable interest of an irrigation water right. In most cases, this can be accomplished without extreme difficulty. All direct uses of water must be protected. But the pure economic interest that is secondary to direct water use probably should not be allowed to have an interest in the water right transfers. Transferring water to a higher-valued primary use should always result in an equally higher secondary economic value. The argument becomes one of distribution or political constituency but not economic value.

The paper by Charney and Woodard describes the local economic impacts from water farming in Arizona, wherein municipalities purchase agricultural land to obtain the associated water rights. The implication is that the land will eventually be retired from farming and the water (right) moved outside the local region for nonagricultural use. Charney and Woodard use a survey approach to estimate the economic impacts of the water transfer. I have some major concerns about this paper.

The first deals with the level of economic activity claimed to be associated with irrigated agriculture in a local economy. The levels of employment and income used for local economic impact are much higher than expected. Compared to similar measures of primary and secondary employment effects from irrigation reported by Howe, Lazo, and Weber and many others, the values used by Woodard are unexpectedly high for state-level impacts. For county-level impacts they are quite excessive.

I am also bothered by the implication that economic impacts are estimates of economic benefit or cost. The impacts described are similar to those measured by an input-output model. They indicate nothing about the net benefit (welfare) derived from any level of activity or change in activity level. If, as implied, land purchases are made in advance of the actual decline in agriculture, the local economy should derive

Norman K. Whittlesey is a professor of agricultural economics at Washington State University.

a considerable benefit from the increased capital liquidity in the region. No measure of this benefit is considered.

Properly, one must estimate the opportunity cost of labor and capital in order to determine the change in net economic benefit from a reduction in irrigated agriculture (Hamilton et al.). Then, the net benefit changes are a result of temporary disequilibria in the labor and capital markets. Not only are the net benefit changes going to be a small portion of total economic impacts, they are short run in nature, disappearing once a new equilibrium is achieved in the capital and labor markets. This type of analysis should be carried out for a long period, say 50 years, using a proper discount rate, in a complete "with versus without" framework, and the accounting stance must be carefully defined. None were properly done in this case. The only conclusion that can be derived from this analysis is that the local economy will probably be smaller after the change than before. Nothing can be said about whether the remaining or previous populations will be better or worse off.

The paper by Howe, Lazo, and Weber uses an input-output model to describe the past and future potential impacts on the Arkansas Valley region of Colorado imposed by water transfers from agriculture to municipalities. The authors are candid in stating that they describe only the negative impacts imposed on local agriculture by the water transfer. Consequently, there is no measure of whether the remaining agriculture in the region or state is better or worse off after the water transfer.

At the risk of being repetitive, let me conclude. These and other similar studies are too quick to describe the negative impacts of water transfers on a local economy while providing no measure of the positive externalities that may come from the transfer. Because of the model used, they are not useful in describing the social welfare impacts of water markets. They may even fuel the inefficient state policies controlling water transfers described by Colby. I would urge practitioners of impact modeling to be more careful in describing the useful limits of their results. We cannot profess our good intentions and expect the politician or policy maker to understand how to properly employ our work. Such results are useful for planning the adjustments to water exchanges but may be very misleading if not carefully presented.

The Impacts and Efficiency of Agriculture-to-Urban Water Transfers: Discussion

Richard L. Gardner

The three papers demonstrate a rapid evolution in thinking about water marketing, from recognizing its potential to improve efficiency, to noting institutional impediments and calling for their removal, to reassessing the need to correct market failures in water transfers. This evolution has largely occurred in the last decade and parallels the transition from water development to an era of water reallocation. Hence, we have papers today by Charney and Woodard; and Howe, Lazo, and Weber that focus on the local economic impacts of water transfers out of agriculture, while Colby argues water markets fail to address public goods and externalities and that the costs imposed by state water right transfer policies help close the gap between private and social costs and actually improve water allocation patterns.

The Colby paper is provocative, well written, and contains important empirical data on transactions costs. Colby's hypothesis is personally appealing because I believe that water markets fail not only because of physical externalities of return flow interdependencies, to pecuniary externalities of secondary economic impacts, and to public good aspects of instream uses, but also because water markets fail to meet the competitive market requirements of complete information, homogenous product, and atomistic, profit-maximizing participants (Gardner). Thus, true, functioning water markets are rare. Instead, voluntary, negotiated transfers are the rule, aided in places by market-like entities.

Although many constraints on water transfers were purposefully developed to address perceived market failures, two other thoughts emerge. First, the implicit notion in Colby's paper that large transaction costs are inherently good should be dispelled. Administrative efficiency remains a policy goal even if the inefficiencies convey a positive externality. Excessive delays, tedious case-by-case analysis, and expensive legal costs can be streamlined. For instance, Idaho presumes the consumptive use for irrigation to be the amount required to grow alfalfa in the region, thus eliminating lengthy arguments over historic consumptive use. In contrast, water marketing in Idaho is needlessly penalized by an administrative rule that water rightholders who rent to downstream users from the Upper Snake Water Bank lose priority in refilling their reservoir space *vis-à-vis* equal rightholders who use their water to irrigate their lands. Although compensation of damages is not a required use of Pigouvian tax revenues, it would certainly be preferred to investment in bureaucracy or litigation. Colby should more carefully differentiate between those procedures designed to correct market failures versus legal or administrative flaws in the transfer system.

Colby's implicit assumption of a competitive market structure was another concern. Rarely do many buyers and sellers act in a local water market at the same time. Marketing activity often accelerates for a time to accommodate the water needs of a single purchasing entity. The paucity of buyers may be aided by another type of market failure—natural monopolies for municipal water supply or hydropower production. A textbook example of a monopsony occurs in the Upper Snake Water Bank where Idaho Power Company accounts for 81.2% of all rentals over the last twelve years. Sellers may limit the number of actors on the supply side by participating in water markets from the wholesale level of irrigation districts rather than as individuals.

The theory of bilateral monopolies applies to negotiated water transfers in such imperfect market settings. The equilibrium price and quantity of mutually beneficial sales are indeterminate; both parties will try to capture the economic rents available from the transaction. However, all three papers would seem to agree that the transaction space between the irrigator's

Richard L. Gardner is a policy economist with the Division of Financial Management of the Office of the Governor of Idaho.

reservation price and the buyer's willingness to pay for a new use is generally quite large and well above transaction costs. The seller's reservation price may be larger than the marginal value of water in irrigation because of noneconomic values (Oamek, Mumme and Ingram), and that price may fluctuate with the seller's expectations of his ability to sell to a higher-valued use (Gardner and Miller).

The Charney and Woodard and Howe, Lazo, and Weber papers are more narrowly focused on the social and economic impacts to basins-of-origin when significant amounts of water are transferred from agriculture to urban uses. Both contain a case study. Howe, Lazo, and Weber evaluate theirs with an IMPLAN input-output model, Charney and Woodard with an econometric impact model aided by partial analysis of the agriculture-related sectors. A key difference is that Charney and Woodard's model retires high-valued crops in proportion to the county crop mix, while Howe, Lazo, and Weber more realistically assumes higher-valued crops will shift to remaining acreage. Because of this assumption and considering that their model measures impacts to a single county, Charney and Woodard's employment and personal income impact estimates seem high compared to Howe, Lazo, and Weber or Keith and Glover. Further, Charney and Woodard should distinguish more carefully between secondary impacts and the much smaller secondary benefits which might be subject to mitigation (Keith and Glover).

Both studies conclude that, while the adverse impacts of such transfers to the regional economy are small, there can be significant impacts to a local economy, and the incidence of costs tends to accrue to different sets of individuals or government entities than the benefits. Both papers call for some form of mitigation or transitional assistance to local affected parties.

Curiously, neither paper offers policy alternatives that might address their findings. Transferring the rights to use a flow resource seems analogous to extracting an exhaustible resource (Metzger), particularly for "mined" groundwater in Arizona. Such transfers forego opportunities to use that resource in the future. The marginal intertemporal opportunity cost is more commonly called the user cost, and this is the theoretical underpinning for mineral severance taxes. The rationale for taxing water transfers seems even stronger because, while the extraction of a mineral resource creates jobs in the present, the extraction of water from a region causes a local loss of employment. Intriguing legislation proposed in Colorado several years ago would have charged a "transfer tax" equal to five times the lost property tax whenever water was transferred out of the area from agriculture. The proceeds would have gone to county "economic augmentation funds," thus providing monies to diversify the local economy in adjustment to the agricultural loss.

At the core of all three papers lies the notion that maximizing economic efficiency is not society's only goal. Other cultural and social values, such as maintaining the opportunity for a rural lifestyle and preserving environmental quality, must be considered. Advocates of maximum economic efficiency through unencumbered, interbasin water transfers should also remember the implicit assumption in neoclassical theory that the current income distribution is appropriate. Budget constraints will have a very real impact on the willingness to pay for water, especially for aesthetic and environmental uses. Water transfers will certainly have distributional impacts but, as Howe, Lazo, and Weber note, they are not at all likely to increase social welfare. To quote two respected legal scholars, "While a society fashioned solely by economists might be very efficient, it is unlikely that one would choose to live there" (Dumars and Tarlock).

Local economic impacts come under the legal heading of "public interest," which most states must consider before approving water transfers. This concept is rarely well-defined. Consider an Idaho definition of the local public interest as "the affairs of the people directly affected by the proposed use." Who are those directly affected? It is not far from Rocky Ford to Pueblo, where new jobs are being created. It is farther from La Paz County to Phoenix, and it is a long way from the Upper Colorado or Columbia River Basins to Southern California. Local perceptions of economic loss seem to vary directly with the distance of the transfer as the positive secondary impacts of the new water use are lost to the basin-of-origin.

I agree with Colby that, while urban transfers will remain a threat to the public interest of irrigated agricultural areas, there is increasing consideration of environmental issues. Water rentals in Idaho have been used for such innovations as maintaining trumpeter swan habitat and meeting the water quality standards for a paper mill in a drought year. A pilot rental program will soon provide rental water for improved spring flows for anadromous fish, and proposals to list salmon as endangered species could precipitate additional transfers within the Snake/Columbia system.

In most states the public interest could be enhanced by increasing minimum stream flows for instream uses. Here, the state is really trying to estimate the vertical summation of the demand for a public good, subject to the availability of unappropriated water. States would do well to allow private parties to purchase consumptive water rights for dedication to instream use. I disagree with Colby that individuals should be allowed to file on unappropriated waters. This may lead to frivolous claims on all available water.

Though riddled with imperfections, I remain convinced that market mechanisms have the potential to continue to improve water management and that public acceptance is slowly increasing. In Idaho two more water banks have formed recently and a third is likely to emerge from a reserved water rights settlement. The three papers in this session highlight the need to recognize the limitations of water marketing and at the same time the need to look for barriers to water transfers that are not intended to correct market failure. In the context of this session, the cliche "Don't throw the baby out with the bath water" takes on new meaning.

Methodological and Empirical Challenges in Analyzing Structural Change in U.S. Food Systems
(Clement E. Ward, Oklahoma State University, presiding)

Economics of Consolidation in the Beef Sector: Research Challenges

Wayne D. Purcell

The beef industry experienced unprecedented structural change during the 1980s. Four-firm concentration ratios in boxed beef production jumped from 51% in 1979 to 79% in 1988. For steer and heifer slaughter, the increase was from 37% in 1979 to 70% in 1988.

In 1980, congressional hearings were conducted regarding the potentially negative dimensions of market power by meatpackers. Concentration levels had increased during the 1970s. Concern was sufficient to prompt the introduction of two pieces of proposed legislation, both of which would have limited the size of packing operations. During the hearings, testimony was replete with dire predictions of what would happen to industry performance if concentration were to increase still further. Parker testified that the research literature documents rapid increases in prices and in profits as the four-firm concentration moves up from 40% to 60% and higher.

Viewed in the presence of the content and orientation of those congressional hearings, the happenings later in the 1980s appear incomprehensible. If the important threshold in terms of the four-firm concentration ratio is around 40%, why was the massive consolidation of the beef sector during the 1980s allowed by the regulatory authorities? What research methodology was brought to bear on these issues? Is it adequate? The answers to these related questions are not apparent, but they are clearly important. If the decisions by the regulatory authorities during the 1980s were not based on solid economic research, then important issues confront the profession. Either the research methodology must be modified or the empirical results of our research were ignored.

Wayne D. Purcell is director of the Research Institute on Livestock Pricing and a professor of agricultural economics at Virginia Polytechnic Institute and State University.

The objective of this paper is to explore the economics of the consolidation in beefpacking, to look at why it occurred and why it was allowed to occur, and to draw inferences about our research efforts. The perspective offered is that of a marketing economist looking ahead to an uncertain future for the beef sector in the 1990s.

Market Power versus Superior Efficiency

A survey of the literature starts to explain the events of the 1980s. During the 1950s, 1960s, and the early 1970s, the regulatory agencies were aggressively enforcing the various antitrust statutes. The basic tenet of the Structure-Conduct-Peformance (SCP) paradigm initially popularized by Bain, that a high level of market concentration leads predictably to socially undesirable performance, was widely accepted. Across the major antitrust statutes (Clayton Act, Federal Trade Commission Act, Sherman Act) the Federal Trade commission (FTC) and the Justice Department (Justice) brought 290 cases in the food system in the 1956–60 period. By 1976–80, the total was down to 64 cases (Marion 1986a, p. 378).

It was a switch to the so-called Chicago School of thought that ushered in the change. Presented by Demsetz, the Chicago School argued that consolidation and concentration lead to increased efficiency. This "superior efficiency" argument was offered to counter industrial organizaton economists who subscribed to the SCP paradigm and who argued that concentration occurs in a search for market power.

The theme underlying the Chicago School of thought was developed into the theory of contestable markets by Baumol, Panzar, and Willig in the early 1980s. Markets were seen as inherently competitive, and ease of entry and exit was

the economic force that blocked any significant departure from competitiveness. A firm could enter, earn temporary profits, and exit. To prevent such hit-and-run entry, incumbent firms must produce efficiently and earn no economic rent. If markets are perfectly contestable, the level of concentration is then irrelevant.

There can be little doubt that a major change occurred at Justice during the 1970s and early 1980s. Alarmed by the developments of the 1980s, the American Bar Association appointed a task force in early 1989 to examine the Justice Department's antitrust program. The task force report identified three reasons for the change to a more permissive policy (ABA, p. 8):

(*a*) The gradual but fundamental change in antitrust economic analysis which invited reconsideration of the wisdom of a number of previous antitrust decisions.

(*b*) The globalization of the American economy, which raised questions about whether a nationally oriented antitrust policy would hurt American businesses.

(*c*) The growing popularity of the "philosophy of deregulation," which led to skepticism about the ability of government to carry out an antitrust policy that would be beneficial.

The task force cited two cases in the late 1970s as evidence that the courts were starting to pay significantly more attention to the arguments involving economies of size and related efficiencies in acquisitions or mergers (*Continental TV, Inc.* vs. *GTE-Sylvania,* 433 U.S. 36, 1977; *Broadcast Music, Inc.* vs. *Columbia Broadcasting System,* 441 U.S. 1, 1979). The task force cited data documenting a continued decline during the 1980s in civil cases involving merger enforcement actions and/or antitrust enforcement actions. The average number of cases for 1979–83 stood at a relatively low 20.5 and declined even further to an average of less than 11 per year for the 1985–88 period.

The task force endorsed the use of economic analysis in deliberations about proposed mergers but also confirmed a continuing belief in the basic tenets of the SCP paradigm. They noted that, in spite of the Justice's 1982 and 1984 guidelines suggesting that proposed mergers are more likely to be challenged when concentration as measured by the Herfindahl Index (HHI) is high, very few of the almost 8,000 premerger notifications during the 1982–86 period were challenged.

In an early 1990 presentation, Sanford Litvack, a former member of the Justice Department Antitrust Division, agreed that Justice was largely out of business during the decade.[1] He noted that the emphasis was on criminal activity and that most mergers and acquisitions were allowed under the banner of increased efficiency. The 1984 merger guidelines, Litvack suggested, are largely ineffective because of two huge loopholes.

The first loophole comes in the form of market definition. Litvack notes that if you define the "market" broadly enough, then there will be no high level of concentration. For example, if the market is not defined in terms of boxed beef but in terms of all beef or all protein foods, then high levels of concentration in boxed beef are not seen as an enforcement issue.

The second loophole involves ease of entry. This is a basic tenet of the contestable markets theory and is closely related to the idea that all markets are inherently competitive and that there are no significant barriers to entry. Litvack was skeptical and, like Marion, criticized the theory as too simplistic (Marion 1986b). The ease of entry idea is built upon the notion that entry is free, that the entrant is just as cost effective as the incumbent firm, and that exist is costless.

It was in this environment of uncertainty and changing attitudes that developments late in the decade ushered in four-firm concentration ratios as high as 80 in boxed beef production. In 1987, for example, Excel (owned by Cargill) purchased Spencer Beef after the U.S. Supreme court overturned two lower court rulings that had blocked the merger in support of a suit by Monfort of Colorado. After the Supreme Court overturned the ruling. ConAgra purchased both Monfort and Swift Independent. The efficiency of large size was the cornerstone of those advocating the merger moves, and it was apparently to those arguments that Justice and the courts were inclined to listen.

A Stimulus for Change

Concentration increased throughout the economy during the 1980s. It happened in the airline industry, food retailing, banking, and energy. But concentration is generally considered a time-stable phenomenon, and it is unusual to see con-

[1] Presentation at the National Conference on "Structural Change in Livestock: Causes, Implications, Alternatives," conducted by the Research Institute on Livestock Pricing, Agricultural Economics, Virginia Tech, in Dallas, 22–23 Feb. 1990.

centration ratios double in less than ten years. Even if we assume that Justice and the courts would eventually approve every merger request, there had to be a stimulus behind all those requests in the beef sector. Decreases in demand for beef, starting in the 1970s, generated a powerful economic force that compelled some type of adjustment.

Highly structured econometric models that are not specified to pick up changes in the level of demand for beef have generated mixed results about changes in beef demand. Data requirements have also been a problem. Some of the models require a number of years of change before a statistically significant change can be confirmed. All this caused some confusion during the decade, but the most recent studies are starting to generate consistent results. In a study commissioned by the National Livestock and Meat Board, Ronald Ward found that demand for beef declined during the 1980s and continued to decline through 1988. In a February 1990 article, Choi and Sosin find evidence of structural change in beef demand, related to a preference change, that started in the mid-1970s.

In the presence of still-mixed opinions, it is instructive to look at the data. The data also provide a measure of the intensity of the shock that swept through the beef industry. Table 1 provides per capita consumption data (retail weight) and both nominal and deflated (CPI, 1982–84 = 100) prices of Choice beef at retail. During a period in which the overall price inflation reached annual rates in excess of 10%, the consumer refused to pay higher prices. Prior to 1988, the retail price of Choice beef had been in the $2.30 to $2.50 range since 1979. In inflation-adjusted terms, the problems are even more apparent. From 1979 through 1986, real prices had to decline over 30% to get the consumer to take what was essentially a constant per capita supply. When we consider that real consumer incomes trended higher during the period and that the prices of both pork and poultry increased relative to beef, it is difficult to avoid a conclusion of preference-related decreases in demand.

The decreases in demand rocked the beef sector. A herd liquidation that started in 1975 from a national herd of over 132 million head continued, with only short-term interruptions, into the 1988–90 period with the herd now under 100 million. At every level of the system, the price pressures emanating from the consumer level brought a need to get more efficient.

The record of accomplishment is impressive. Figure 1 shows beef production and January 1 inventories. In recent years, beef production has paralleled production of the late 1970s and early 1980s when the herd was 10% to 15% larger. But the increases in per unit output were not sufficient to offset the price pressures. A recent USDA publication by Shapouri et al. indicates that all producers except those producers with over 500 beef cows lost money consistently during the 1980s prior to 1987, when an accumulating reduction in supply levels pushed cattle prices higher.

With overall price inflation reaching double-digit levels in the early 1980s, the packers and processors were vulnerable to the demand-based price pressures. They had to become more efficient to offset the pressures or risk being forced out of business. Figure 2 indicates efforts to in-

Table 1. Per Capita Consumption and Price of Choice Beef at Retail, Actual and Deflated (CPI, 1982–84 = 100), 1970–89

Year	Per Capita Consumption	Retail Price	Deflated Retail Price
	(lbs. retail weight)	——— (¢/lb.) ———	
1970	84.4	98.6	262.0
1975	88.0	154.8	287.7
1977	91.4	148.4	244.9
1979	78.0	226.3	311.8
1980	76.4	237.6	288.4
1981	77.1	238.7	262.5
1982	76.8	242.5	251.3
1983	78.2	238.1	239.0
1984	78.1	239.6	231.1
1985	78.8	232.6	216.3
1986	78.4	230.7	210.4
1987	73.4	242.5	213.4
1988	72.3	254.7	215.3
1989	69.0	265.7	214.3

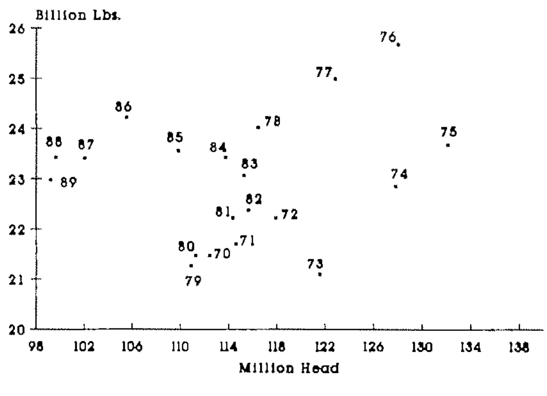

Figure 1. Commercial beef production related to 1 Jan. inventories, 1970–89

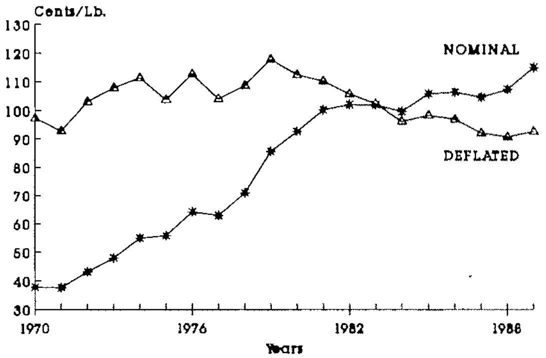

Figure 2. Nominal and deflated farm-retail price spreads for beef, 1970–89

crease efficiency were effective. The deflated (CPI 1982–84 = 100) farm-retail price spread declined significantly during the decade, suggesting the packers (or distributors and retailers) were either accepting reduced margins or were decreasing per unit costs significantly.

Figure 3 provides a plot of packer margins developed by the Helming Group by month from 1982 through early 1990. It appears that part of the significant reduction in the farm-retail price spreads early in the decade of the 1980s resulted from smaller margins at the packer level. Later in the 1980s, the data suggest packers were able to earn a slightly higher average margin, indicating that the continued decline in the farm-retail spread was at least partially caused by significant increases in efficiency at the packer-fabricator level.

Many economic forces were at work in the beef industry in the 1980s, but the problems on the demand side were arguably the most important. In an *ex post* context, it is clear that decreases in demand were a stimulus for change, for industry-wide adjustment, and for consolidation.

The incentives for consolidation were apparent. Figure 4 shows Clement Ward's estimated average slaughter cost function for beef plants with a capacity ranging up to 350 head per hour. Ward estimated comparable per-head reductions in per-head costs in the large fabricating plants. The plant killing and fabricating 330–40 head per hour across two shifts, a total of 5,440 per day, has per head costs of up to $20 below the costs of the plant killing and fabricating 100 head per hour, a large plant by the standards of the 1970s. The demand side problems portrayed the need to adjust in vivid terms and, simultaneously, turned theretofore sound operations like Wilson, Armour, and Swift Independent into takeover targets. It was often cheaper to buy the capacity than to build it, and IBP, Excel, and ConAgra emerged as the giants of the industry.

Review of Actions at Justice

The acquisition of Swift Independent by ConAgra in 1987 was apparently the last big decision at Justice with regard to consolidation in the beef sector. The Department's 1984 merger guidelines call for close scrutiny on any proposal that would push the post-merger HHI up by more than 100 points if between 1,000 and 1,800, or up by more than 50 points if the index was already above 1,800. The ConAgra-Swift Independent merger should have met one or both of these criteria but the proposed action was approved.

Figure 3. Estimated packer margins (slaughter plus fabricating) by months, 1982–90

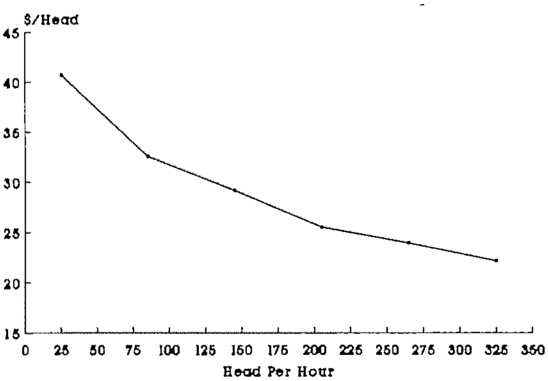

Figure 4. Estimated costs of cattle slaughter by size of operation

The courts had made clear in decisions in the 1970s that they were no longer willing to subscribe to a "big is bad" theme. But Justice may have moved to the other end of the continuum. Purcell concluded that the consolidation generated short-run benefits in that it brought efficiencies and saved part of the cattle industry by avoiding the need for still lower prices at the producer level. This conclusion is seen by Justice as confirming the correctness of the decisions in the ConAgra and Swift Independent case. The situation is more complex than that, however. The efficiency benefits can develop quickly and are amenable to possible documentation by looking at price spreads and proprietary packer-level margins. The farm-retail price spreads have not increased with overall price inflation across the past ten years and that has been immensely important to the beef sector. Connor (1989) concluded that profits in beefpacking have been near profits in other sectors of the food system, suggesting the reduction in farm-retail margins for beef was in fact the result of reduced costs at the packer level.

Generalizing the short-run positive impact of consolidation as a response to demand-side problems to a longer-run horizon would be inappropriate, however. It is important that the actions of Justice be considered in a broader context, and it then becomes clear how fragile the current situation could be.

Fed cattle slaughter has declined with the decline in the inventories. At the packer level, there is an estimated 20% to 30% excess capacity. The relatively small supplies of cattle when compared to existing slaughter capacity are providing a safety net of protection at the producer level against any market power levied by the larger packing firms. Excessive profits are not expected in the current environment. Instead, we would expect to see actions by packers designed to secure a supply of cattle.

The packers have taken action. With the consolidation have come changes in the way the industry operates. Kilmer discusses vertical integration as a way to achieve coordination of technically related states of activity when the external markets fail. In the presence of largely adversary relationships between cattle feeders and packers, the open-market price mechanism has never generated the highly stable flows of cattle that the packer would like to see, and we could argue the open market has failed. With the consolidation has come a number of mechanisms designed to achieve stability in cattle flows. They range from the business arrangement between IBP and Cactus, the world's largest cattle-feeding operation, to cattle being fed for packers either on contract or on a custom basis. There is no indication that the changes in the way the industry would operate were either anticipated or evaluated by Justice. But changes have come in the presence of large firms that dominate the buying side of the fed cattle markets, firms large enough to exert an influence on behavior in the cattle feeding sector.

The long-run implications of the consolidation continue to emerge and grow. They are reaching beyond the immediate impact on the sectors from which packers buy cattle and the sectors to which packers sell their products. Producers rely on publicly supported activities by the U.S. Department of Agriculture (USDA) for price and related information. In a consolidated industry, trade in carcass beef has all but disappeared. The USDA has dropped reporting of prices from the very thin carcass trade and has been forced to change and report a price index. Concerns that the cash fed cattle market is now so thin that it would be subject to manipulation prompted Kahl, Hudson, and Ward to recommend against moving to cash settlement for the live cattle futures contract.

The purpose here is not to provide an exhaustive list of all the issues that surround the consolidation. Rather, the purpose is one of suggesting that many important dimensions of the consolidation were not considered by Justice when the focus of attention was on the short-run increases in efficiency and on the arguments that ease of entry was an adequate safety net against the market power that was being created for three giant firms.

The Research Issues

The actions of Justice during the 1980s ran counter to the basic tenets of the SCP paradigm as a base for the enforcement of the antitrust statutes. There are some who now argue that the antitrust statutes are no longer appropriate and who call for legislative action. But the more informed observers appear to agree that it is not the statutes that need examination, it is the philosophy at Justice and the way the agency is looking at the issues that are the critically important dimensions. It is not the short-run efficiencies of a consolidated industry that are being questioned, it is the appearance of emphasis on

those short-run efficiencies to the exclusion of thoughtful deliberation on the long-run issues that is the concern.

The recent comments of Michael Porter, offered in another context, help to establish the perspective we might need to adopt. In discussing the actions of European nations to move toward greater economic unification, Porter is concerned that the orientation is wrong. He observes: "Their view of competition is a static one, in which eliminating inefficiencies and reaping economies of scale hold the key to success. . . . Greater dynamism, in the form of rapid technological progress, far outweighs the potential of static efficiencies to increase long-term prosperity" (*The Economist*, p. 17).

Is the consolidated beef industry of 1990 sufficiently competitive to generate the dynamism that Porter refers to and that leads to an industry that will perform in the best interest of society in the long run? If the answer is no, then the actions by Justice and the courts during the 1980s were wrong, and it is important that we move to a research methodology that helps generate a sound intelligence base to guide future decisions.

There is widespread empirical support for the SCP paradigm as a conceptual and methodological base. Weiss noted, after an extensive review, that the SCP paradigm is one of the most widely researched concepts in the history of economics. He concludes that the preponderance of the research efforts identify a causal flow from structure to conduct to performance. Connor (1989) discusses empirical findings relating structure to performance where the beef sector is concerned and references work of a number of market analysts dealing directly with the beef sector. A recent analysis of the meatpacking sector by Azzam and Pagoulatos, which employed data through 1982, concludes that market power was present on both the selling and buying sides, with the greater presence of power on the buying side. Schroeter looked at data for beefpacking through 1983 and found market power in both the selling and buying functions, but noted it was of small magnitude. Koontz, Hudson, and Garcia conducted a study of packer behavior in important cattle-feeding areas using a game-theoretic approach. The authors concluded that firms in the more concentrated areas would engage in "cooperative behavior" in the buying of cattle, with any deviations from that cooperative behavior coming during periods of exceptionally small supplies of slaughter cattle.

In 1980, Connor concluded there was no evidence of significant monopoly power in the meatpacking industry. But concentration levels at the time of the study were one-half of what they are in 1990, and almost nothing had been done to update research when the Justice made the important decisions in 1987. Connor concludes his recent search of the literature, conducted in 1989, with the overall conclusion that there is at most a modest (1.2% to 2.5%) price-depressing impact on fed cattle prices in the more highly concentrated packer buying areas. He notes, however, that much of the published literature covers time periods prior to the recent surge in concentration rates and continues in a qualitative assessment: "It is difficult to believe that the higher levels of concentration seen today . . . would not permit some price elevation" (Connor 1989, p. 90).

It is, therefore, not difficult to reconstruct the decision process at Justice. The literature supporting the SCP approach showed mixed results and was coming under attack from the Chicago School and contestable market advocates. In a political environment that was dedicated to deemphasizing the role of the federal establishment and in the presence of easily documented (by the merging firms) economies and efficiencies of large size, the arguments coming from the SCP school of thought were summarily dismissed by Justice. The arguments surrounding market definition and ease of entry were used to beat down any dissenting opinions as merger requests and proposed acquisitions were discussed.

The procedure for defining a market written into the Justice Department's 1984 merger guidelines helps to illuminate what occurred at Justice. Recognizing that the definition of "market" is very important in antitrust considerations, the guidelines pose a test based on a price increase. The guidelines read: Markets are delineated by postulating a "small but significant and nontransitory" price increase—generally an increase of 5 percent for one year—for each product of each merging firm at that firm's location and examining the likely response of buyers, sellers of other products, and sellers in other areas. If these competitive responses would cause the price increase to be unprofitable, then the area and group of products are expanded to include additional products and areas until the price increase would be profitable to impose (*Merger Guidelines*, p. 4).

It would appear that such a criterion would be

difficult to interpret, difficult to confirm empirically, and would be subject to virtually any conclusion. If there is predisposition to define the market broadly based on selected estimates of relatively high cross elasticities, the result is likely to be a conclusion that the increase in price would elicit a competitive response across many products and across a broad area.

The ease-of-entry argument is often devoid of conceptual or empirical rigor. To argue that firms could, or would, rush into boxed beef activity to earn a short-term profit and then escape with the investment intact involves heroic assumptions. An operation that is large enough to compete with the existing giant beefpackers would require a huge investment. The uncertainty of success in such an operation would dictate a discount for the uncertainty involved.

The incumbent and large beefpacking operations would be fierce competitors for their markets, and any firm considering entry would be acutely aware of that fact. The literature is full of arguments that advertising and product differentiation create formidable barriers to entry. Because the three large beefpackers are not heavily involved in branding fresh beef (Excel is the exception) there is a tendency to dismiss the possibility of barriers to entry, but that is a serious mistake. The firms may not differentiate their product at the consumer level, but they work aggressively to differentiate their product line and their services to their primary buyers, the retail chains. It would be extremely difficult for a plant killing cows, for example, to "slide" easily into boxed beef activity and combat the dominant control of the distribution, merchandising, and pricing networks of IBP, ConAgra, and Excel.[2] But there is clear implication in unpublished coverage of the deliberations during 1987 that Justice assumed such entry would be easy and would deter exploitation by existing firms.

It thus appears that the long-run implications of the consolidation in beef in the 1980s were all but ignored. With the efficiencies argument dominating attention, the pros and cons of the longer-run implications were not widely discussed. It is the long-run issues in consolidation that will set the agenda for the economist who conducts research in this area.

The long-run negatives will be those developments that come with the accumulation of market power in the hands of a few large firms. In spite of the safety net in the form of a tight supply of slaughter cattle, we are seeing the following:

(*a*) A cost-plus approach to pricing which insulates the packer and the equity investment in packing companies from the vagaries of the volatile livestock and meat markets. IBP has announced intent to sell boxes of beef on day $t + i$ at a derived price, calculated from live cattle prices on day t, plus a constant per head margin.

(*b*) A lack of progressiveness in terms of research and development. There is no evidence that the large packers are making the massive investment in market and product development needed to revitalize the beef sector.

(*c*) A move to captive supplies (contracted cattle, cattle fed for packers, etc.) in a consolidated industry that threatens to destroy the publicly visible price discovery base and to complicate efforts of public agencies to keep the producer informed.

There are also potentially positive long-run impacts of the consolidation. Among the possibilities are the following:

(*a*) The continued existence of economies of size. The dominant issue in the short-run evaluation of the mergers of the 1980s, those advantages will not disappear.

(*b*) The possible increase in efficiencies associated with vertical coordination via contractual and integrated activities. Modern kill lines and fabricating operation are designed to handle a specific quantity flow, and per unit costs increase rapidly at other volume levels. Contractual procurement and vertically integrated cattle-feeding operations allow the scheduling of cattle into the plants and help to insure the cost benefits of high-speed lines.

(*c*) The possibility of efficiencies in the form of increased responsiveness to economic stimuli. Weaver, Chattin, and Banerjee considered the speed of price response to changes in raw material prices or to changes at the consumer level. They found some evidence that concentrated industries are able to respond more quickly to price changes and other economic stimuli.

In an overall context, the methodological issues involve bringing increased conceptual rigor

[2] The four-firm concentration ratio for lamb slaughter is also very high, at 70 and above in recent years. In 1985, a new lamb-slaughtering operation was opened in northern Virginia by Rocco, a large poultry operation. The word in Washington and at Justice was that the Rocco effort was an indication that a new firm could come into a highly concentrated industry, and the effort was seen as verification of the ease of entry argument. Rocco operated for over two years, lost several million dollars in the process, and shut down in December of 1988. Company officials indicate they had major problems penetrating the existing distribution network in their targeted markets in the northeastern part of the United States.

to the existing empirical base in research on market structure. It is not sufficient to quantify a relationship between some measure of structure and profits if we do not know whether any increase in profits is caused by a reduction in costs or an increase in price. It is not enough to conclude that a highly concentrated industry is pricing the product above the so-called competitive price if a more nearly atomistic organization of the industry would preclude the reaping of important economies of size and economies of multiplant firms. We need less aggregation in the data in the econometric models that relate structure to some measure of performance, and we need to better understand the conduct or behavioral link in the SCP model. We need better measures of the costs and benefits of consolidation, more analysis of the benefits of changed operating procedures that come with consolidation, and investigation of the possibility of improved response to economic stimuli in a concentrated industry.

It is also important that we do analysis in both short-run and long-run contexts. It would appear that Justice and the courts gave far too much attention to the short-run cost and benefits of consolidation in the decisions of the 1980s and far too little to the possible problems associated with moves to cost-plus pricing, captive supplies of livestock, the lack of progressiveness in product and market development, and the private and public adjustments that must be made to the disappearance of a publicly visible price base for slaughter cattle.

At this point, it is overly optimistic to anticipate a methodology that sorts out the positives and the negatives and provides a measurement of the net impact of consolidation. But we can move in that direction. In looking at the beef industry and its continuing demand problems, a choice may be needed. We could, perhaps, have continued an industry structure with a four-firm concentration ratio of 40% and a 10% return on investment as a measure of profits with no firm possessing the financial capacity to do something about the market and product development needs. Alternatively, we could have the current structure with a concentration ratio of 80% and a return on equity of perhaps 20% and the financial prowess necessary to do something about the demand problems. I would applaud the actions of Justice to allow the consolidation if there were ways of insuring the product and market development work would be done and if there were means of insuring that the now-large and presumably more efficient firms would be forthcoming in reporting prices and in working with the other sectors of the industry. But those conditions are not being met. Perhaps research is needed to document the pros and the cons and to suggest legislative action to protect the interest of the public. If profit margins and expenditures on research and development are treated as strictly proprietary, then we may need to consider the required reporting of expenditures on research and development. If the huge firms show an increased propensity to internalize transactions such that no prices are involved or prices are not publicly available, then the need for required reporting must be discussed so that the many small producers are not denied access to market information.

It would be counterproductive to discuss reversing the massive consolidation in beef. Much of what happened was in response to a major economic shock from the demand side. But developments in the beef sector provide an excellent case study to sort out the pros and cons of consolidation. If we can put together the research thrusts needed to measure the implications of consolidation, then future deliberations by Justice and by the courts dealing with other parts of the food systems can be on a broader and more nearly balanced base of information.

Empirical Challenges in Analyzing Market Performance in the U.S. Food System

John M. Connor

When viewed over the last century or more, the changes in the market structure of the U.S. beef subsector resemble nothing so much as a roller coaster.

Beef slaughtering and processing were dispersed, on-farm activities until well after the Civil War. During the 1880s, meatpacking was among the first food industries to become significantly monopolized. The appearance of a radically new distribution technology, the mechanically refrigerated rail car, and new corporate forms of ownership provided the stimuli for both horizontal mergers and extensive vertical integration. The "Beef Trust" controlled about 85% of U.S. sales of dressed beef in the 1880s (Yeager);[1] this is consistent with the Big Four meatpackers (all red meat species) control of 71% of U.S. federally inspected slaughter in 1920 (Nicholls, p. 333).

The machinations of the Beef Trust, believed to have depressed western cattle prices and elevated retail beef prices in eastern cities, were in no small measure responsible for the Sherman Antitrust Act, which became law in July 1890. Later, by order of President Wilson, the Beef Trust became the target of the first investigation of the newly established Federal Trade Commission. As a result of the FTC 1919 report, the Big Five meatpackers were compelled in 1920 to sign a perpetual consent decree with the Department of Justice. The decree required the Big Five to cease their market-pooling arrangements, to forego further consolidation in meatpacking, and to sell their stockyards, railroad equipment, refrigerated warehouses, retail meat stores, and non-meat food-processing plants. The Packers Consent Decree is often cited as one of the first examples of successful antitrust policy (Aduddell and Cain, Connor et al.) The peak of control of cattle slaughter by the Big Five was around 1918 (fig. 1). Concentration glided slowly downward for the next sixty years, reaching its nadir in the 1970s, when the top four accounted for a more 20% of national cattle slaughter (Connor, p. 80).[2] Except for a slight rise in lamb slaughter concentration until the mid-1930s, all other red meat slaughtering also declined to historical lows between 1967 and 1977. Part of the success of the decree may lie in the monitoring and licensing powers of the Packers and Stockyards Administration, formed in 1921.

It is a strange sort of roller coaster that can climb higher on its second loop than at its start. Yet, beefpacking appears to be defying the gravity-like laws of market-structure change.[3] Abetted by the most permissive period of federal antitrust enforcement since the early 1930s, beefpacker concentration has risen to new heights. From 1977 to 1987, the top four companies' share of U.S. steer/heifer slaughter climbed from 29% to 67% (Connor).[4] This astounding 131% increase in concentration is more than twice as rapid as any other historical decennial increase in other U.S. food and beverage industries. Furthermore, much as the case a century before, the

Purdue Journal Paper No. 12, 609.

The author thanks his colleagues Paul Farris, John Helmuth, and Bruce Marion for their helpful comments.

[1] The Beef Trust was not, as its name implies, a single company linked by common stock ownership. Rather, it was a market-pooling arrangement effected through a jointly owned subsidiary company. The Big Five Meatpackers from 1890 were Armour, Cudahy, Morris, Swift, and Wilson. In 1923, Armour acquired Morris; thus the Beef Trust became the Big Four. These same four firms remained the leading meatpackers until at least 1959.

[2] Four-firm national sales concentration in meatpacking (SIC 2011), which is computed on a somewhat different basis by the Census Bureau from slaughter concentration, also reached its lowest level (19%) in 1977.

[3] More precisely, the 1947–77 historical pattern of concentration change in food manufacturing has been one of convergence toward the mean (Connor et al.). Since the early 1980s, beefpacker concentration has diverged from the food industries' mean.

[4] Slaughter concentration data were available separately for steer/heifer and cow/bull types beginning in 1969. During the same period, cow/bull slaughter concentration rose 82%, and for all cattle rose 145%. Boxed beef concentration data begin in 1977 when the top four accounted for 54% of volume.

Figure 1. Four-firm U.S. beefpacker concentration, 1909–89

increase in business consolidation was spurred by a major technological innovation in manufacturing. First commercialized in the early 1960s, the new "boxed beef" technology became the dominant form by 1980, largely supplanting carcass beef by the late 1980s. During this period, packer margins narrowed and economies of plant scale enlarged considerably. I have argued (Connor) that from its inception boxed beef was sufficiently distinct as to warrant classification as a separate market at the processing and distribution stages of the beef subsector. Boxed beefpacking is even more concentrated than beefpacking generally: about 40 firms operate boxed beef plants today, compared to more than 1,000 other beefpackers, with the top four handling 80% of production volume. Packer concentration among other red meat species has also risen since the 1970s, albeit more slowly. Many observers believe the hog slaughtering may be the next industry poised for rapid concentration increases.

In light of these historical developments, what can industrial organization analyses tell us about economic performance in the beef subsector, particularly since the mid-1970s? A recurring theme of this paper is that there has been marked progress in the measurement of market structure-performance relationships. Yet, by the early 1980s, gaps in this body of knowledge were apparent, and the deficiencies were further exposed by developments affecting the field of industrial organization generally. Thus, I believe that a number of exciting challenges await empirical researchers studying the livestock subsectors in the 1990s, challenges that arise from the evolving vertical linkages, rapid structural changes, and increasing internationalization of some subsector stages.

In the next section, I shall sketch with a broad brush the principal areas of progress in market-structure research in the food industries, drawing illustration mainly from the beef subsector. In the final section, I will discuss a number of problems with the present state of knowledge and suggest four promising areas for empirical research.

What We Have Learned

In the beginning was Bain (1959). His textbook defined the field of industrial organization. Not only did Bain specify the structure-conduct-per-

formance paradigm such that it encompassed the burgeoning body of oligopoly theories that had been accumulating since the early 1930s, but also he set the stage for statistical analyses of cross-industry date that were to become the dominant model of empirical testing. Until Bain's seminal 1951 article, hopes for validating the structure-conduct-performance paradigm had rested on cross-industry comparisons of in-depth industry case studies (Bain 1972). However, because of limitations inherent in the historical method, the case studies did not prove generalizable and were largely abandoned by the end of the 1950s.

Profit Margins

Bain's empirical work in the 1950s was primitive by today's standards.[5] It employed aggregated, multiyear-accounting profit rates of selected industries for its peformance index; four-firm national concentration ratios and judgmental classification of ease of market entry were the only two determinants of profitability considered. Progress in statistical cross-industry studies was rapid in the 1960s and 1970s. The major improvements and refinements can be well illustrated by the twenty or so published studies of manufactured foods surveyed in Connor et al. (pp. 280–97). Improved data permitted more objective measurement of proxies for product differentiation and barriers to entry. Market share information allowed researchers to match the profits of diversified firms more precisely to the market environments that were partially responsible for generating excess profits. Moreover, models were able to take into account such nonstructural sources of variation in profitability as product quality differences, market growth, capital intensity, firm size, and sales diversification. A number of studies were able to avoid the diversification problem entirely by utilizing establishment-level or profit-center data on price-cost margins, which are rather good representations of the Lerner index of market power. Greater attention was paid to whether results were sensitive to the business cycle or to definitions of submarkets with distinct conduct patterns, including the vertical relationships, alternative marketing channels (private label and foodservice, for example), and international dimensions (trade and direct investment). Finally, the robustness of results was checked against alternative econometric formulations; generalized-least-squares and simultaneous-equations techniques were tried.

Despite the impressive variety of approaches taken by a large number of independent researchers, Connor et al. concluded that "the profit-structure relationships estimated for the food manufacturing industries show a remarkable consistency across the empirical studies reviewed . . ." (p. 289).

In a nutshell, all of the studies with decent data and appropriate analytical tools had shown that market concentration and product differentiation were positively associated with profitability, whereas economies of scale and other technical barriers to entry were unrelated to profits. Alternative data sources, time periods, econometric models, and nonstructural factors did not affect the statisitical significance of the principal relationships. Moreover, depending on the degree of aggregation, the market structure-performance models were able to explain as much as 80% of interindustry variability in margins, which is more than satisfactory for cross-sectional studies.

Selling Prices

Although the finding that concentration and product differentiation determined industry and firm profits seemed indisputable as an empirical regularity, already by the early 1980s nettlesome doubts had begun to creep in concerning the interpretation of extant profit-structure studies. Researchers conceded that claims of statistical causality (in a Grangerian sense) could not be made (Connor et al., pp. 285–86). Hence, concentration (as a proxy for the recognition of mutual dependence among sellers) and product differentition (resuting from the nature of demand or to barriers to entry created by it) could only be deemed "determinants," not causes. However, it was noted that time-series analyses had shown secular persistence for the manufacturing sector as a whole (Connor et al.).

A more serious criticism concerning interpretation of results focused on the concentration variable. As concentration rises, so do the market shares of leading firms. From the point of view of consumer welfare, the higher profits associated with greater concentration could mean one of two things. First, under conditions of nondecreasing unit costs of production (as in Industry 1 of fig. 2), unit selling prices would rise

[5] Of course, profit or price-cost margins address only one of several dimensions of market performance, viz., allocative efficiency. Connor et al. (pp. 297–321) also addressed other dimensions of performance (income redistribution, technological progressiveness, technical efficiency, and so forth), but the points I wish to make are likely to be unaffected by focusing on allocative efficiency alone.

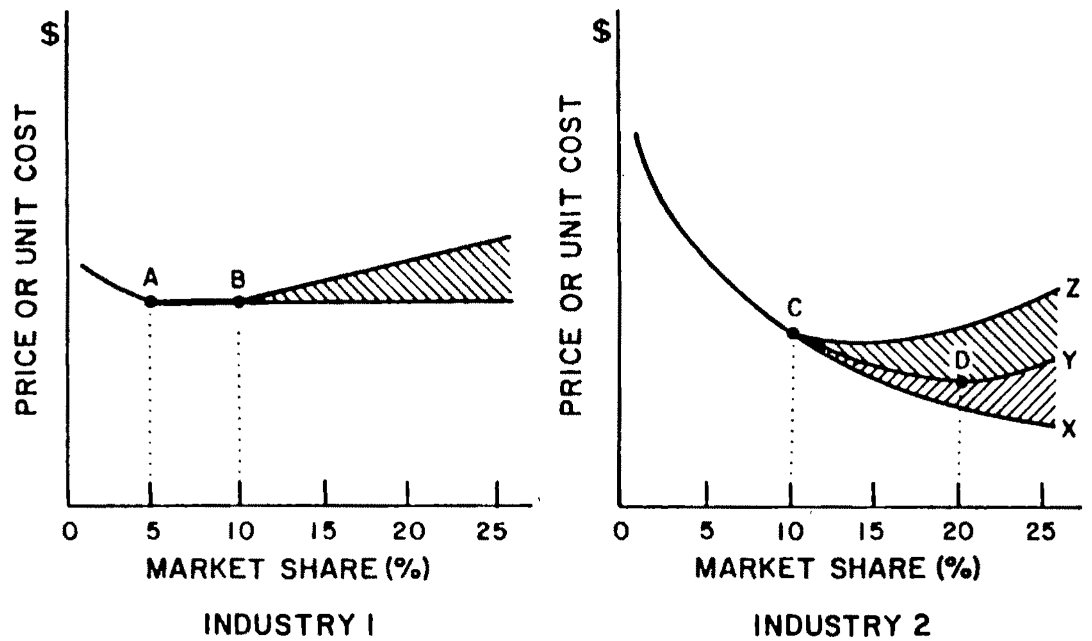

Figure 2. Hypothetical cost and price curves in two industries with different economies of scale

in tandem with increasing a profit rate. Indeed, in the presence of X-inefficiency (often alleged to be correlated with profitability) consumer prices would rise proportionately higher than profits. Second, when economies of scale are present (as in curve CX for Industry 2), consumer welfare can actually increase even though excess profits are being generated by the high market share. In other words, firms may be profitable simply because they are innovative (an early entrant), lucky (market share the result of random growth processes), or more efficient. In these cases, high profits are socially condoned because they are generated by lower costs and not necessarily because of higher prices (that is, prices are lower at D than at C).

The reasoning behind the second theoretical possibility is unassailable. But what empirical evidence can be brought to bear that would decide between the two cases?

One riposte is that some food-manufacturing studies utilizing detailed firm profit data have included both market shares and concentration as explanatory variables. Presumably the "efficiency effect" should be picked up by variations in market share, whereas the "collusive effect" will be captured by the industry-wide concentration variable. If both variables are positive and significant, market power is present. While the evidence from the rest of manufacturing is mixed on this point, food-manufacturing studies consistently display the market power result (Connor et al.).

A more direct approach is to test the relationships between market structure and selling prices directly (Weiss). This is most easily accomplished in the case of intra-industry prices across geographically segmented markets, such as airfares, retail grocery prices, gasoline, or bank interest rates. Here, the relationship of concentration to price is uniformly positive, which tends to dismiss the efficiency hypothesis as empirically groundless.

Because so many of the markets for processed foods are national in scope, testing structure-price relationships is considerably more challenging. However, one such study did overcome the data and modeling constraints (Wills and Mueller). Price variation was obtained by developing an index of prices of various brands of the same products keyed to the price of the leading brand. Not surprisingly, process food prices were found to be positively determined by brand market share and advertising intensity, especially when the latter was electronic. The result held for both retail and for wholesale prices.

Having this sort of corroborating evidence on food prices available, Connor et al. were so bold as to display with some confidence the estimated effects of noncompetitive market struc-

tures in the early 1970s on 1975 manufacturers' prices (p. 291). The results for the meatpacking industry indicated a consumer overcharge of practically zero; the meat processing industries, on the other hand, had a predicted overcharge of a little more than 1%. Taking into account other performance dimensions, both industries were judged to have quite low consumer overcharges (pp. 328–29).

There is contradictory evidence on whether beef selling prices are as competitive today as they were in the 1970s. The notable price rivalry of the Big Three suggests that they are. On the other hand, the countervailing power of meat buyers has probably fallen. In the 1950s to 1970s, beefpackers' sales were less concentrated than the principal buyers of carcass beef. The main buyers are the divisional (regional) buyers for retail grocery chains and specialized beef wholesalers. In 1958, the average U.S. metropolitan area had 48% of grocery sales concentrated in the hands of the four largest companies (Connor, p. 82). In rural areas, concentration is even higher. Among specialty beef wholesalers, city concentration was about 30%. I know of no way of blending these concentration figures, but total beef distributor concentration at the metropolitan level was somewhat above the 22% to 30% national seller concentration of the packers. Distributor concentration today has increased since the 1950–70 period, but not nearly as fast nor as far as packer concentration. Four-firm retailer concentration is now above 60% in the average U.S. city, and wholesaler mergers have likely driven meat wholesaler concentration to at least 40%. Despite these substantial increases on the distributors' side, since then packer concentration has raced far ahead. Moreover, in the case of boxed beef, retail chain purchases seem to have become more centralized, and national sales concentration of grocery chains is much lower than average metropolitan concentration. I take this to be weak evidence of a shift in the balance of power between packers and distributors in favor of the former.

Buying Prices

The original structure-performance approach had estimated the impact of market structures on overall margins. But firms with market power can in principle exercise that power either by raising selling prices of products (as just discussed) or lowering the procurement prices of inputs. Which of the two routes powerful firms will choose to emphasize will depend largely on the degree of countervailing power they perceive downstream as sellers or upstream as buyers.[6]

Several systematic studies are available supporting the exercise of market power on the buying side—monopsony power. Packers buy mainly from independent feedlots, some of which act as agents for beef producers. Whereas regionalized buying by distributors tends to raise concentration in ways unfavorable to packers, the geographically limited (100- to 200-mile radius) procurement zones for live cattle tends to favor the packers. Views differ on the appropriate number of cattle-buying markets, but in the principal cattle-raising areas west of the Mississippi River the number of proposed markets ranges from ten to twenty. A painstaking study of cattle concentration in the western United States placed four-buyer concentration at an average of less than 50% in 1971. By 1987, the average exceeded 90% (cited in Connor, p. 81). Feedlot concentration in the same areas is far lower.

There are several careful statistical, cross-sectional (or pooled time-series/cross-sectional) studies of the relationship of buyer concentration and cattle prices. The studies employ a variety of time periods from 1971 to 1980, geographic market definitions, and control variables. In my judgment, the concentration-price relationship that is estimated by the three most ambitious studies is remarkably similar (Menkhaus et al., Quail et al., Ward). Allowing for numerous nonstructural factors, each study found that fed-cattle prices were from 1.2% to 2.5% lower in the most concentrated procurement zones relative to the least concentrated. Similar analyses of slaughter lambs and hogs also found the expected inverse relationship between buyer concentration and livestock prices.[7]

What We Do Not Know

Perhaps, like any new technology that has come close to being perfected (by the standards and objectives established at the beginning), the in-

[6] Of course, this oversimplifies. Firms may decide to try both or neither.

[7] One of the few areas of disagreement is the plant-closing studies. While they show that prices fall (relative to some reference point) when plants close (increase in buyer concentration), they disagree on the length of time for which prices are lowered.

novators of the statistical cross-industry method of analysis were destined to become disenchanted by their creation. While self-criticism was certainly important, an additional stimulus to the reappraisal of structure-performance analysis was the increasingly influential criticism of the Chicago school of economic analysis (Posner). The well-known Arlie House conference reported in Goldschmid, Mann, and Weston may be regarded as the opening shot in the oftimes rancorous debate that followed.

In an influential review of interindustry studies of the market structure-performance relationships, Schmalensee harshly asserts that inter-industry studies are now out of fashion. The main reasons he gives are that inappropriate data and methods have been used, "conventional," i.e., Bainsian, interpretations are wrongheaded, and "formal models" of conduct are absent. Schmalensee also faults traditional interindustry studies for failing to yield consistent estimates of structural parameters and are useful only to provide stylized facts to guide theory construction.

Perhaps a more useful view is the Hegelian one suggested by Martin. The thesis is the fundamentally empirical structure-performance studies in the Bainsian mode. The antithesis is the essentially microeconomical-theoretical position of the Chicago school, which views the model of perfect competition as the actual long-run equilibrium of markets unobstructed by the dead hand of government.[8] The synthesis is what has been dubiously dubbed the "New Industrial Economics," a convergence in views that recognizes the importance of explicit theoretical models as underpinnings for empirical tests while at the same time allows the data to produce results that diverge from perfect competition (rather than treating it as the maintained hypothesis or untested assumption of the research). Much of the best empirical research of the future will probably try to satisfy the requirements of both camps, the mainstream (Bainsian) and the Chicago.[9] At this juncture, the "New IO" empirical studies strike most mainstream researchers as woefully lacking in the richness of detail that was attained by the best IO studies of the 1970s.

Despite these caveats, there are four areas of research I would point to as especially promising ones.

The Specification of Conduct

The IO empirical literature of the 1960s made rather vague appeals to a priori reasoning in formulating testable models of structure and performance. It is true that nearly all oligopoly models predict equilibrium prices that are above competitive (but below pure monopoly) levels. But the standards of the literature are rising in the sense that a behavioral model is expected to be formally derived from a theoretical model of, say, profit maximization incorporating an explicit mode of pricing conduct. Connor and Peterson is an example of a cross-industry test based on such a formally derived model. In this instance, the derivation justified the inclusion of the Hirshman-Herfindahl index of concentration and the conventional industry advertising-to-sales ratio; however, the model also required data on the elasticity of demand with respect to own price, an explanatory factor largely ignored in previous structure-performance studies. It is perhaps comforting to note that parameter estimates, where comparable, were similar to previous studies. Another published study of the food industries, though not directed at estimating static allocative efficiency, is the article by Gisser, which adopted two explicit pricing behaviors.

The major disadvantage to introducing explicit conduct modes is the necessity of choosing one when many are possible. When one of several options is adopted as an operating assumption, suspicion may naturally arise about the sensitivity of the results to the assumption. Of course, testing alternative paradigms is standard operating procedure for social scientists, but it could diminish the chances that the results will be of practical policy relevance. Perhaps realistic market experiments with experienced players playing for large stakes would offer insights into pricing behaviors (Plott).

Time-Series Approaches

A major alternative to the cross-industry analysis that has emerged since the early 1980s may be termed the intra-industry time-series approach. Data from only one industry or group of related industries are used to determine whether firms exhibit behavior consistent with compe-

[8] Alternatively, all private monopoly power is temporary. "Chicago concedes that monopoly is possible but contends that its presence is much more alleged than confirmed, and receives reports of its appearance with considerable skepticism. When alleged monopolies are genuine, they are usually transitory . . ." (Reder, p. 12).

[9] Policy research is, however, another matter. The two schools are so far apart here that a synthesis seems highly improbable.

tition or consistent with market power. These intra-industry studies require an econometric model, but profits or price-cost margins are treated as nonobservable. Often, but not necessarily, parameters are described in terms of firms' conjectural variations, their expectations about the reactions of rival firms to a change in quantity of output.

More than a dozen such studies have been published covering a range of industries, including meat, all food processing, roasting coffee, and tobacco (see Bresnahan). In general, the results of the new technique support the traditional structure-performance approaches. Industries with relatively high concentration levels have substantial power over price, as indicated by the implicit price-cost margins. The food and tobacco studies found price-cost margins in excess of 50%; the coffee industry displayed mostly price-taking behavior, except for the largest firms. The meatpacking study by Schroeter also finds evidence of noncompetitive behavior.

This type of empirical analysis, while admirable in its theoretical rigor, has many limitations. The very simple model formulations imposed by the requirement of mathematical tractability leave little scope for assessing the sources of market power, only its longevity. Moreover, many of the interesting, policy-relevant questions in IO cannot yet be addressed. The impact of product differentiation, the role of entry conditions, and the detection of strategic entry deterrence are examples (Bresnahan).

Long-Run Equilibrium

Both the cross-industry and intra-industry approaches assume that the industry(ies) being observed is(are) in long-run equilibrium. As we know, if deviations from the long-run equilibrium are uncorrelated with the independent variables, then a cross-sectional econometric model will yield consistent estimates of long-run parameters. Unfortunately, many of the instrumental variables employed in cross-sectional studies are not truly exogenous; there are, for example, many feedback effects from performance to structure. Multiple equation models cannot resolve this problem, although recursive systems and time-series panel data might well yield consistent estimates.

There can be little doubt that in the 1980s the beef subsector was in disequilibrium. The effects of radical technological change in production are still radiating throughout the industry. The pressures to keep huge, new plants running at full capacity may well have caused cattle prices to be higher for the first few years, until other beefpackers closed or sought new market niches in order to survive. After fifteen to twenty years of running at full capacity, even boxed beef processors began to experience substantial underutilization of capacity in the late 1980s. One possible implication, so far undocumented, is that the excess capacity was allowed to develop to discourage new entry, thereby making pricing discretion by established firms greater than before.

International Dimensions

Traditional structure-performance analyses have treated international trade and foreign direct investment as exogenous influences. Trade, most commonly modeled as an import/supply ratio, is interpreted as a measure of the ease of foreign market entry; alternatively, the export/sales ratio is sometimes used to indicate the extent to which a firm or industry is able to exploit economies of scale that may be constrained by a national or regional market. I have argued that the disciplining impact of beef imports is negligible, except perhaps in the case of lean beef purchased by fast-food hamburger chains (Connor). The export side is much more complex. The United States is a net exporter of beef products, most of which are hides, other nonedible byproducts, and variety meats. Exports of grain-fed boxed beef are increasing, but they are influenced by regulatory and structural restrictions in the importing country as well as by the exports of the joint products mentioned. If leading beefpackers export more proportionately than smaller firms, then national concentration ratios are overstated. It is not known whether exporting is an integral part of overall selling strategies or simply seen as a "vent for surplus."

In general, foreign direct investment has had a greater impact on overseas sales by U.S. food manufacturers than has export trade; similarly, foreign food companies now sell far more in the United States through their affiliates than through imports (Connor). The trend toward inward investment has accelerated since the mid-1970s. Foreign investment in ranches, feedlots, and beefpacking was negligible as of 1987, but recently a number of smaller West Coast packers have been acquired by Japanese interests purportedly to serve the Japanese market. So far,

foreign investment is too small to have had an impact on competition in the domestic beef market. Even if investments were to become large, it is only through adopting different conduct that the competitive impact of foreign ownership becomes of interest. There is precious little research on even those food industries with high levels of foreign investment as to how industry performance has been affected.

Conclusions

The Bainsian (SCP) analysis of food industries has yielded results that are impressively rich in detail and remarkably consistent estimates of structural parameters. Faulted for the rigor of its theoretical underpinnings, the cross-industry method of analysis is being supplemented by the New Industrial Organization. Four areas of research in the food industries would appear to offer the greatest promise for satisfying the dictates of both schools: (*a*) models with explicit modes of firm conduct, (*b*) time-series or conjectural-variations approaches, (*c*) studies of entry conditions, and (*d*) models that permit differential conduct by foreign-owned firms.

Measuring Market Power in Food-Processing Industries: Discussion

John R. Schroeter

Historical developments in the evolution of industrial structure in beefpacking, particularly the rapid increase in concentration over the past ten years, provide the point of departure fot both of the papers in this session. Purcell notes that the wave of consolidation of the decade of the 1980s built upon already substantial concentration in the industry. The fact that it nonetheless was allowed to proceed reflects the political and philosophical attitudes that prevailed in the courts and the Department of Justice during the period. Proconsolidation arguments demonstrating the clearly documented potential for economies of scale flourished in a regulatory climate characterized by a general aversion to government interference in the private sector. Anticonsolidation arguments, raising the specter of abuses of market power, were easily deflected by rebuttals that sought to minimize the degree of concentration, through broad market definitions, or the danger of concentration, through endorsement of the monopoly-deterring powers of potential entry.

Purcell argues that the regulatory authorities simply dismissed traditional concerns founded upon an assumed causal linkage between concentrated industrial structure and antisocial economic performance. Connor's paper reviews what we know about this structure-performance link in the beef sector and in food-processing industries in general. Most of the accumulated evidence on profitability-concentration and price-concentration correlations comes from cross-industry studies in the spirit of Bain; that is, studies employing the traditional "structure-conduct-performance paradigm" (SCPP). A clear consensus emerges from these: The studies generally demonstrate a positive relationship between food industry concentration, on the one hand, and both profit and selling price, on the other. In the beefpacking industry specifically, there is also agreement among several studies on the existence of a negative relationship between packer concentration and price of slaughter cattle in regional procurement markets. In recent years, however, industrial organization economists have become skeptical of the ability of the Bainsian cross-industry approach to detect the presence of market power. Connor notes this conversion and points out that the religion it has established, the "new empirical industrial organization" (NEIO), has both merits and shortcomings. I would like to devote the bulk of my discussion to an elaboration of these, particularly as they manifest themselves in the analysis of packer oligopsony power in cattle procurement markets.

The SCPP approach is widely familiar. In the unvarnished extreme, it involves the use of cross-sectional data to estimate an ad hoc reduced-form equation expressing a performance measure (price-cost margin, rate of return on equity, price) in terms of various structural measures (concentration, conditions of entry, product differentiation) and possibly additional "exogenous" variables inserted as controls for other important cross-industry differences (market growth rates, advertising intensities).[1] In the NEIO approach, on the other hand, time-series data from a single industry is used to estimate a system of structural equations that obtain from a clearly specified, firm-level optimization problem. Indices of conduct and performance are treated as parameters to be estimated rather than observables.[2] Bresnahan attributes the development of the NEIO to three beliefs that undermine the validity of the SCPP methodology:

(*a*) Industries have important idiosyncratic characteristics that cannot be summarized adequately by a few exogenous variables.

John R. Schroeter is an associate professor, Department of Economics, Iowa State University

[1] Several cross-industry studies model the determination of more than one endogenous variable using a simultaneous equations approach. Schmalensee argues that even these models are unlikely to provide consistent estimates of structural parameters.

[2] In many of these studies, the device of a conjectural variation is used to parameterize conduct and/or performance. Examples of applications to food processing include Lopez, Roberts, and Schroeter.

(*b*) Meaningful performance indices (Lerner's index, for example) cannot be directly measured using available accounting data.

(*c*) Estimation of ad hoc reduced-form relationships between structure and performance is not very informative.

Connor notes that the three most ambitious SCPP studies of packer market power in cattle markets (Ward; Menkhaus, St. Clair, and Ahmaddaud; Quail et al.) reach general agreement on the existence of modest oligopsony distortions in fed-cattle prices. How do these three studies, all similar in technique, fare in light of Bresnahan's three criticisms of the SCPP? To my mind, they are relatively safe from attack on the first two counts. They use data sets consisting of observations corresponding to geographically and/or temporally separated versions of essentially the same market. Consequently, the degree of heterogeneity among observations in these studies is far less than in Bain's pioneering study or any of its descendants using census data on diverse manufacturing industries. The similarity of the markets also suggests that cross-observation differences in packers' marginal net revenue product for cattle might be, if not insignificant, at least adequately explained in terms of a few exogenous variables. Under these circumstances, the price paid for cattle is an acceptable index of the degree of oligopsony power. Thus, dependent variable measurement is not a problem because price is easily observed and, at least in these markets, scrupulously recorded.

This brings us to Bresnahan's third point, the alleged superiority of the theory-based structural models of the NEIO approach to the ad hoc reduced-form models of the SCPP approach. The underpinnings of the econometric models of modern NEIO studies certainly are much fancier than the informal theory supporting the regression equations in SCPP studies, but does this additional formality contribute anything beyond an outlet for mathematical pedantry?

We estimate empirical models because we seek answers to certain key questions; in the present context, questions of how market performance compares to the competitive benchmark. With ad hoc models, the only method for validating the empirical results is to check whether the implied answers to these key questions are "reasonable"; or, to put it somewhat less delicately, to check whether they conform with the analyst's prejudices. This method of model confirmation builds in an obvious bias toward validation of the conventional wisdom: Models are "good" if they confirm our beliefs. In contrast, NEIO empirical models are structural in nature. Each parameter has an economic interpretation which, in light of theory, often suggests checks on model validity that are independent of the questions of interest.[3] In other words, NEIO theoretical models imply overidentifying restrictions that provide an objective basis for model evaluation.

NEIO theoretical formulations also contribute identifying restrictions that enhance the credibility of the models' assessments of market performance. Conventional approaches usually fail to impose certain relevant theoretical restrictions. These omissions cast doubt on the models' ability to identify correctly market power effects.

For example, consider the fed-cattle market studies of Ward; Menkhaus, St. Clair, and Ahmaddaud; and Quail et al. Figure 1 illustrates the basic model underlying these studies. Regional supply and derived demand, or marginal net revenue product, determine a competitive price P_c. If packers exercise oligopsony power, actual price will be lower than P_c. The regression equations include supply and demand variables, that affect P_c, as well as a linear term in concentration that is supposed to capture the magnitude of the oligopsony distortion, the gap between P_c and the actual price. But, in reality, the oligopsony distortion also depends on supply elasticity in a systematic way. To see this,

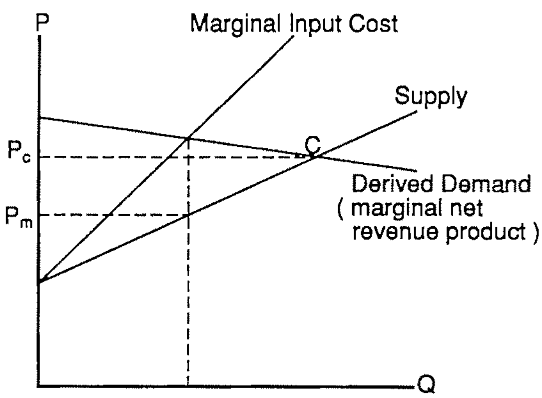

Figure 1. Basic model for fed-cattle studies

[3] Estimated supply or demand elasticities can be compared to results from independent studies. Cost function parameter estimates can be checked for consistency with the properties of monotonicity and concavity. In Schroeter and Azzam (Selected Paper, this issue), the theory implies the testable overidentifying restriction that an expression for a farm/wholesale margin contains no constant term.

imagine two initially identical, regional markets with concentrations that are equal and sufficiently high so as to enable the areas' packers to effect the pure monopsony outcome, P_m. Now imagine that the exogenous supply determinants in one region cooperate in performing the following thought experiment: The supply curve rotates clockwise about the competitive equilibrium point, C. The oligopsony price distortion will now be smaller in the market with more elastic supply even though the competitive price level, concentration, and conduct (pure monopsony) remain the same in both markets. The point is that theory imposes restrictions on market performance; in this case, restrictions relating supply elasticity to the magnitude of the oligopsony price distortion. If these are not built into the model, there is nothing to insure that the concentration term captures the whole of the price distortion and nothing else. It is conceivable, for example, that the negative relationship that the authors found between packer concentration and cattle price reflects a spurious correlation with omitted variables that shift supply or demand and therefore affect P_c, not $P_c - P_m$.

So the principal advantages of the NEIO approach to the measurement of market power stem from the fact that it is built on a foundation of a clearly specified optimization problem. As Connor points out, its major disadvantage is that the analyst must first specify that optimization problem in terms of one particular objective function to the exclusion of others. What is the appropriate objective function for modeling firm conduct in oligopoly settings? In one sense, "profit maximization" is the indisputable answer since most viable "alternatives" to profit maximization can be reconciled with it, given an appropriately lengthy decision horizon or an appropriately broad set of choice variables. Of course, this observation merely restates the question in different terms. As a practical matter, most NEIO studies to date model industry equilibria over time as solutions of a series of independent, static profit-maximization problems. While this may be a reasonable approximation in many cases, it usually is inappropriate in the case of food-processing industries. Food-processing firms face agricultural supply curves which, because of inherent production lags, incorporate important dynamic elements. In utilizing market power to move industry equilibrium along a market input supply curve this period, food-processing firms alter the menu of price/quantity options that will be available to them next period. A rational firm, anticipating these future impacts of today's actions, will incorporate them in its decision-making calculus: The relevant objective function is intertemporal in nature. Recent work by Karp and Perloff has taken an important step toward showing us how to measure market power in dynamic oligopoly settings. I hope that future work will follow this initiative.

Structural Change in Food Systems: Discussion

Larry Martin

I like the two papers by Purcell and Connor, although they both leave me with a sense of frustration. This is due to the fact that, while we are mathematically more sophisticated, the conflict about the relationship between market structure and market performance that raged when I was in graduate school twenty years ago has clearly not yet been resolved.

The two authors took different approaches. Connor provided a useful overview of the literature during the past decade, with some emphasis on results for meat packing. Purcell's paper concentrates more on the actual events and outcomes in the beef sector. Perhaps it is because of their different approaches, but I felt there were two (fairly minor) conflicts in the two papers. The conflicts will be discussed below, followed by a set of largely eclectic points about the issues of concentration and performance in the beef packing industry.

Conflict One

Purcell says structural change in beef processing was largely the result of the decline in demand for beef. Connor attributes it to the introduction of boxing technology.

They are probably both right, but in my view Purcell is more right. The decline in demand has been extraordinary, and its implications for economic survival have been no less so. We should all applaud Purcell's rather lonely campaign to get our profession and the beef industry to clearly understand this phenomenon and to untangle its implications. His work in *CHOICES* and other places has clearly defined the demand problem and has pointed out our profession's delinquency in understanding and helping. The fact that the econometric literature he cites has finally begun to include enough time-series observations to find statistical evidence of the glaringly self-evident merely illustrates, once again, how good we are at arriving too late with too little to be of relevance. We need to expose more graduate students from major land grant institutions to Purcell's graphical analysis and a few right brain analytic techniques.

Larry Martin is Distinguished Professor of Agricultural Policy in the George Morris Centre, University of Guelph.

Conflict Two

Purcell says consolidation in the packing industry has resulted in increased efficiency. Connor seems to reject this mainly by omission, but also by citing Weiss. Once again I find Purcell's straightforward analysis to be quite compelling. It fits my priors about what has happened in this industry as the "Big Three" have driven it in terms of technology, management, and capacity utilization. Even from the perspective of the Canadian industry, the need to compete with the American firms at some level has put tremendous pressure on Canadian firms to improve their efficiency and productivity.

Some Additional Points

Below, a number of points are addressed about the beef-processing industry from my perspective in Canada.

First, both papers, Purcell's especially, were a little unclear at some points concerning whether they were addressing slaughter, fabricating, or value adding when they were discussing concentration ratios. The (roughly) 80% four-firm concentration ratio could be misleading if, as in Canada, it is different for the three levels in the United States. My sense is that concentration ratios are much lower in the value-adding portion of the industry. If this is correct, and the packers and fabricators are attempting to penetrate and hold this growing market, then one would expect the competitive implications to be quite different than if the value-adding segment were highly concentrated. This is one of those com-

plicating factors that makes the structure-conduct-performance paradigm so oversimplified.

A second point involves the long-term implications of international trade for the concentration issue. I think more emphasis needs to be placed on international trade than was done in the papers. There are at least three components of my concern. First, the tarrification of the Japanese market in 1991 will bring substantial change to this industry, as will the emergence of a strong market in Korea. Papers by Hayes and by Kerr, Hobbs, and Gilles at other sessions of these meetings give a clear indication of the nature of the Japanese market and some notions about its implications for the United States and Canada. Japanese demand is highly specific and highly quality conscious. In order to penetrate that market and to compete with other countries, products will require a longer shelf life than we are now able to provide, and they must be processed with a slow and costly technique. It is a situation that does not lend itself to the massive economies of scale of the processes currently used by major U.S. packers. Who will fill this niche, and what implications will the emergence of such companies have on competition in the North American market? We may even find that North Americans will become quality conscious.

The second issue with respect to international trade involves the Canada-U.S. trade agreement and a potential trade agreement with Mexico. Once one starts using a relevant market that goes beyond the boundaries of the United States, concentration ratios get lower and more competition is added. Substantial competition is occurring in the northern plains and southern prairies for cattle during these times of short kills. I do not believe the results are consistent with the expectations that devotees of the structure-conduct-performance paradigm would assign to a three-firm concentration ratio of 80%.

The third issue having to do with international trade is the apparent conflict between domestic concerns by U.S. economists regarding concentration ratios and their unconcern with U.S. trade law. If there is increasing concern about improving the competitive outcome in the United States, then one would think that U.S. agricultural economists would be concerned about insuring as much competition as possible. Despite this, U.S. agricultural economists do not seem to be concerned that the United States obtained a waiver of its GATT obligations on dairy in 1955 but then takes steps to stop other countries from using exactly the same trade restrictions for dairy products as the United States uses. They seem to be not concerned about the fact that the United States has imposed highly questionable countervailing duty actions on Canadian pork imports, threaten to do so on beef, and have been successful in convincing European interests to voluntarily restrict exports to very low levels into the U.S. market.

Finally, while the United States has agreed to harmonization of meat inspection procedures with Canada under the Canada-U.S. trade agreement and is, apparently, about to agree on harmonization in the GATT, it is clear that we are far from the point at which these agreements are followed by the United States. Harmonization should, in theory, make it easier for countries to compete in each other's markets. Therefore, the corollary is that failure to harmonize makes it more difficult for others to compete in your market. Failure to harmonize when one pays homage to harmonization should not be a matter that U.S. agricultural economists stand idly by and witness.

Purcell briefly made a point about the quality of data from the U.S. industry. I am increasingly wary of using U.S. price data because of the thinness of markets. In Canada, we have kept much of our price-discovering mechanisms in the open, and at least some of the data are reliable. This is in part because we have mandatory marketing legislation in the case of pork, and because a number of producers and packers had the good sense to use either electronic or sealed bid transaction techniques in the case of beef. In the United States, you are coming dangerously close to the point where the analysis conducted for antitrust action will have to be based on the data of the accused. In my experience, the accused may have a vested interest in insuring that the data are appropriate for their cause.

A fifth point is a seeming inconsistency between the concern about market power and Purcell's concern with a lack of product development. Purcell makes it sound as if there is a vast untapped market for beef that is not being exploited because companies have failed to do the required product and packing development. This is a bias with which I identify. However, if this market opportunity is available and the three major packers have such market power, then one wonders why they are not pursuing it and turning it to their advantage. Either they know something we do not or we have misinterpreted what they are doing.

My final point is with the narrowness of the structure-conduct-performance paradigm. Lis-

tening to the discussion in this session, I have heard several measures of performance discussed. They include cost, profit, product development, research and development, and market differentiation. Taking two of Purcell's points that I have discussed above illustrates a dilemma. We can combine his notion that packing plants have become more efficient with his concern about lack of product development in the face of declining demand. The bottom line for this combination is that the industry has become increasingly efficient at producing a product that consumers do not want. My concern is that market performance is an extremely complicated and multifaceted concept. To try to measure it by using a four-firm concentration ratio and one or two other variables in an equation that explains internal rates of return seems to me to be absolutely useless in measuring the utility and public welfare produced by an industry. To continue along this route when the business school literature is uncovering and elucidating such concepts as total quality and the extremely complex and multifaceted nature of becoming competitive, as pointed out by people like Peters and Porter, is to miss the boat rather strikingly. We simply have to move to a more complete, if mathematically less appealing, model of performance if we are to use antitrust notions to improve public welfare.

Agricultural Changes in Eastern Europe at the Beginning of the 1990s

Csaba Csáki

Rapid political and economic changes are occurring in Eastern Europe. The political fermentation grown out of economic difficulties has resulted in a sudden change in all countries of this region. The decrease of economic output, backwardness in world development, and the failure of economic and political reform attempts have radically countered the grounds of the post-Stalin economic and political structure. The changes in most countries have overstepped the traditional reform boundaries and suggest a total rejection of the socialist-communist system.

When studying the current Eastern European agricultural problems, we should recognize that the agricultural changes underway represent a much more profound process than the reforms in past years. The formation of a new agricultural structure built on private ownership, real cooperation, and a market economy has begun. This process is still in the initial phase; the details are often taking shape in heated discussions. Thus, I can only summarize the most important general and country-specific developments, trends, possibilities, and dilemmas.

The Current Position of Eastern European Agriculture

This study will survey the problems of Bulgaria, Hungary, the GDR, Poland, Romania, and Czechoslovakia, the six "small countries" out of the European CMEA countries.[1] These six countries comprise about 2.5% of the world's population (112.8 million) and they have little influence, except for some exceptional cases, on the world market of agricultural products. In these countries, industry now is a dominant branch of the national economy, although the importance and consequences of the agrarian sector are still stronger than in the majority of the developed countries. Agriculture's proportion of net national production is between 8% and 20%. The lowest is the GDR and Czechoslovakia and the highest is in Hungary and Romania. The conditions are similar considering the proportion of agricultural population (9% in the GDR, 10.6% in Czechoslovakia, 13.9% in Hungary, 14% in Bulgaria, and 24% each in Poland and Romania). The agricultural population is tending to decrease, but the decrease of agricultural workers slowed considerably in the second half of the 1980s.

All the countries are found in a temperate continental climate zone. In the northern countries the climate is more humid, cooler, and soil quality is less. But, the conditions of agriculture are above average in Romania, Hungary, and Bulgaria.

Across all six countries, 57.8 million hectares of agricultural area are available for production. The agricultural areas have decreased in some of the countries over the long term, although the decrease of tillable areas has slowed in more recent times. The proportions of agricultural cultivation areas range from 53.3% in Czechoslovakia to 70.5% in Hungary.

Agricultural Growth—Production Outcomes

The agriculture of the six countries developed quickly in the early 1970s, but the process then slowed. At the beginning of this period, the total annual rate of production growth was about 3% to 4%. By the beginning of the 1980s, the growth rate was in the 1.5% to 2.5% range and

Csaba Csáki is a professor of agricultural economics, Rector at Budapest University of Economic Sciences, and president-elect of the International Association of Agricultural Economics.

[1] At the end of the 1980s, numerous studies and analyses were written on the position of the Eastern European agriculture: e.g., Wadekin, Csáki (1988, 1989), and a series of USDA and FAO studies.

differed significantly among countries. By the end of the 1980s, the total growth rate declined to 1% to 1.5%. Nonetheless, the agricultural growth of more than 2% a year, which is characteristic of the entire region in the long run, is going to be a significant result.

The large fluctuation of production growth in each country is striking. In the countries concerned, the decrease of agricultural production growth paralleled the decrease of general economic and industrial development. In fact, the relative decline in nonagricultural activity exceeded the agricultural decline, thus bringing agricultural and nonagricultural activity closer together.

In all the countries concerned, the main agropolitical objective was to increase self-sufficiency and especially to develop grain production. In past years, the grain-producing areas remained essentially constant, falling in the 54% to 58% range of sown crop land. The planted area of major crops is shown in table 1. Even though improved yields were increasing production in most countries, imports were still needed to satisfy the increasing demands. In general, the efforts to increase grain production cannot be considered successful. Although the balance of grain trade of these six countries is still negative, only Hungary exports a considerable amount of grain, about 2 million tons a year.

The contradictory development of past years is shown by the average crop yields in table 2. Relatively poor crop yields and high annual fluctuations in output characterize all of the countries. The output levels reached by the Western European countries are approached only by Hungary, the GDR, and Czechoslovakia.

Since the early 1970s, the six countries have made continual efforts to develop animal husbandry (table 3). The numbers of animals have increased, and professional breeding technologies were introduced. The production of animal products outgrew the increase of grain and fodder production in each country. The development was quicker in the first half of the 1980s and in some of the countries, especially Hungary and Bulgaria, the growth of animal husbandry and meat production decreased by the end of the 1980s.

Within meat production, poultry and pork production in particular were developing. In poultry production five out of the six countries increased production by more than 10% per year in the last decade. Beef production was relatively stable, while mutton production was less than average. Egg production was developing rapidly, but milk production was developing only moderately; here Hungary is an exception in that its milk production was one of its most rapidly developing areas.

As we can see, many factors explain the constraints on agricultural growth following the dynamic developments of the 1970s. The problems of the total economy are significant. In addition, a distinction occurred in the late 1970s between the development of plant cultivation and animal husbandry.

Animal husbandry and the development of breeding technologies could not keep pace with the development of plant cultivation. Animal husbandry was not economic, and the efficiency of feedstuff consumption fell behind the levels achieved in well-developed countries.

Table 4 shows that tractors used in agricultural production have grown considerably in all the countries, although the number of tractors has decreased in the GDR and Hungary as a result of structural changes. The development has clearly shifted towards larger, more efficient machines. In past years, the change of the machine fleet has slowed considerably, which is harmful to the agricultural production capacity, especially in Poland and Romania.

The increase of chemical fertilizer consumption, measured by effective substance, leveled off in the second half of the 1980s. Stagnation and recession are characteristic (see table 5). Above all, the quick rise of chemical fertilizer prices curtailed the increase of chemical fertilizer consumption.

The Development of Food Consumption

In the first half of the 1980s the standard of living of people in most of the countries was still improving. But this increase stopped in the second half of the decade, and a recession in the standard of living can be observed in almost every country. In most of the countries, calorie consumption per person fell with a range of 3,300 to 3,500 calories a day.

The differences between the countries are substantial. Considering the well-developed countries, cereal consumption per person in Eastern Europe is relatively high. Within vegetable consumption, cabbages and tomatoes are dominant. Generally speaking, fruit consumption is low, especially tropical fruits.

The food markets hide interesting contradictions in the region. In some of the countries, where a market economy has already begun, the change in prices of the past period resulted in the absolute recession of food consumption. Although exact data are not yet available, in the first half of 1990 food consumption is estimated to have declined in Poland by 30% and in Hungary by at least 15%. In these countries a market situation is increasingly dictating the demand-supply conditions of foodstuffs. The food market is still characterized by excess demand in

Romania and Bulgaria, where consumption is at a much lower level. In both countries, deficiencies of supply and the governments' export preference policies are the primary reasons the inhabitants are still missing vital foodstuffs.

Eastern Europe and International Food Trade

The changes of the agrarian world's trade in the last decade adversely affected the Eastern European countries. In 1988, 2.8% of the world's agricultural imports were directed into these countries and they provided 2.5% of global exports. On the whole, the agro-export structure of these countries has not accommodated to the new world market situation of the 1980s. Agrarian protectionism affected most of the countries unfavorably.[2]

In years past, the level of grain self-sufficiency was increasing, as mentioned above, but the balance is still negative. Meat self-sufficiency is higher than 100% in the entire region. The region is traditionally independent in vegetable oils, and some of the countries are, or soon will be, ready for export. The six countries are largely self-supplying in fresh vegetables; if market conditions are provided, they can easily offer important exports. The degree of self-sufficiency in fresh fruit supply is in the 90% to 96% range, although the demand for tropical fruit is largely unsatisfied. The balance of agrarian trade in the region is negative on the whole. The total negative balance is $1 billion to $1.5 billion a year, which covers a self-sufficiency level of about 98% (table 6).

In agrarian trade the six countries can be classified into two groups: The GDR, Czechoslovakia, and Poland are in an import position. For GDR and Czechoslovakia, the amount of net import is particularly important. Besides significant imports, Poland has considerable exports, too; its net agricultural imports fell to about a quarter of the amount during the past ten years. Hungary, Romania, and Bulgaria are exporting countries. Hungary's food production export surplus is especially important; in 1988 more than one-third of the total European CMEA agro-export came from Hungary.

The differences in structure of exports and imports are substantial among the European CMEA countries. Cereals, industrial crops, meat products, fruits and vegetables, tropical fruits and tropical agricultural products, and above all coffee are dominant among imports. For exports, if Hungary's grain export is disregarded, meat and meat products, vegetable oils, and fresh and processed vegetables and fruits prevail.

The turnover of agricultural products differs among each country's economy and international trade relations. The proportion of agricultural products is the highest, about 25%, in Hungarian exports; second is Bulgaria at about 18%. In Czechoslovakia, agricultural products have a share of only 6% to 7% of exports. On the import side, the GDR is in first place, and Romania is in last place; in Romania, agriculture comprises less than 10% of imports. Disregarding absolute rates, the foreign exchange outlay of agricultural trade and export returns is very important for the balance of payments in all of the countries. This statement is particularly valid for the countries with relatively large amounts of debt, where the hard currency balance of agricultural trade in both positive and negative directions can be of significant importance.

In the agrarian trade of the Eastern European countries, Western European relations are most important among the well-developed countries.

[2] Agrarian protectionism has an extremely disadvantageous influence on the Eastern European agro-exporting countries which were not able to support export. It was not accidental that Hungary joined the Cairns Group. Of course, the importing countries here also enjoy the advantages of relatively low world market prices. See this topic also in Csáki (1989).

Western Europe is the most significant demand market for the quality food products of the Eastern European countries, although the share of the six countries from total Western European imports is extremely low, 2.5% to 2.7%.[3] In years past, agricultural exports from Western Europe to the six countries exceeded imports. The GDR, Czechoslovakia, and Poland are the leading buyers. The main sources of grain sales are the well-developed industrial countries outside Europe, although these exports are not significant; sales by Romania, Hungary, and Poland in North American markets (primarily meat products and highly processed food stuffs) are examples.

Particular attention must be paid to agricultural trade within the European CMEA region. Traditionally, the smaller European countries, above all Hungary and Bulgaria, and in lesser amounts Romania and Poland, exported food products to the Soviet Union according to long-run agreements. The Soviet Union paid for the food stuffs in energy and raw materials.

In the 1980s, about half of the Hungarian agricultural exports and more than two-thirds of Bulgarian food products found their market in the Soviet Union. This network of relations is deteriorating. In the Soviet Union, the energy-transportation facilities are becoming more limited. In addition, Soviet balance of payments is not in a favorable position. On the Soviet side, these developments have led to the accumulation of a relatively significant negative balance of trade against several Eastern European countries by the end of the 1980s. Of the countries concerned, first Hungary reacted with food export restrictions. They are not able to grant the credit needed by the Soviet Union, similar to the credit on food imports from the well-developed countries. It is not accidental that, in the last nine months (e.g., simultaneously with the decline of the Eastern European food export directed into the Soviet Union) food exports of the European economic community into the Soviet Union grew by almost 300% (AgriEurope 1990).

[3] Senior Nello has studied the agrarian trade relations between the EEC and the Eastern European countries in detail.

Reform Attempts in Eastern European Agriculture

In the 1950s and 1960s a socialist reorganization of agriculture was carried out in all six countries. It was equivalent to the collectivization of an agriculture of mainly smallholders according to the Soviet models. The state estates and agricultural cooperatives became dominant in all the countries except Poland by the mid-1960s (table 7). The organization of socialist large-scale farms was accompanied by the development of a planned economy and by a centrally prescribed and planned agricultural production. A significant recession accompanied the reorganization in all the countries except Hungary. It was obvious even in the middle of the 1960s that the administrative central direction was constraining agricultural production growth. Other signs of dissatisfaction with the system also appeared. As a result, in the second half of the 1960s, the first period of reform of the socialist agricultural systems occurred.

The main objective of reform was to change the character of direction. Two alternatives were

[a] State and cooperative farms together.

considered. One of the reform groups saw security only in the perfection of planning methods; the other group supported decentralization, the increase of companies' independence, and the increased use of economic incentives. Finally, in most countries reforms which weakened central direction and fostered decentralization were adopted. However, the practical implementation of these reforms was problematic. Publication of reform ideas did not assure implementation; in several countries, parts of the planned arrangements were introduced experimentally. In this first wave of reforms, only in Hungary did a significant change finally occur; here the indirect direction system introduced in agriculture outperformed the solutions applied in industry. The new economic mechanism resulted in a relatively rapid development of Hungarian agriculture (Csizmadia and Székely).

Disregarding the Hungarian reforms, the agricultural directions systems considered new at the beginning of the 1970s did not achieve the expected results; they did not accelerate the agricultural development process. Moreover, in 1972–73, some retirement occurred in the decentralization process of almost every country because of political pressures. However, in the second half of the 1970s, a new situation was developing. The changes in the world's economy and the oil crisis increased tensions about the economic problems in the region. It became clear, particularly in some countries, that an agriculture organized and directed by earlier methods could not keep up with the demands of consumers. Thus, a second wave of reforms was initiated which basically sought to more thoroughly advance the objectives of the first reform; but it was without much success.

The third period of agricultural reforms in Eastern Europe began in 1985–86 and lasted through 1989. The general economic crisis of the region and its backward development can be considered the antecedents of this wave of reforms; moreover, in some of the countries high indebtedness occurred as well.[4]

The failure of past reforms and the sharpening political tensions ripened the demand for radical changes. In this period the central objectives of agricultural reforms were as follows: to improve efficiency and quality of production, to move toward a price policy reflecting the real costs of production, to increase the role of financial incentives, to provide greater decision-making freedom for firms, and to widen the possibilities of private agricultural production.

The third wave of reforms did not equally affect the countries because of differences in patterns of political changes. In the GDR and Romania, the decision-making freedom of companies and decentralization were quite limited. In Czechoslovakia, to a lesser degree, the independence of companies, economic incentives, price reforms, the role of financial instruments, and private production support were all increased considerably and reinforced. In Hungary, where these arrangements had begun earlier, the food industry and foreign trade were partially decentralized. The idea of transforming the weakest cooperatives into a loose cooperation of private producers also arose. However, in the latter four countries these changes coincided with the final days of planned economy, and they could not produce perceptible results.

In the second half of 1989, the political turn sweeping Eastern Europe meant the beginning of a new agricultural era as well. The sequence of attempts to reform the socialist agricultural systems was over. Efforts to formulate a new agricultural structure replaced the reform ambitions. This change is clearly evident today only in the GDR, Hungary, Poland, and Czechoslovakia (Wos, Wadekin) where, together with the introduction of the real multiparty system, the power of the communist party also came to an end.[5] Similar progress is occurring in Romania and Bulgaria, although the positions of Communist parties here are rather stable. Thus, the political and agricultural perspectives of the future are still doubtful. The character of change in the Soviet Union is similar to that of the Eastern European countries, but here, too, the official language is still using the term "reform."

[4] This period is analyzed in detail by Csáki (1988).

[5] Wos studies Polish reforms; Wadekin analyzes the latest happenings in detail in the agriculture of the GDR, Czechoslovakia, and Bulgaria.

Change in Eastern European Agriculture

The main direction of the transformation of Eastern European agriculture, similar to the general economic and political changes, can be easily identified. In every country the objective is to develop an agricultural structure based on a market economy with private initiatives and private ownership. The principal characteristics of the new system and the critical points of the future can only be outlined today. However, the most important tasks are the following:

(*a*) An unambiguous requirement is to create marketable landed property.

(*b*) The farming structure, which is presently large scale, must be adjusted toward small and medium-sized agricultural private ventures and a system of cooperatives of various types existing together with the state or communal farms.

(*c*) Develop a governmental attitude which fosters these ventures, supports the emerging private entities and attends to the transformation of the cooperative sector.

(*d*) An agricultural policy which serves the efficiency of agricultural production by means utilized in the market-oriented, well-developed countries and enforces the traditional objectives of income parity of agricultural producers is needed.

(*e*) A real agricultural market is needed which guarantees fair competition.

(*f*) A basic, fundamental change in the role of government.

(*g*) The agricultural policy under transformation must consider as an objective the environmental protection of nature.

The Landed Property, Reprivatization

One of the biggest dilemmas in Eastern Europe involves landed property. It is clear that the creation of marketable landed property is unavoidable. The adaptation of farming structure to the market conditions is also needed.

Numerous alternatives are possible. First, it is helpful to survey the landed property relationships in Eastern Europe. Except for the Soviet Union, in the countries concerned, land was not completely nationalized after the war. In addition to state property, cooperative landed property also arose, and private landed property existed in various forms as well. Over the years, proprietary rights came to be only formal, over and above the proprietary rights of land in private handling. Together with the abolition of the land market, land lost its character as a valuable asset. In Eastern Europe, land values cannot be found in the registry of agricultural implements. Land costs are not calculated in various agricultural accounts either.

It is not accidental that one of the most debated political and economic questions involves landed property. All over Eastern Europe a host of opinions currently exist; the most important are the following:

(*a*) To keep the present forms of property ownership and to allow land control through leasing.

(*b*) To give the land to those individuals who wish to be agricultural producers.

(*c*) On the basis of proprietary rights before collectivization, to give land to all those who aspire to work in agriculture, together with financial compensation for earlier proprietors who did not take an active part in agricultural production.

(*d*) To reestablish with no restrictions the landed property relationships existing prior to collectivization.

The land property decision is unknown at present, but the process will probably differ among the countries. In Czechoslovakia, Hungary, and the GDR, the discussion about such land issues is currently underway (Wadekin, Csáki and Varga); however, in Bulgaria and Romania, the question has not yet been formally put on the agenda, although the land demand of private producers is noticeable here as well.

Future Farming Structure

The agricultural structure of the countries was formed by the collectivization process of the postwar period. The objectives of collectivization were similar in each country, but the methods of execution and resulting structures differ. In the GDR, Czechoslovakia, Bulgaria, and Romania, the socialist reorganization of agriculture was consistent with the Soviet model. In these countries the typical form of agricultural enterprise was the state or cooperative large-scale farm of several thousand hectares (table 8). In Bulgaria the agri-industrial complexes emerged as special entities that fused the state and cooperative forms. In the middle 1980s in Bulgaria, 150 large complexes were working and spanning most agricultural regions. A particular characteristic of Eastern Germany is the separation of plant cultivation and animal husbandry. In Czechoslovakia and Romania, the co-

Table 8. Main Indicators of State and Cooperative Farms in 1988

[a] In 1985.

operatives and state farms have been largely independent until now.

Collectivization has followed its own course in Hungary, where cooperatives have always been relatively independent. In terms of household farming plots, private agricultural production still exists. Poland was able to preserve the predominance of private farms, but the government long impeded the natural progress of private ownership in agriculture. The classical private farms could survive the reorganization of agriculture only in low numbers. Only in Hungary was household and complementary farming often supported by the government. The production structure of private agriculture was also unique. Private growers dealt primarily with animal husbandry and gardening; grain production and plant cultivation were almost exclusively concentrated in the large farms. The rate of private production is the lowest, about 10%, in the GDR and, apart from Poland, highest in Hungary, where one-third of the production came from the private sector in recent years. In Czechoslovakia the contribution of private production to total agricultural production is 10% to 12%, about 25% in Bulgaria.

What will be the future of cooperatives and estates in Eastern Europe? In their present form, these farms are not suitable for a market economy. They are too large, not profit centered, and are lacking in entrepreneurship. It is probable, based on the results of tests in the GDR and Hungary, that much of the cooperative membership does not want completely independent production (Wadekin, Csáki and Varga). So it is probable that part of the cooperatives will be abolished, and new forms of cooperation will open the way to individual farming along with the present cooperatives. Private production will gain strength, but it is impeded by numerous factors: lack of capital, undeveloped credit systems for villages, high interest rates, the lack of buying systems for farm products, lack of technical implements used in private farming, and managerial deficiencies, especially in finance and economics.

The reprivatization processes for the state-owned estates in other parts of the economy must be considered. Agricultural enterprises in state and public ownership which operate with a joint stock structure are found in the countries as well. Their role will be important in seed grain and breeding stock supply and in consultation services. Some of them will function as diversified agribusinesses, and they may be instruments for attracting foreign capital to support agricultural production.

The above processes will fundamentally change the enterprise structure of agriculture in Eastern Europe. It is questionable whether these changes can occur without a temporary decrease of agricultural production, given the political tensions in the region. The peasant people's love for work and perseverance suggest optimism, as the historical examples also show. Nonetheless, during the transition period the temporary disturbances of agricultural production can be avoided only by well-considered government policy.

Agricultural Market Creation

The new agroeconomic structure presumes that a real market system of food economy can be developed. This market system must support production, the domestic food market, and international markets, too. Organizational, institutional, legal, ethical, and economic regulatory issues are involved as well.

A fundamental requirement to create a market is to make the processes of food production and sale and the production and supply of factors of production a unified system joined by economic relationships. In all the countries food processing is a bottleneck.

Considering the formation of agricultural markets, the improvement of technical conditions cannot be neglected either. Nowadays, the wholesale trade of agricultural products, delivery to consumers, and retail trade are all very primitive in the countries involved. The proper facilities, organizations, and technical knowledge all are missing. The building up of a fi-

nancial system joined to the agricultural sector and the creation of a provincial network of banks and credit institutions are also needed.

The governments are trying to make up for this backwardness, but conditions for true competition have not yet been reached, and the lack of these conditions impedes the gains from price liberalization as well.

The State's New Responsibility

The removal of the bureaucratic state management system has already started, but this work will take time to complete. The degree of change differs in each country. The system of planned targets has been abolished, but several bureaucratic and attitudinal barriers still exist. The pivotal question of the state and production relationships involves price and assistance policy. The characteristic features of the classical Eastern European agricultural price system are as follows: The majority of the producer and consumer prices were pegged by the government; the agricultural producer prices were fixed on the basis of domestic production costs, mainly those of large farms. Thus, most prices were significantly different from both the norm and as proportions of the world market export prices; the earlier economic policy fixed the producer prices of food products at reduced levels.

Rapid changes are occurring in the policy areas as well. State regulation of consumer and producer prices is weakening. The transformation is strongest in Poland and Hungary. In Poland in 1989 and in Hungary in January of 1990, producer and consumer prices of foodstuffs were almost completely liberalized, along with the reduction of consumer price assistance.[6] (Currently in Hungary only wheat for meal and milk have official prices among the agricultural products).

All the countries apply some kind of agricultural export subsidies. The effects of these subsidies cannot be distinguished in the data. It is unlikely that such subsidies will be abolished until the effects of protectionism are substantially reduced in international agricultural markets.

The global budgetary system of relationships of agriculture is being transformed. A complex set of taxes and subsidies can be found in all of the countries. In general, the burdens of economic difficulties are being increasingly shifted to agriculture by the governments. As a result, the balance of the budgetary relationships of agriculture has become negative in most countries in recent years.

Political Transformation of Rural Areas

In all the countries the classical party state has been abolished. In addition, political reforms in rural provinces are rapidly occurring.

In the GDR, Czechoslovakia, and Poland peasant parties existed in an earlier time as well, but their operation was only formal and was strongly subordinated to the party in power. These peasant parties have now become independent political forces. Moreover, in Hungary, Bulgaria, and Romania the peasant-related parties are being revived.

The political force of the revived peasant parties differs among the various countries. A particularly strong and vigorous policy characterizes the peasants' party of Poland and the smallholders' party of Hungary, which are both members of the ruling government coalition. In Hungary the political party favoring the agricultural cooperative sector also was founded. And, in Bulgaria and Romania the peasants' parties in opposition are significant powers.

Transformation is characteristic of the agricultural representative organs as well. The representative system of agricultural producers and rural people is also being formed. In all the countries new unions, chambers, and associations are marking the beginning of a fundamentally new political era.

International Agricultural Relationships

As already cited above, the CMEA and the Soviet-oriented, traditional, agricultural international system of relationships of the Eastern European countries has been dismantled. The future of the GDR is clear. In the immediate future, the country will become an integrated part of the agricultural structure of the common market and will also become a part of the unified Germany and thus a member of the EEC. Similarly, agriculturally import-oriented Czechoslovakia is leaning toward the western countries and gradually opening its agricultural markets.

[6] Today in Hungary, for example, among agricultural products, only wheat for meal and milk have official prices. Related to this, among food products, only the price of white bread, crescents, rolls, and milk of 2.8% fat content were officially fixed.

The reinforcement of western orientation is likely for Hungary and Poland as well. In the case of Hungary, Poland, and Czechoslovakia the process of developing new markets is assisted in various ways by the EEC and by the most-favored nation status guaranteed by the U.S. Congress. The Western European orientation of these countries is strengthening day by day. The European relationships and western orientation of Bulgaria and Romania are similarly strengthening, although their future is more difficult to predict.

The agriculture of Eastern Europe is experiencing intense transformation. The success of these changes fundamentally depends on the agricultural economy of the given countries, but the help and understanding of western countries are needed as well. Undoubtedly, the reforming of Eastern European agriculture will become a rival. But, I am convinced about the mutually advantageous possibilities which will be offered by the democratic Eastern European countries with their opening market economy for the agriculturally developed world.

Agricultural Reform in Developing Countries: Reflections for Eastern Europe

Avishay Braverman and J. Luis Guasch

Eastern European countries and the USSR are embarking on a breathtaking political and economic transition. They are venturing into uncharted economic territory encumbered by institutional rigidities, property rights dilemmas, high external debt, nonconvertible currencies, and inadequate safety nets, all of which pose severe problems for traditional macroeconomic and price reforms. The move toward a market economy has shocked the stagnant and deceptively stable socialist system, bringing unemployment and inflation.

The people of these countries, however, are not the only ones who are moving into uncharted territory—so also are economists usually designated "Western," i.e., those working in the tradition of economic theory that developed unconstrained by strict Marxist dogma. Modern economic theory offers little insight into the dynamics and institution building necessary to move from a centrally planned to a market economy. Our Arrow-Debreu paradigm even in its most modified version, allows analysis of small changes in a market economy. It assumes the existence of well-defined property rights, financial and marketing institutions. In their absence, our ability to predict the impact of major reforms, such as freeing the price system, is limited.

The reform of formerly centrally planned economies involves freeing the price system, developing a competitive environment, and privatizing many of the state-owned or controlled assets and services, while simultaneously generating the social, economic, and legal infrastructure that undergirds a market economy. These processes require varying time dimensions in an atmosphere of political uncertainty. Any *ex ante* analysis of the transition in Eastern Europe and the USSR should, therefore, be approached with the utmost humility and with the knowledge that we have many lessons yet to learn as we expand our theory to comprehend this phenomenon.

The experience of developed and developing countries offers some lessons relevant to the transition. In this paper we focus only on lessons relevant to the agricultural sector. The agricultural or rural sector in developing countries is important. In many countries it is still the main engine for growth and a major contributor to foreign exchange. The rural sector engages between 50% and 80% of labor in most developing countries and contributes more than a quarter of gross domestic product (GDP). Most of the poor in developing countries still reside in rural areas. Agriculture has traditionally been subject to discriminatory practices, through exchange rate, price, and tax policies known together as the urban bias.

Many developing countries have attempted to remedy the problems caused by the urban bias plus the budget deficit, balance of payments problems, and massive external debt by embarking on the so-called process of structural adjustment. In response, international financial institutions, in particular The World Bank, have generated a new lending mechanism, the structural adjustment loan conditioned on various policy reforms. We prefer to view these loans in a broader context, since structural adjustment should be seen as a process of ongoing policy reform. The areas of reform include monetary and fiscal policies, exchange rate and domestic price reforms, institutional reform (especially in areas of credit, marketing boards and land and property rights), and policies to improve technology transfer and adaptation. In addition, special attention has been given to programs to pro-

Avishay Braverman is president of Ben Gurion University of the Negev, Israel, and former division chief of the Agricultural Policies Division at the World Bank. J. L. Guasch is a professor of economics at the University of California, San Diego, and a research fellow at the World Bank.

The opinions expressed here are those of the authors and should not be attributed to the World Bank.

The authors are grateful to Gershon Feder and Lorraine Mitchell for their helpful comments and in particular to Karen Brooks for her insightful suggestions.

tect the poor, with an insufficient degree of success. Adequate investment in physical and human infrastructure, including health, education, and nutrition, is critical to supplement structural adjustment programs, and these investments have a high payoff, particularly for the poor.

The process of reform in developing countries differs from that in Eastern Europe and the USSR because the physical infrastructure, human capital, and cultural context that comprise the initial conditions differ. The differences limit the degree to which the less developed country (LDC) experience generalizes the Eastern Europe and the USSR. The suppression of markets in the former socialist countries is greater than in the LDCs. The distortions within the agricultural sector are more massive and more difficult to measure without meaningful prices and exchange rates. The urban bias in aggregate has been less in the post-Stalinist period than is the case in LDCs because subsidization on a large scale through the state budget and the banking system has allowed producer prices and earnings to rise even though labor productivity is low. The urban bias in several countries, most notably the USSR, has increased in the transitional period as controlled producer prices have fallen behind increases in the general price level. The bias is still less than in many LDCs, however, and the large subsidies of recent years affect rural people's evaluation of the gains and losses that the transition will bring. The implications of these differences in initial conditions for the two types of policy reform, structural adjustment in developing countries and transition to post-collectivist market-oriented agriculture, will be discussed below.

Getting the Prices Nearly Right

Four issues usually must be addressed in an effort to get the prices nearly right: (*a*) a credible correction of the exchange rate must be achieved; (*b*) relative prices within the agricultural sector must be adjusted; (*c*) the transmission mechanism that links domestic to international prices and consumer to producer prices must be changed; (*d*) the needs of vulnerable groups must be monitored and addressed.

Achieving A Credible Devaluation

The intent of devaluing the exchange rate is to increase the relative price of tradables with respect to nontradables. Given the prevalence of urban bias, this tends to increase agricultural producer prices at the expense of incomes of urban residents. One clear lesson on devaluation that has been learned is that devaluation will achieve its original purpose only if there is political commitment, manifested through fiscal discipline, to change the rural-urban income distribution. If the government offsets the devaluation by expenditure that increases the income of the urban sector, particularly the government sector, the results will be the nullification of the devaluation and generation of cost-push inflation (see Braverman and Kanbur for an example in an African context).

The Importance of Relative Price Changes

A uniform price shift, such as that which takes place in devaluation, is important, particularly when urban bias is great. In both developing countries and the former socialist countries, however, change in relative agricultural prices can be more important because the distortions in these prices are quite high. Moreover, when the aggregate supply elasticity of output and employment in the agricultural sector is low, the response to a uniform shift in prices, as is achieved through devaluation alone, may bring modest welfare gains. The greater impact on the budget deficit, foreign exchange, and on the distribution of income derives from response to adjustment in relative prices of key commodities. In addition, because the aggregate response has very high own and cross effects, the costs of inappropriate relative prices within agriculture are high, and the welfare gains to remediation correspondingly great. In assessing price reform which involves tradeoffs, we empirically use estimated elasticities, and the newly reformed centrally planned economies present a real dilemma. We do not have price series that are meaningful for the generation of these elasticities. We are forced, as is the case in analysis of many data-poor developing countries, to resort to guesstimates and judgment.

In the case of Eastern Europe and the USSR, exchange rates have historically been grossly overvalued, but their impact on resource use has been muted by bureaucratic restrictions and hidden interventions. Devaluation is essential, but the response to a uniform price shift and to changes in relative prices will be modest unless the instruments of bureaucratic intervention are also removed. Much of the gain from price reform (both devaluation and changes in relative

prices within the agricultural sector) will come from removal of distortions in regional comparative advantage achieved through price bonuses and assignment of quotas. In the former socialist countries, the removal of direct bureaucratic costraints on agents' decisions is an integral part of successful price reform; price reform and institutional change are linked. In LDCs the potential direct impact of remediation of price distortions is greater, although there, too, institutional changes promoting competitive behavior, such as the removal of monopolistic marketing and procurement boards, are essential.

Producer Prices, Consumer Prices, and International Prices

The usual prescription for price reform has been to move domestic prices toward international prices. Many people question this remedy because world prices are distorted. International prices for agricultural commodities are low in part because of the subsidization of agricultural producers in the EEC, the United States, and Japan. These price subsidies stand in the way of shifting comparative advantage in agriculture toward the developing countries. Moreover, current price support policies in all countries provide income transfers skewed toward large, more commercial, farms, and they encourage inefficient use of inputs, such as fertilizers, thus contributing to environment degradation.

East European and Soviet producers also suffer from these policies of developed countries. A breakthrough in the GATT negotiations through reduction of subsidies and quotas will improve the lot of their agricultural sectors. Therefore, strengthening the momentum of the negotiations on trade liberalization is very important to the long-run success of the reform process in Eastern Europe. The removal of relatively cheap subsidized imports, however, will exacerbate in the short run the difficulties of economies in transition in meeting the needs of their most vulnerable consumers.

Whatever the outcome of trade negotiations, small countries have to take international prices as determined by world markets, and policy reform should direct domestic prices towards international prices. This does not imply, though, a dogma of immediate equalization of domestic prices with international prices. Rather, we advocate assessment of tradeoffs involved in price reform in terms of government revenue, foreign exchange, and the real incomes of different groups. The reality of LDCs often implies a limited set of instruments for raising revenue and influencing income distribution, and therefore price reform must on occasion address conflicting objectives.

More specifically, domestic prices may diverge from international prices for several reasons: First, when a country exerts market power over international prices, the need to use marginal revenue translates into the need for an optimal tariff (tax). This special case applies to very few countries and a few primary commodities, and often the degree of market power of individual countries is overstated. This argument is irrelevant to the small countries of Eastern Europe but may have some relevance to Soviet wheat imports or eventual exports.

Second, the presence of significant price volatility might force the government to deviate from the full transmission of international prices to the domestic economy. Maintaining stable prices has importance for the macroeconomy by reducing the impetus for cost-push inflation and swings in government revenue and foreign exchange. Moreover, price stabilization can protect the very poor from transitory movements in real income below subsistence level. The macroeconomic consequences and protection of the very poor are probably more important than some of the microeconomic considerations which have received most of the attention of research on the economics of price stabilization up to now (Newbery and Stiglitz, Kanbur, Braverman et al.).

The third justification for price intervention involves subsidies of industrial countries. A developing country facing a reduction in world prices because of subsidies or other factors may be reluctant to pass these prices on to farmers if the reductions are deemed temporary. The motive is to avoid the adjustment costs of moving out of an activity with expectations of returning to it later. Supporting prices during periods of transitory decline may be justified to maintain production and employment in agriculture, but only if there is a strong consensus that the decline is transitory and the adjustment costs are high enough. Although price stabilization programs have often been costly and inefficient because of their misuse, the concept cannot be brushed completely aside. There is a need to look for an appropriate mechanism for income insurance and/or price stabilization devised in more effective ways. Given the absence of risk insurance markets together with producers' and consumers' inexperience in managing risk, the costs of variability may be higher in

the transition. Therefore this issue should be reopened.

Fourth, political and administrative problems may make income tax and other broad-based taxes impractical, particularly in some poor developing countries. The government thus has difficulty raising revenues to finance essential public expenditures, e.g., for infrastructure and poverty alleviation. In Eastern Europe and the USSR, the political and administrative problems associated with introduction of a new tax system are formidable but do not justify the substitution of commodity taxes for a more modern fiscal system. The difficulties with the changeover to a new tax system are transitional, rather than endemic, and delay in the introduction of more appropriate taxation will simply build new distortions into the reformed economies.

Protecting the Vulnerable

In developing countries, policy reforms in agriculture often imply raising food prices to provide better incentives to producers. Eliminating food subsidies reduces urban income in relation to rural income because food prices go up. These changes require political will because the urban sector is much more politically sensitive and influential than the rural sector. They raise the distributional issue of how price reform adversely affects vulnerable segments of the population. In Eastern Europe, the same problems can occur, as the recent severe increases in food prices in Poland have demonstrated. Several important differences between Eastern Europe and developing countries should be noted, however. In the former, basic nutritional needs have been met in general, and expectations and standards of living are higher than in many developing countries. The changes in Eastern Europe, however, are of tremendous magnitude; economies that have known little unemployment will experience a great deal of joblessness. Many real wage earners are experiencing declines in their real income because of increasing prices. The decline of real wages is exaggerated, since during the period of low prices many consumers experienced quantity rationing and resorted to black or free market purchases at higher prices. Safety nets, such as social security, have yet to be created. Agricultural employment is proportionately less than in most LDCs, and changing the rural-urban terms of trade may thus adversely affect a large number of people in urban areas.

Despite the differences in their circumstances, the experience of poorer segments of society in developing countries is relevant to that of Eastern Europe. In LDCs higher food prices hurt the urban poor, landless farmers, and small farmers with a negative marketed surplus, at least in the short run. To protect these vulnerable groups during the adjustment, targeted programs are desirable and have been implemented. The track record for such programs in developing countries during the last twenty years has not been very good, however. They should be advocated only when the appropriate political will and administrative capacity exists in order to avoid corruption and mismanagement of resources. Otherwise, it is still advisable to resort to subsidization of commodities that the poor significantly consume much more than do the rich (that is, inferior goods). The financing and implementation of large safety nets during the adjustment process of the Eastern bloc will require large amounts of capital transfer from the Western world, including international organizations. The challenge will be to design, monitor, and implement these programs to guarantee that large sums of money will be appropriately distributed to the needy population during the transition.

Institutions

Credible price reform can achieve the desired price response only if supplemented by institutional reform to provide for well-defined property rights, easy access to capital inputs, financial institutions that distribute credit effectively, and competitive marketing boards that allow producers rather than institutions to retain rents. There is also a need for a coherent policy on research and development to induce innovations and to diffuse technical knowledge and information through extension services. Without such policies the potential gains of price reform probably will not be realized (Chhibber). Crops have to reach markets quickly, and only farmers with access to credit will choose the right mix of inputs or exert the right amount of effort. The provision of public goods, like water and irrigation systems as well as extension services, can be a most effective way to increase yields; but one can hardly expect individual farmers to invest much in them. The evidence suggests, however, that many countries, particularly low income Sub-Saharan African economies, have seen the efficacy of price reforms undermined by the pres-

ence of severe infrastructural constraints and market rigidities. In consequence, many structural adjustment programs should have policy components addressing those issues.

Credit, Financial Institutions, and Marketing Boards

Improved access to credit in LDCs was intended as a major policy instrument to accelerate development in the rural areas and to improve the income distribution between rural and urban residents. In addition, it was advocated as a second-best remedy to counter the common discrimination against agriculture through the urban bias in tax, price, and exchange rate policies.

The record of companion policies to price reform, particularly on credit and institution building, is disappointing. Over the past thirty years, massive amounts of credit, most often at subsidized interest rates, have been channeled to rural sectors in developing countries. But more often than not, those subsidies have benefitted the wealthier and influential farmers. Little formal credit reached the small farmers. Also, many institutions created to support the agricultural sector, in particular formal credit institutions, suffer from inefficiency and ineptitude, engage in arbitrary practices, and lack financial viability (Adams; von Pischke, Adams, and Donald; Braverman and Guasch).

The above-mentioned shortcomings in performance of financial institutions, however, could easily apply to the developed countries. The Savings & Loan crisis in the United States will probably end up costing $250 to $500 billion, an amount that dwarfs the obligations of even the most debt-ridden LDCs. The creation of long-term accountability in financial institutions is becoming a global issue. Eastern Europe must learn from the failure of incentives in many financial institutions in LDCs and the developed world and build credible mechanisms for monitoring, enforcement, and accountability. Banks in the socialist system were essentially agencies for transmission of funds and fulfilled few of the functions of full financial institutions in a market economy. Therefore, technical assistance from developed countries will be necessary in order to develop basic skills in the technology of banking, accounting practices, and generation of financial instruments. Financial institutions must be created immediately, for without them, a market system cannot function.

The needed institutional changes go beyond the financial sector, and, as argued above, are critical in the area of marketing. Reforms in marketing boards and procurement agencies are urgently needed to promote competition, since many of these organizations exhibit monopoly power and overly tax the farmer. Their noncompetitive behavior reduces farmers' supply response and inhibits improvement in the rural sector. Experience in developing countries has shown that attempts to interfere directly with supply through rationing, licensing, targeting, and other direct controls have been open to abuse. At best, the attempts breed inefficiency. At worst, they increase monopoly power, increase inequality, and encourage corruption. The key characteristics to strive for are accountability, noninterference, and responsiveness to market forces which will generate competitve behavior.

Property Rights, Land Tenure, and Privatization

Structural adjustment policies often involve reassessing property and land rights as well as titling the land. A major issue here is whether and how the absence or ambiguous definition of land rights harm agricultural productivity. One usual line of reasoning is that when land or property rights are not well defined, farmers are reluctant to sink fixed (irreversible) investment or to make long-term investments in their land, even though doing so is socially efficient. Another is that farmers' access to credit is hampered because their land is not accepted as collateral.

Evidence of the reality of these links is ample. For example Feder's case study on Thailand shows that the lack of land title prevents small farmers from access to credit and induces underinvestment of capital. The policy implication is that property rights should be fully exclusive, transferable, alienable, and enforceable to facilitate the development of an active land or rights market. Property rights or long-term land use rights with these characteristics induce efficient and higher levels of labor and management, as well as greater investments to enhance land yields. This point is very important in the East European and Soviet context because these countries enter the transitional period with a strong ideological bias against fully functioning markets in land. Restrictions on land markets will constrain the extent to which reform in the financial sector can move forward because

the state will be forced to retain an active role in agricultural lending (Brooks).

A point to consider in the land privatization process is what should be the level of land fragmentation. Of course, that could be left *ex post* to the market to resolve, but that could take years and large transaction costs to bring the desired changes. An argument for maintaining the current size, where the average farm size is over 1,500 hectares, except in Poland, is that it would allow for the reaping of the existent and significant economies of scale in agricultural activities, giving those countries an advantage over the countless smallholdings of the EC, provided that the managerial and agency incentive problems are accounted for.

The developing countries offer few lessons on the particular issues of farm reorganization and privatization of land relevant to Eastern Europe and the USSR simply because few collectivized on the scale of the socialist countries. The available lessons lie mostly in the successes and failures of the Chinese and Israeli experiences, but the generalizations are limited. In China price reform and division of the land (albeit suboptimally) brought an immediate supply response due in part to a divisible technology amenable to small-scale production. The Chinese experience suggests that uncertainty as to the duration and renewability of the land contract limits investment and constrains long-term growth (Lin). The Israeli experience with long-term marketable contracts in land also offers some lessons (Zusman; Kislev, Lerman, and Zusman). In Israel long-term leasing of land has provided security of tenure adequate for investment and producers have jointly contracted for use of nondivisible technology. The Israeli agricultural sector, however, has been plagued by financial overextension because of the existing unlimited joint liability both among members and among cooperatives that lead to significant "free-riding."

In addition to land reform, the privatization of agrarian enterprises is at the core of the agricultural reform in Eastern Europe. When, where, and how to privatize these organizations, and how to structure efficiency and fair access into the process present dilemmas for the former socialist countries that the LDC experience does little to elucidate. The public sector in most developing countries is of course proportionately smaller than in Eastern Europe. Many developing countries established state enterprises with the intention to correct market failures and improve income distribution. Although some state enterprises, like the Kenyan Tea Authority and the Botswana Meat Commission, are relatively well run, many public enterprises in developing countries and throughout Eastern Europe and the USSR are statutory monopolies or are given advantages over private concerns through open or indirect subsidies. In addition, they often lack competitive or fiscal discipline as they perceive themselves—unfortunately rightly so—as being subject to soft budget constraints (Kornai). The absence of financial discipline shelters their survival and riddles them with inefficiencies and inequities. Some developing countries have in response moved haltingly toward the privatization of large state complexes. The results of their cautious approach have been mixed. In Malaysia and Togo, selective privatization has been vigorous, but these countries have been the exceptions despite widespread disenchantment with the public sector.

The efficiency argument for privatization or divestiture emphasizes the potential benefit to the consumer from lower production costs. Those benefits can be reaped and passed to the consumers only if there is a competitive environment and a supporting infrastructure. Privatization in itself will not bring competition and improved performance. In Poland, despite much privatization in agricultural production, systemic and institutional impediments in extention, credits, input supply, and marketing depress agricultural productivity. Noncompetitive behavior in marketing prevents the private sector from benefitting from the superior incentives of private ownership. Moreover, transferring monopoly power from a public enterprise to a private one will transfer value added from one privileged group to another (or sometimes to the same people in larger amounts!), but will have ambiguous net impact on consumers and on total factor productivity.

The question of how and when to privatize is a complex one. The conditions under which privatization can fully implement the social objectives of equity and efficiency are restrictive. Economic theory convincingly argues for the allocative superiority of competition, but it is much less forceful, if not ambiguous, about the superiority of private ownership. There is a cost to privatization, as we have learned through the principal agent literature. In providing incentives, the government receives less than the expected discounted value of enterprise profits, because of risk aversion, informational constraints, and capital restrictions. Moreover, some objectives might be very difficult to obtain in

the course of privatization, like the right risk taking, the socially optimal innovation, and the equitable division of capital, particularly in these societies where over forty years of collectivization have significantly undermined the psychological prerequisites for private undertakings.

The appropriate balance between the public and private sectors hinges on establishing who has a comparative advantage in the productive or service activity. If measures can be taken to ensure a competitive environment—a large determinant of efficiency—it would be foolish to claim that no government intervention could improve welfare. Opening formerly closed economies to foreign competition can induce competitive behavior even if the domestic industry remains concentrated.

Given the severity of the price and market distortions affecting Eastern European countries, it is difficult to determine *ex ante* which state enterprises would perform effectively under a bona fide market system and which would not. The issue of privatization illustrates our need for humility—if we could distinguish the viable from the nonviable enterprises, which should be privatized? The bankrupt ones, trading fiscal solvency for higher unemployment? Or the potentially profitable ones, releasing profits where they can grow under better incentives, and retaining weak firms under the shelter of the state's portfolio? If it is possible to harden the budget constraint and change managerial incentives, privatization may not be necessary. The credibility of the commitment to a hard budget constraint is difficult to promote, however (Brooks).

Equity and fairness are key issues in the privatization debate and must be considered along with efficiency. We have learned from developing countries that severe inequities can result on two fronts. First, equity will suffer if small, powerful groups within the society are allowed to gain ownership of large amounts of property. Conversely, East Europeans and Soviets now face the rare opportunity to put in place a relatively equitable distribution of agricultural assets and wealth that minimizes the need for costly contractual negotiations and can serve as a foundation for future growth (Stiglitz). Second, a situation in which the prices of capital are much lower than the actual market valuation can result in the inappropriate large transfers to foreign interests with greater access to capital. Even if valuation is correct, wealth will pass to foreigners if domestic citizens have poor access to international capital markets.

The distribution of the gains from privatization within the country depends on the distribution of information and access to capital markets, which often privileges people well placed in the old order. Valuation also critically affects the distribution of gains. Care should be exercised to avoid "spontaneous privatization," or the illicit or unfair capture of sale proceeds or asset value by the former managerial class. Denying ownership to former managers, however, eliminates a class of people who presumably are relatively better trained to run the enterprise. If the enterprise can be fairly valued, the problems of spontaneous privatization are reduced, but not eliminated.

Research, Extension and Technology

Much agricultural growth can come from new technologies. Research generates innovations, and extension brings them to the field. Research and extension are public goods, and the private sector alone will underinvest in them without government intervention. Most developing countries have neglected agricultural research, as is exemplified by the lack of government commitment to research, budget cuts, and a low level of funding for operational expenses. Research and extension expenditures have barely exceeded 1% of the value of agricultural product in most developing countries, whereas three times as much is allocated in the industrial countries, where the relative importance of agriculture in the national economy is lower. Perhaps the shortage of trained scientific and technical staff and the difficulties in measuring positive returns in extension and research investments in the short run have been some of the causes. The developing world has consistently shown lack of a coherent strategy, the lack of a review of the status of research for each agro-ecological zone, and the lack of an evaluation of the expected net gains from research.

The most common type of research has been applied or adaptive. It is less costly, more oriented to quick results, and essential because research developed elsewhere cannot be directly transferred without some adaption to local conditions. But even where successful research programs have been developed, problems have occurred in the dissemination of those advances. Research and extension services have not always been linked.

East Europeans and Soviets can learn from the shortcomings in research and extension in the

developing world, but they can learn the same lessons from the poor returns to their own larger investments in agricultural research. Satisfactory links depend on cooperative attitudes among the scientist, the extension worker, and the farmer. Regional committee, joint or farm trials, having research workers function as subject matter specialists, running periodical in-the-field training sessions can all help in strengthening these links.

The experience of agricultural research and technology transfer in the developing world is not one of uniform failure. There have been significant successes, as well, and many of these have been achieved in coordinated international efforts that link participants from many countries of the developed and developing world. Linkages with the international scientific community can be expected to have a higher payoff in Eastern Europe and the USSR than in the developing world because the initial investment in basic scientific knowledge is higher.

The Environment

Environmental degradation is one of the more ominous problems facing Eastern Europe and the USSR, and in this area the experience of LDCs offers an important cautionary note to temper the enthusiastic rush toward markets in the former socialist countries. In developing countries, a focus on growth without careful consideration of the long-term consequences has resulted in pollution, erosion, and consumption of nonrenewable resources. The classic problems of externalities have made markets myopic with regard to the needs of future generations and very hard on the environment. Given the inherited environmental degradation, the former socialist economies cannot afford leisurely lessons in environmental protection. Technical assistance will be necessary in order to find ways drastically to reduce industrial pollution, deforestation, and soil degradation.

The severity of the environmental degradation associated with market-oriented growth raises an important question: Should the wealthier countries subsidize poorer nations to encourage them to choose an environmentally more responsible path? This question arises more concretely when a wealthy neighbor provides tied assistance to a poorer neighbor, with the objective of reducing transboundary pollution. In both cases instruments must be created to transmit the incentive to cease pollution to the agents actually engaged in environmentally destructive behavior. This involves creation of instruments such as marketable pollution permits, but these will achieve the desired effect only if indirect effects on employment are included, as well.

Conclusions

The transition to postcollectivist agriculture presents unprecedented opportunities and dilemmas. The experience of developing countries has much relevance for the countries of Eastern Europe and the USSR, but unfortunately it offers no magic formulas or guaranteed solutions. The scope of change is greater than that attempted in the structural adjustment programs of the developing world, and, because of its comprehensiveness, the potential that the parts will fit together is greater. The dilemmas and pitfalls are correspondingly large. A central dilemma is the tension between commitment and flexibility. Economic agents must believe that the government will and will force others to play by the new rules. Yet the rules must occasionally be changed or adjusted as ignorance clears or circumstances adjust. The merger of flexibility with credibility is indeed an art.

In this process of artistic science, modern economic theory is of limited help. Rarely have economists encountered the kind of consciously undertaken, sweeping changes that Eastern European societies and the USSR have proposed including the creation of new legal, political, and social infrastructures. Western technical assistance with the support of international financial institutions can be effective only if professionals of the East and West work together since this is a process of joint learning, not a pure transfer of knowledge.

Implications of the Structural Adjustment Experience in the Developing World for Eastern Europe: Discussion

Gordon C. Rausser

The presentations in this session were far more interesting than the formal papers. I make this assessment in a world of limited information, as I have only just received Csáki's paper and have yet to see Braverman's. This condition leaves me with the freedom to pursue my own thoughts rather than evaluate two papers, one of which I can only imagine from the verbal presentation. While presenting my own thoughts, however, I will make some reference to the fine presentation of Csáki and the comments and observations of Braverman.

Communism has failed. In the aftermath of last year's extraordinary events, it is clear that the ideological appeal of communist political systems has been irrevocably damaged. Throughout much of Eastern Europe and the donor community, there is a clear vision of where each country wants to arrive; unfortunately, there are few clues about the path that should be traveled to get from here to there. Csáki informs us that the most important task is to develop a market-oriented and competitive agricultural structure. Yes, but how? To be sure, some individual policies that have formed the basis for successful market economies, if introduced with the wrong timing or in isolation from other reforms, can make an inefficient economy perform even worse.

For each of Csáki's five major issues, he outlines a number of policy alternatives. As with Csáki, Braverman's presentation largely focuses on the policy instrument space: the right setting of producer prices, consumer prices, pricing of credit, allocation and ownership of land, and so on. It is my view that prescription in this space, the selection of policy instruments, is misguided and is most likely to lead to the wrong path in getting from here to there. Instead, our prescription should focus on the underlying constitution that establishes the guidelines and mechanisms for economic, political, and civil freedoms. In this setting, we must be concerned, for example, with more than simply the rule of law, but the choice of law and the extent of liberty as well. This includes a selection from among the legal traditions that rule mankind: civil law, common law, Oriental law, Hindu law, Muslim law, and socialist law. In this choice, as in all constitutional economic selections, the political-economic landscape, the culture, and the customs of the country in question must be formally recognized.

Experience in the Developing World

The above observations are based on the empirical evidence that has emerged in developing countries. This evidence is drawn from developing countries which differ not only in the details of their economic policies but also in their underlying constitution and institutional framework, the extent of freedom and liberty, and their entire approach to growth and development. Serious inspection of this evidence reveals that (*a*) "getting the prices right" or "setting the property rights straight," or both, is not sufficient for an economy to reach its full potential; (*b*) bad governments and institutions have been a serious, if not the most serious, obstacle to economic development; and (*c*) all public sectors pursue a mix of predatory and productive activities—bad governments emphasizing the former and good governments finding a way of promoting the latter.

Available evidence reveals that the more centralized the system of economic decision mak-

Gordon C. Rausser is Robert Gordon Sproul Distinguished Professor, Department of Agricultural and Resource Economics, University of California, Berkeley.

Giannini Foundation Paper No. 954 (for identification purposes only).

ing, the more opportunities are presented to officials to behave in a predatory manner. The degree of centralization in economic decision making is one of the characteristics that distinguishes those countries that were successful in achieving desirable economic reforms from those who failed to do so during the 1980s. In Bolivia, for example, one of the least-developed and poorest countries in South America, a large informal sector existed, while state intervention and control was confined mainly to an obsolete formal sector. In Argentina and Brazil, computer-assisted bureaucratic administration and control were overlaid by large and pervasive systems of quasi-governmental production and resource allocation. These systems, in turn, created their own large and powerful constituencies. They also created enormous opportunities for corruption and graft. The general rule is: He who decides who gets subsidized can get very rich, especially in an economic system characterized by central administration and control.

The degree of centralization in Eastern European agricultural sectors concerns both Csáki and Braverman in terms of the ownership, operation, and distribution of land resources. Based on the experience in developing countries, some economists have identified equity of land distribution as an empirical characteristic useful in explaining economic performance across countries. Here, the Latin American economies and the Philippines—where land ownership is highly centralized in patterns inherited largely intact from colonial periods—may be contrasted with the model economies of East Asia, such as Taiwan and Korea, or even Japan. In Korea and Japan, land redistribution was instituted by the allied powers following World War II. Land ownership in Taiwan began to change when the Nationalists took over the island in the 1930s. But land distribution, itself, is hardly an explanation for the far superior, postwar economic performance of the East Asian economies.

Instead, the most intriguing aspect of land distribution is what is implied about the political influence of the land-owning, agricultural factions in each country. An alternative hypothesis is that, although land redistribution partially rearranged the old political-economic alignments in Korea and Japan, this was not sufficient to allow new export-oriented policies (e.g., competitive exchange rates and low tariffs) to be implemented without significant opposition from the domestic agricultural factions. In Taiwan, too, the postwar agricultural sector was closely aligned with the Nationalists and was clearly a faction to be reckoned with. Each of these countries instituted economic policies to compensate agricultural interests (via high-tariff and nontariff barriers) in return for the freedom to proceed with *export-oriented* policies in the balance of the economy. This policy mix has proved to be remarkably stable and survives largely intact to this day in each of those countries.

Although traditional or in-power factions may have a stake in opposing change, often there are no viable alternative factions within the political system. Peruvian Hernando de Soto details the enormous political and institutional hurdles that must be overcome by individuals and businesses when they are not a part of the dominant political-economic faction. His prescription is to mobilize alternative factions so that they can represent their own interests. However, this may not be feasible without political and institutional reforms to remove the barriers to such advocacy. Even in a democracy, alternative constituencies must be enlightened as to what various policy options would imply. They must also be given the means to voice their concerns and interests within the constitutional process. And there must be checks and balances that limit the ability of any single faction to gain and retain unchallenged political and economic control.

Available evidence suggests that, when domestic constituencies have emerged that favor and benefit from new policies, reforms have been sustained and credible. Occasionally, special inducements, e.g., export subsidies and export-processing zones, have succeeded in creating those new constituencies. Often the objective is not to achieve a trade-neutral regime but, instead, to bias the system in favor of exports, at least temporarily, in what might rightfully be called redistributive governmental policy making. This policy, in isolation, however, has not generally been successful. Once again, it is crucial that comprehensive economic reforms be designed covering the mix of policies across all sectors as well as fiscal, monetary, and exchange-rate policies. When accompanied by appropriate exchange-rate and macroeconomic policies, special inducements can assist in sustaining export-oriented policies in the initial stages introducing structural reform. Successful examples of this tactic in the 1980s include the Dominican Republic and Costa Rica.

It must be acknowledged that the best examples of successful economic developments in the 1980s were not nascent democracies but, rather, holdover authoritarian regimes. Chile,

Thailand, and Korea are the most often cited; examples from earlier decades might include Hong Kong, Taiwan, or Singapore. Yet, the overwhelming weight of empirical evidence in modern times suggests that the most open and democratic societies are the most successful economically and that free and decentralized markets are the most successful in producing sustained economic growth, a condition conducive to political liberty. Sustaining economic success in the long run, in fact, may require democracy. Certainly, there are no examples of modern industrial countries that have continued to achieve success in economic growth and development under authoritarian or totalitarian governments. Even in the short run, the civil, legal, and political institutions of democracy, in many cases, seem to be an important ingredient of success in the economic sphere.

Democratic systems sometimes produce extremely disappointing economic policies—hence the lure of authoritarianism. Likewise, there sometimes are significant instances of market failure that can be improved through nonmarket organizational structures, including governmental intervention and regulation (Csáki's reference to environmental protection). Depending on what one believes to be market failure, this reasoning, if taken to extremes, can imply central planning and economic control. Moreover, in many developing countries, as was the case recently in Poland, the pain of adjustment in attempts to move from "here" to "there" is often blamed on the new policies rather than on the failed policies of the past. If the distribution of political power leads to an unwinding of currently designed reforms, market expectations of failure will induce inflation, capital flight, hoarding, and so on. This has often led to reversals of experiments with decentralized economic decision-making reforms.

The irony is that dictatorship, far from being necessary for economic growth, may be its antithesis. In this instance, corrupt and inept regimes cannot be changed by the will of the citizenry. There is no better confirmation of this statement than the postwar experience of Eastern Europe under communistic dictatorship, or the postrevolutionary experience of Stalinist Russia. And it is also true that for every example of economic success among the authoritarian regimes of the third world there are several examples of failure. The distinctive feature of dictatorship is that, by its very nature, it is unaccountable to most citizens and their representatives. Although this may seem like an advantage when unpopular decisions must be taken that would be in the public interest, it also means that economic policies which hurt society generally but benefit a "crony elite" are immutable to change, at least through constitutional means.

In contrast, democratic pluralism can and does provide an important discipline on the performance of governments and officials. Democratic pluralism means a political and legal system that allows citizens to assemble and to speak out against and remove from office governments that do not serve their interests. Moreover, it means protecting their human and civil rights so that they can perform these responsibilities. Unless one is willing to believe that politicians and bureaucrats are inherently benevolent and wise, democracy is ultimately necessary for successful economic performance. In the final analysis, elections allow citizens (who may on occasion be confused about cause and effect) to replace inept and corrupt officials and governments that have pursued failed economic policies. An open polity may be the single most important underpinning for an open economy in the sense that diffusion of political power, ease of entry and representation in the political arena by alternative economic factions, the fair rule of law, and clear limitations on the powers of and access to governmental officials all facilitate the growth of decentralized and private markets. Productive economic reforms and capitalism flourish best in a climate of freedom and diffuse political power. In turn, diffuse political power is alive and well in a world of ample mobility and widely diversified asset portfolios.

Prescriptive Paradigm

To change the relative costs and benefits of adhering to old constitutions, institutions, and policies, it is generally necessary to form coalitions that stand to benefit from reform. In this context, what are the basic characteristics of a paradigm that allows meaningful prescriptions to be assessed? This paradigm must recognize that power is distributed among the various interest groups and that the maldistribution of power can blunt any and all reform efforts; it must recognize that governments can have some separate autonomy and can seek "leadership surplus"; it must provide an internally consistent framework which admits the possibility and necessity of accommodating various interests; it must conceptualize the bargains, pacts, compromises, and efforts that are undertaken to shape policies that

are acceptable, not only to those who have the greatest capacity to obstruct the policy but also to others who have stakes in the outcome; and finally, it must be the basis for an integrative framework that recognizes the joint determination of both predatory and productive governmental interventions.

Some of the above characteristics are self-explanatory, and some require elaboration. Leadership surplus is a crucial concept in this prescriptive paradigm and provides an alternative hypothesis to the theories advanced by Stigler, Becker, and others. In essence, leadership, much like institutions, can be induced by economic phenomena or external crises. What makes leadership for reform possible? Or equivalently, under what circumstances will individual agents and interest groups modify their rational self-interest and subject themselves to the "public interest?" Here, we can draw from other disciplines, particularly social psychology which has offered the hypothesis that interest groups are surprisingly willing to engage in obedience contrary to their own convictions when there is only a gradual escalation in actions they are asked to take. With each escalation, their previous action sets the norm for their current behavior. For those agents who have the power to obstruct reform, predatory policies can be offered as political compensation.

In the prescriptive paradigm, current policies are viewed as some rational outcome of the political-economic process—conditional, of course, on the constitutional and institutional structure. This political-economic process is one where the public sector plays a crucial role and in a fundamental sense must be part of the coalition that supports reform. In any organizational structure that might arise, the public sector is naturally exposed to attempts by various interest groups to exert their influence. In this framework, if all power does not reside with the leadership pursuing the public interests, organizational failures naturally arise. Accordingly, the prescriptive paradigm must balance market failures with organizational or collective action failures.

To minimize market and organizational failures, at the prescriptive core of the proposed paradigm is constitutional economics. The basic questions of constitutional economics are: Is the constitutional order of the country conducive to free inquiry and social experimentation, or is it fundamentally repressive? Does the constitutional order provide ease of entry into the economic system, the political system, an ease with which legal foundations of new institutions can be established? Does the constitutional order provide sufficient self-correcting mechanisms to limit excessive predatory governmental behavior? Does the constitutional order motivate agreement on basic values and processes for conflict resolution—a sense of civil order—to reduce the cost or risk of innovation?

Concluding Remarks

Appropriate answers to the core constitutional economic questions will allow a country to find a desirable path to get from "here" to "there." It will admit practical prescriptions for economic reform that take the political environment into account. In some cases, it will prove necessary to compensate interest groups with the power to impede reform. In other cases, an opening of the political system to the broader representation of alternative interest groups will prove to be the only means for sustaining effective economic policies.

Solutions at the constitutional core will allow the appropriate mix of both productive and predatory policies to emerge endogenously. The mix of policies must be comprehensive, covering not only policies for the agricultural sector but fiscal, monetary, exchange-rate, competitive, trade, privatization, as well as other policies. If the constitutional core is properly structured, we will not find privatization emerging without effective liberalization or the issue of ownership dominating an appropriate restructuring of incentives. Moreover, given the emergence of effective leadership pursuing the public interest, an appropriate response to the core questions can be expected to provide the foundation for endogenously determining the sequencing of reforms that will enhance credibility and sustain economic growth.

For the prescriptive space advocated here, there is much useful theory and empirical evidence. There are, of course, gaps; and there is much to be learned about the relationship between open, democratic societies and open, liberal economies. Furthermore, there is much to be learned about how democratic pluralism can provide an important discipline on the performance of governments and officials in setting economic policy as well as the role that democratic institutions play in diffusing political and economic power. As a result, for those of us who are interested in these issues, we are witnessing in Eastern Europe perhaps the greatest experiments

of this century on constitutional economic reform, institutional change, and the endogenous political-economic determination of public policy. In the final analysis, any prescriptions that we advocate as a profession, based on previous theories, empirical evidence, or new developments in economic thought, must heed the advice of the current IMF Director, Michel Camdessus, ". . . economic growth, in its broadest sense, is too rich in meaning, too complex, and too essential to mankind's future to be left only to economists."

Lessons Learned in Structural Adjustment Lending in the Developing World and Implications for Eastern Europe: Discussion

Robert Saint-Louis

Conditional program assistance, which has come to be designated as "structural adjustment" (SA), was and still is the order of the day in many countries in Africa and elsewhere (Tweeten, Mosley and Toye). Also, from both methodological and pragmatic viewpoints, the experience of several countries which perhaps, each in its own way, found themselves in the "obligation" of improving their efficiency through the removal of disincentives and economic distortions and by allowing markets to operate as freely as possible, is becoming increasingly recognized (Roberts; Asiedu-Saforo; Koester, Schafer, and Valdés; Jaeger and Humphreys).

The central questions raised in this session are (*a*) whether or not important lessons have been learned from those countries that have already sustained some of the pains of outward-driven and/or self-imposed SA, and (*b*) to what extent some of these lessons can be applied to emerging market economies of Eastern Europe.

This session was also to evaluate, I supposed, the specific needs of a few countries in Eastern Europe by way of structural adjustments for their agricultural sector.

First I will discuss very briefly three major points raised in Braverman's paper. Then I will also scatter here and there a few short comments on the general theme of this session. Emphasis will be put on stressing the fact that extremely important differences between the two speakers' views on the macroeconomic situations involved lead them to emphasize the prominence which must be given both to the original content and the specific sequencing of the rehabilitation treatments in SA.

The main points raised by Braverman are (*a*) the nexuses (which are still far from being perfectly clear) between SA, policy reforms in agriculture, and the rest of the national economy, and overall societal and political changes in the countries having undergone SA or presently undergoing SA, as well as in those countries which are in the post-SA stage, by World Bank standards, (*b*) the specificity of economic adjustments needed for the agricultural sector and the rest of the economy in Eastern Europe, and (*c*) the lessons to be learned from the Bank's experience in dealing with SA treatments in the developing world.

First, concerning the nexus between SA and their enshrining policy reforms in rapidly changing societies, Braverman takes a rather humble, yet ambitious, look at the World Bank's experience in the Third World. He describes it almost as a set of enterprises which were as much about part of a larger process of changing the third world as a constant attempt to understand it before coping with specific medium and long-term investment decisions.

Also Braverman reminds us that overall societal and political changes in the Third World must be perceived as being time-specific and location-specific sets of *ceteris paribus*, and the variability of each set will continue to make all economists uncomfortable including those making analyses for the World Bank and the IMF, I presume. Specific national situations in Africa, for instance, are on that regard totally different from those in Eastern Europe at the present time. For the 1980s in the Third World, Hettne's opinion that the manifestation of crisis and of economics of survival were dramatic but to a large extent "definable" despite the fact that different sets of specific problems overlapped and were so pervasive, seems to gain Braverman's agreement.

But how right is it to argue that the Eastern Europe crisis still defies definition? Braverman raises the question in his own way by emphasizing that it has already manifested itself in so

Robert Saint-Louis is a professor of agricultural economics, Université Laval, Quebec City, Canada.

many fields at the same time: trade (including agriculture), industrial development, employment, integration, cultural values and life-styles, etc.

Thus, how should one interpret precisely the host of reasons why, for instance, the Supreme Soviet postponed, in June 1990, a crucial decision to triple the price of bread (from 20 to about 60 kopecks)? And is there any economist, either in the USSR or elsewhere, who has yet a precise idea as to what total quantity supplied and total quantity demanded at the contemplated price will be after this decision is made? Braverman does indeed raise a set of troubling questions when one thinks of such nonmarginal policy changes.

Coming now to the second point, where specific characteristics of economic adjustments in Eastern Europe are examined, Braverman suggests that we all must be very humble economists because we basically lack both theories and practice as to how one country ought to go from control planning to a market-oriented economy.

In a sense, it is not at all surprising that in the USSR, for instance, most republics find it rational, at least in the short run and from a regional point of view, to charge world market prices for their "exports" (even for agricultural products which are presently subjected to severe international price distortions) and pay for their "imports" from other republics the existing Soviet prices.

Turning now to lessons learned, Braverman states that attention needs to focus on issues having to do with (*a*) external incentives, (*b*) issues of institutional reforms, and (*c*) transfer of technology in favor of the agricultural sector.

The main thrust of his argument seems to be that international prices cannot and should not be imposed upon countries undergoing SA, without full and strong support from various segments of the population in any given country. International prices, however, can be used as benchmarks for setting up internal prices by rightfully taking into account the true trade-offs between issues of real levels of income, distribution of revenues, etc.

For the sake of brevity, I will terminate this discussion by pointing out that I fully agree with Braverman's opinion that institutional reforms must give a pivotal role and must put an important weight on "accountability," perhaps as the dominant variable in determining whether or not each institution and/or parastatal serves a useful purpose in any emerging market economy and perhaps even more so for those supplying agricultural credit to peasant economies.

In conclusion, the two papers illustrate the critical process that will lead both the third world and Eastern Europe to progress through SA. And perhaps the two speakers will appreciate being reminded that their own thinking seems to be best summarized by the following quote: "Profit seeking may get the economy close to its goals but even more specific instruments such as market prices serving as weights which set the social ordering of goods and services may prove more successful" (Aston).

Arresting Renewable Resource Degradation in the Third World
(Duane Chapman, Cornell University, presiding)

Resource Degradation in Africa and Latin America: Population Pressure, Policies, and Property Arrangements

Douglas Southgate, John Sanders, and Simeon Ehui

Degradation of renewable natural resources in the developing world is taking a serious toll. Deforestation threatens biological diversity and could alter global climate. Soil erosion reduces the capacity of many countries to satisfy expanding demands for agricultural commodities. It also jeopardizes the benefits of water resource development. Deposition of eroded soil in reservoirs, for example, diminishes hydroeletricity production and reduces irrigation water supplies.

In spite of widespread concern over these environmental problems, analysis of resource degradation in poor countries is rudimentary. Simple Malthusian explanations, in particular, are widely circulated. Other than the general recommendation that human fertility be controlled, these explanations offer little guidance for the design of conservation strategies.

In this paper, a broader perspective is taken on the causes of depletive human interaction with the natural environment in Africa and Latin America. We find that the impacts of rural population growth and increased demand for agricultural commodities depend greatly on government policy and property arrangements. Examination of environmental problems in the Sahel, humid tropical Africa, and Amazonia reveals that the causes of resource degradation are similar in each of these regions.

The Causes of Environmental Degradation

As every student of economics knows, strong assumptions underpin the writings of Malthus and his contemporaries. One is that population growth is reflexive, accelerating whenever living standards rise above subsistence levels. In addition, the idea that agricultural technology never changes was widely shared two centuries ago. Together, these assumptions imply that shifts in the agricultural frontier are the only possible response to market or demographic "shocks."

Investigation of social realities in Africa and Latin America reveals that the behavior of rural people is much more complex than classical economists believed. Demographers find that increased rural population density induces various reactions. Fertility rates tend to fall as incomes rise. Relocation to urban areas or the agricultural frontier is also a possibility (Bilsborrow).

Similarly, the assumption that technology for crop and livestock production never changes has been rejected. In various ways, agricultural land can be used more intensively as rural populations rise or as demand for agricultural commodities increases (Boserup; Pingali, Bigot, and Binswanger). Intensification often begins with a decline in fallowing cycles, which usually diminishes soil quality. However, other options (e.g., increased employment of nonland inputs and a switch to new crops), which can enhance output without accelerating resource depletion, are also available.

The central point of this paper is that government policy and property arrangements have much to do with the countryside's reaction to market and demographic shocks. In many parts of the developing world, deforestation is a prerequisite for formal or informal land tenure and conversion of forests into cropland and pasture is directly or indirectly subsidized. In addition, research and extension needed for sustainable land intensification are inadequate in many countries. Under these circumstances, population growth and increased demand for agricultural commodities usually induce excessive migration to hinterlands as well as depletive forms of extensive settlement.

Resource degradation is acute in the three parts

Douglas Southgate is an associate professor, Department of Agricultural Economics, Ohio State University; John Sanders is a professor, Department of Agricultural Economics, Purdue University; Simeon Ehui is an agricultural economist, International Livestock Center for Africa, Addis Ababa, Ethiopia.

of the world that are the geographic focus of this paper. The Sahel, humid tropical Africa, and the Amazon Basin each feature unique natural and cultural conditions. Neverthless, the causes of depletive human interaction with the environment are similar. Population growth is a primary catalyst for expansion of agriculture's extensive margin as well as the abandonment of fallowing and other practices that maintain soil fertility. Inadequate investment in research and extension, governmental interventions that keep food prices artificially low, and other policies hindering agricultural development also accelerate the depletion of renewable natural resources. In addition, formal and informal tenurial regimes often discourage the adoption of conservation measures, encourage excessive land clearing, or both.

The Sahel: The Challenge of Sustainable Development of Semiarid Lands

World attention has focused on the region lying between the Sahara Desert and the coastal nations of West Africa since 1968, when an extended period of drought began. A classic Malthusian disaster has seemed to unfold in the Sahel. Populations have grown and soils with limited potential for agriculture have been brought into production. Resulting land degradation may have exacerbated harsh climatic conditions. Always marginal, living standards have failed to improve (Landell-Mills, Agarwala, and Please).

Social conditions and the physical landscape are not uniformly bleak in the Sahel. Almost one-fourth of the region's crop land lies in the Sudano-Guinean climatic zone, where rainfall exceeds 800 millimeters nine out of every ten years (Gorse and Steeds). Where soils are good, French development efforts involving agricultural research and extension, use of pesticides and fertilizers, and cotton price guarantees have yielded positive results. In southwestern Burkina Faso, for example, cotton and cereal yields have risen dramatically during the last two decades.

Demands on renewable natural resources are growing in the Sudano-Guinean zone. As control of river blindness has improved, for example, farmers have immigrated from drier areas. In addition, research is needed to improve conservation of soil organic material as well as the efficiency with which chemical inputs are used. However, sustainable development in the zone serves as a model for what can be accomplished elsewhere.

The challenge of sustainable development is considerably more daunting in drier areas farther to the north. Slightly more than half the crop land in the Sahel lies in the Sahelo-Sudanian and Sudanian climatic zones (Gorse and Steeds). In the former zone, where there is a 90% chance that total precipitation will be between 350 millimeters and 600 millimeters in any given year, soil fertility is low and it is difficult to retain water around plant roots. Also, cutting trees to plant millet accelerates wind erosion and aggravates sand blasting problems. Dregne recommends that forestry and grazing be the primary activities in the Sahelo-Sudanian zone and similar areas.

Nowhere in the Sahel is resource degradation more acute than in the Sudanian climatic zone, where rainfall is between 600 millimeters and 800 millimeters nine out of every ten years. Rural population densities are high. Soil fertility is declining because land is being given less time to recover between cropping cycles. As a result, millet (which grows better in poor soils) is being planted in place of sorghum, marginal grazing areas are being converted to crop land, and emigration is taking place. In addition, fuel wood is becoming scarce, which means that women are obliged to go great distances to gather it.

Sustainable development is possible in the Sahelo-Sudanian and Sudanian climatic zones. Unfortunately, resource conservation and income growth are difficult to achieve under current policies. The region's governments maintain low food prices for the benefit of urban consumers and ignore marketing bottlenecks responsible for price instability, generally, and the collapse of farmgate prices at harvest time, specifically. In addition, agricultural research and extension are not strong. Incentives to adopt high-yield, sustainable crop production systems, then, are weak. Farmers opt instead for extensive production, generally on fragile lands.

Finally, some property arrangements discourage environmental conservation. Under communal tenure regimes that prevail in the Sahel, a family wishing to plant crops is entitled to temporary use of a parcel. However, planting trees or even perennial crops is often regarded as an attempt to assert permanent individual rights in communal land. Under these circumstances, an institutional constraint on reforestation exists.

Humid Tropical Africa: Agricultural Expansion and Timber Extraction

Nearly one-fifth of the world's closed tropical forests are found in a belt that runs along the Gulf of Guinea and extends eastward to Lake Victoria. Changes in tree cover are modest in much of central Africa. Farther west, however, deforestation is very high, approaching 5% a year in the Ivory Coast and Nigeria (FAO).

All major catalysts for agricultural growth are at work in humid tropical Africa. The region's rural population is increasing, as is urban demand for food and fiber. Global market conditions are also appropriate for the establishment or expansion of export crop plantations.

As in the Sahel, the sequence of adjustments caused by population growth and increased demand for agricultural commodities often begins in humid tropical Africa with diminished fallowing. Land formerly lay idle for two decades between cropping cycles. In recent times, fallow periods have contracted to a few years. Continuous agricultural production is now the norm in some places, resulting in very low yields.

In most of the region, there are natural resource constraints on land intensification. Because soils tend to be thin and not very fertile, diminished fallow periods cause yields to fall off substantially. Applying fertilizers often compensates for only part of this decline (Lal). As land deteriorates, farmers colonize marginal hinterlands or migrate to urban areas.

A major threat to the forests of humid tropical Africa is the extraction of commercial timber. In and of itself, logging alters the natural environment. For example, using heavy equipment to remove commercial timber results in secondary losses. Logging is also a catalyst for agricultural land clearing. Roads originally constructed to bring in equipment and to haul out timber enhance access to tree-covered hinterlands. Furthermore, a logging site is relatively easy to clear for crop and livestock production. Because of these two positive impacts on rents captured by settlers, timber extraction accelerates colonization.

The strength of population growth, logging, and related catalysts for resource degradation in the countryside is enhanced by government policies. As in southeastern Asia, the terms of timber concessions generally do not encourage sustainable, intensive management of small forested tracts (Gillis). Similar to what occurs in the Sahel, extensive crop production on fragile lands, rather than sustainable land intensification, is the norm because research and extension are weak and commodity prices are low and controlled.

Governments also accelerate resource degradation by attempting to supplant local tenure regimes. Ignoring the distinction between common property (*res communis*) and open access (*res nullius*), they have failed to offer legal mechanisms for protecting communal land rights. Instead, attempts are often made to convert common properties into government lands and private properties even though the public sector's capacity to manage "its" resources and the legal infrastructure needed to enforce private tenure are both poorly developed. Weakening traditional property arrangements without providing a viable institutional alternative diminishes the incentives for forest dwellers to conserve natural resources (Bromley and Cernea).

The Amazon Basin: An Ideal Policy Environment for Deforestation

Appeals to save tropical forests take on special urgency when South America's Amazon Basin seems to be threatened. Satellite images from 1987, when the dry season was unusually pronounced, showed that agricultural land clearing and reclearing were widespread in Brazil. Fearing that the "lungs of the earth" were going up in smoke along with many plant and animal species, environmentalists, politicians, and rock stars called for quick action.

The true nature of environmental problems in Amazonia is not well understood by many expressing concern for the region. For one thing, the region's sheer size tends to be ignored. Since the nations of the European Economic Community could fit in Brazil's Norte Region (comprising six northern and northwestern states and territories), it should come as no surprise that vast stretches of forest remain intact there. Agricultural land clearing is significant primarily along roads penetrating the basin's margins. For example, one-fourth of Rondonia state, in the southern reaches of the Norte Region, has been settled by farmers (Mahar). Deforestation is also extensive in western Amazonia, just downhill from densely populated Andean highlands.

Just as it is erroneous to think that all land in the Amazon Basin will soon be cleared, explaining deforestation in the region in simple Malthusian terms is a mistake. The Brazilian government estimates that 8.6 million people (6%

of the country's population) live in the Norte Region. Of those 8.6 million, 4.7 million reside in cities and towns. Both intraregional migration and immigration from other parts of Brazil are directed primarily toward Manaus (which is a duty-free zone with substantial manufacturing), Belem, and other urban centers. The region's rural population rose at a 2.7% annual rate between 1987 and 1990. During the same period, its urban population grew 3.8% per annum.

A causal analysis of deforestation in the Amazon Basin, then, cannot concentrate on population growth. In addition, diminished fallowing on the part of an indigenous population of farmers is not a predominant form of land degradation in the region, as it is elsewhere in the developing world. To understand environmental change in Amazonia, one must examine how government policies and property arrangements influence the behavior of immigrants.

To date, economists have concentrated on government policies' contribution to deforestation. Subsidies for agricultural land clearing have been scrutinized. As Mahar points out, cattle ranchers converting forests into pasture used to receive cheap credit and other financial assistance. In addition, making it easy for all Brazilian farmers to avoid taxes has encouraged smallholders from the southern part of the country to sell off their land and move to the frontier (Binswanger).

Part of the blame for excessive encroachment on tree-covered hinterlands must also be assigned to low investment in the scientific base underpinning agriculture in the Amazon Basin. In Brazil, research and extension have been strong in other regions outside Amazonia. The same cannot be said of neighboring countries. As a result, crop and livestock yields in Amazonia are low, which means that growing demands for agricultural commodities tend to be satisfied through shifts in agriculture's extensive margin.

Furthermore, settlement of Amazonia causes excessive damage to the environment because the information base needed for rational colonization has not yet been developed. Resource inventories are incomplete and, although there has been successful experimentation with rice production on hydromorphic soils and with perennial crops, research and extension services available to farmers in the Amazon Basin are generally meager.

Along with subsidies and inadequate research and extension, inappropriate tenurial arrangements contribute to excessive land clearing throughout the Amazon Basin. As in humid tropical Africa, a classic open access problem arises wherever public sector claims on resources outstrip the government's capacity to manage its properties. "Illegal" settlement of the region's "paper parks" is a prime example.

Recognizing the consequences of an institutional vacuum, national governments grant settlers property rights. However, deforestation is usually a prerequisite for tenure in a frontier parcel. This arrangement encourages degradation of existing farm land as well as excessive encroachment on forests (Southgate). Even though they sometimes resist, indigenous groups and other long-term inhabitants of Amazonia, who long ago developed viable resource management regimes, have had to accommodate themselves to the outside world's wasteful property arrangements.

Conclusions

Population growth explains a large part of depletive human interaction with the natural environment in the developing world. To appreciate the importance of demographic pressure, one only needs to travel through Haiti and parts of Central America, where burgeoning populations are picking the countryside clean.

Accepting a simple Malthusian analysis of resource degradation, however, does not leave much room for optimism. Poor countries' populations are overwhelmingly young. With numbers of women capable of bearing children expected to rise for many more years, continued population growth is inevitable, even with the decline in fertility rates currently taking place in parts of Latin America and Africa.

It is fortunate, then, that simple Malthusian explanations of resource degradation do not entirely suffice. As pointed out in this paper, government policies and property arrangements have much to do with the use and management of natural resources in the developing world. Intervention in agricultural markets is widespread and research and extension are weak throughout Africa and Latin America. As a result, extensive agricultural production on fragile hinterlands, instead of sustainable land intensification, is the principal response to demographic and market shocks. In addition, existing tenure regimes often discourage tree planting and encourage deforestation.

Our analysis suggests that, before the long-term benefits of fertility control can be realized, policies and property arrangements must be

changed in order to foster environmental conservation. The difficulty of reform should not be underestimated. Powerful interests support many of the policies that discourage conservation. In the Sahel, for example, urban dwellers benefit from artificially low food prices which diminish the profitability of local cereal production and discourage the efficient management of environmental and other inputs to agriculture.

Effective reform is also a challenge because piecemeal changes in policy and property arrangements can be ineffective or even counterproductive. For example, if food and timber markets are deregulated but tenurial disincentives for resource conservation remain in place and no investment in research and extension is made, then wasteful exploitation of the countryside is likely to worsen. The chances for environmental conservation are significantly better when all policies and tenurial arrangements are reformed simultaneously.

As indicated in this paper, resource degradation is caused by similar factors in the Sahel, humid tropical Africa, and the Amazon Basin. Accordingly, many countries face the task of developing an integrated conservation strategy, one involving population control in the long term as well as policy reform and the development of suitable property arrangements in the near future.

Resource Policy Reform in the Context of Population Pressure: The Philippines and Nepal

Wilfrido Cruz and Christopher Gibbs

The degradation of renewable resources in the developing world now threatens not only the economic prospects of future generations but the livelihoods of current users as well. For example, in many countries overcutting has so depleted timber stocks that the traditional contribution of the forestry sector to income and employment is starting to decline. Shifting cultivation in marginal lands leads to soil erosion and declining productivity. Watershed deforestation, from both logging and upland farming, has reduced the downstream irrigation and energy-generation potentials of water resources. While price and tax reforms can be critical ingredients in reducing the damage in commercial sectors, where large communities of individual resource users exploit common property or open-access resources, institutional changes are also required.

This paper presents a framework to incorporate the role of population growth and institutions in understanding the pressures for resource overexploitation. The problem of resource degradation is elaborated in the context of two Asian countries—the Philippines and Nepal—where population pressure on forestry and agricultural resources is substantial. The discussion shows that there has been a shift from a pattern of agricultural intensification and development to poverty and resource degradation. The last section suggests that the assessment of resource degradation must recognize this pattern and that policy reform must focus on the problem of population growth and inappropriate institutional structures.

Wilfrido Cruz is an associate, World Resources Institute, Washington D.C., and Christopher Gibbs is a program officer, Aga Khan Foundation in Geneva, Switzerland.

The Role of Population and Institutions in Resource Degradation

The role of government policy in altering the structure of incentives to reduce resource degradation can be substantial. Such reforms focus on tax or pricing policies where market institutions are fairly well developed and where resources are commercially exploited. However, in many rural areas of the developing world, the lack of well-defined property and market institutions and the presence of substantial population pressure on resources require that policy reform should also address changes in rules governing access to and use of natural resources.

The institutional problem is most apparent in forest lands. While most governments consider forest lands as part of the public domain to be kept under forest cover, their limited enforcement capabilities make these *de facto* open access resources. Such forest lands have therefore been rapidly converted to nonsustainable agricultural uses, causing severe erosion impacts. On-site production potential is reduced, and downstream siltation of waterways and agricultural lands is increased. Because of the environmental externalities associated with upland farming, simple privatization solutions are not efficient. Also, because of population pressure problems, exclusion of the neediest from large areas of the public domain is neither equitable nor feasible.

The need to recognize the role of migration and population growth in this context is especially important in South and Southeast Asia, where conditions of population pressure and increasingly tight land constraints prevail. Agricultural assessments show that Asian countries have higher population densities (FAO 1984)

compared with other parts of the world where economic policies, such as tax breaks for forest land clearing, may be the more important factor in resource overexploitation.

The Philippines: Economic Stagnation and Resource Degradation

In the Philippines, the pattern of population pressure on marginal resources include unchecked population growth, declining absorption of labor in both industry and lowland agriculture, and widespread poverty. With an area of only about 30 million hectares, the Philippines' population is about 62 million, with a growth rate of 2.4% (World Bank 1989b). The economy has had increasing difficulty in absorbing population growth, so unemployment and poverty are widespread.

In agriculture, expansion occurred in the accessible lowlands, first with rainfed cultivation and farmer-developed irrigation up to the early 1960s, followed by public investment in irrigation systems. Public irrigation development coincided in part with the arrival of green revolution technology in the mid-1960s. When the area that could be easily converted was exhausted, attention turned to dispersing green revolution technology more widely and to improving water management. However, the limits of both lowland expansion and intensification have now been reached, and farming has been moving to upland areas, resulting in deforestation. Forests now cover only about one-fifth of total land area versus an administrative target of 40%. Extensive agriculture and grasslands cover 40% of land area (World Bank 1989b). Actual cover differs from the jurisdictional classification which places about half of total land area under one government department.

Both upland farming and commercial logging are involved in the conversion of forest lands to extensive cultivation. Undervaluation of timber and rent seeking promote logging; in turn, the expansion of logging concessions encourages migration and shifting cultivation. The charge for timber is about $1.50 per cubic meter when international log prices are in excess of $200 per cubic meter. Thus, rents were about $60–$140 per cubic meter for 1987 (De los Angeles and Lasmarias). Surpluses motivate the continuing demand for logging concessions, although forest area has already declined and is now concentrated in inaccessible locations. Current area under concessions (or Timber License Agreements) has declined since 1970 and has been claimed as part of the success of reforms. However, as a proportion of actual forest cover, logging concessions have increased from 42% in 1970 to 125% in 1987 (based on forest inventories and timber license data of DENR 1988).

The expansion of logging promotes upland farming by reducing the cost of migration and settlement. Two factors normally discourage the colonization of forest lands by upland farmers: their relative inaccessibility and the difficulty of land clearing. Land clearing may require as much as 60% of the total labor associated with upland production. While some studies assert that upland farming is the main cause of deforestation (FAO 1981), the link with logging is important because it reduces the two constraints mentioned above: (*a*) logging roads make forest lands accessible, and (*b*) logging itself reduces the work required to clear the forest.

Once roads are built, most forest lands become effectively open access because neither the timber concessionaires nor the government have the resources to police these lands. The result has been high migration and population growth rates in forest lands. The latest official estimate of detected squatters in the forest zone was about 1 million in 1986 (DENR 1986), when total population was 56 million. This grossly underestimates upland population, implying that only about 2% of the population inhabit more than half of the country's 30 million hectares. In fact, it has been shown with census data that in 1987 close to 18 million, or 30% of the Philippine population, are in the uplands, with 8.5 million occupying forest lands (Cruz, Zosa-Feranil, and Goce; World Bank 1989b).

Aggregate Resource Scarcity and Patterns of Degradation in Nepal

Nepal is extremely poor, with a GDP of $180 per capita in 1988. Only ten countries have a substantially lower per capita gross domestic product (World Bank 1989a). Between 40% and 60% of the population live at levels below the minimum food threshold. Population growth critically affects Nepal's development prospects. Ninety percent of Nepal's workforce are primarily engaged in agriculture, and agricultural land is already fragmented into uneconomic parcels and overused. Thus, the problem

of poverty is one of an aggregate shortage of resources rather than their redistribution.

Current population is about 19 million, with a land area of 13.7 million hectares. The annual growth rate increased from 1.6% in the 1950s to 2.7% in the 1980s. Public efforts to expand agricultural production initially focused on about 1.8 million hectares potentially irrigable with gravity systems, almost 75% of which are in the Terai, Nepal's lowlands. However, constraints to further irrigation development are already substantial, especially in the hills, where most new development will require suitable power to raise water to elevated terraces (World Bank 1990). Water management performance has also been very poor. Less than 30% of the command area actually gets water in the summer and winter, limiting the application of green revolution technology. Thus, between the mid-1970s and the late 1980s, agriculture grew at only 2.4% per year versus the 2.7% population growth rate (World Bank 1990).

Nepal's forests were nationalized in 1957, upsetting centuries of tradition of local control of forest use and shifting the locus of control from the village to the center (Wallace). However, while government assumed legal ownership of forests, it was unable to manage them effectively. Thus, forests became *de facto* open-access resources capable of being privatized if they were cleared. There have been efforts made recently to return the forests to local control, but significant damage has already been done. Population growth, combined with open access, reduced area and quality of the forest and pasture available per household and per livestock unit. Inadequate fodder reduced manure production and application to crops, contributing to stagnating yields. Existing terraces were overworked, and agriculture shifted to more marginal lands in the hills, including areas too steep to support farming without being destabilized.

The result has been significant seasonal and permanent migration to the Kathmandu valley and the Terai. The 1981 census showed that 61% of migrants originated from the hills, and 75% had the Terai as their destination (CBS). Exacerbated by immigration from India, the population of the lowland Terai, originally the most sparsely populated region in the country, grew to 42% of total population, equal to the hills' population (World Bank 1989a).

The Terai represented Nepal's outlet for the overpopulated uplands, but the pace and mode of development mean that the sustainable potential of the Terai is rapidly being used up; forests, soil, and water resources are being depleted or degraded. More than half of holdings are now less than one hectare in size, and 45% are less than half a hectare (IDS). In the hills, 73% of holdings are less than a hectare, with 54% less than half a hectare in size. Nepal's very small farms cannot provide even a poverty line income for the majority of rural families, even if they were to employ state-of-the-art technology. In the absence of significant growth in industrial and service sector employment, most Nepalese will continue to live in poverty.

A Framework for Assessment and Policy

Boserup originally proposed the role of population growth as the stimulus for technical change in agricultural development. Interpreting population growth as the key factor behind long-term changes in relative factor scarcities relates the Boserup hypothesis to models of induced technological innovation (Hayami and Ruttan). According to the induced innovation framework, declining land-labor ratios determine the path of technical change, leading to the mix of technology and new inputs associated with the "green revolution."

In Philippine agriculture, output expanded initially through increases in cultivated area up to the early 1960s. When lowlands that could be easily converted into agriculture were exhausted in the mid-1960s, output expanded through yield increases associated with the green revolution. In contrast, in Nepal the demand to expand agriculture came from the hills. The movement into Nepal's lowlands is relatively recent, following the large-scale eradication of malaria in the 1950s and 1960s and the clearing of much of the Terai forest. Because agricultural research on improving productivity in the hills has produced few results, environmental constraints limited the adoption of high-yielding varieties. Thus, attempts to introduce green revolution technology and to develop irrigation have been largely confined to the Terai.

With population growth and limited employment in lowland agriculture and in industry, the development pattern has gone beyond the green revolution framework. In the Philippines, population pressure has shifted to marginal resources, to forests and uplands for alternative livelihoods. Economic stagnation in the early 1980s exacerbated this process and promoted migration from the lowlands to forest lands. In

Nepal, the upland population continues to expand very rapidly and cannot be absorbed by agriculture in the degraded hills. The impact, therefore, of population on resources has been to force the cultivation of increasingly marginal lands in the hills and to clear and colonize the Terai very rapidly, eliminating much of the Terai forest in the process. For both countries, the result has been continuing poverty for the populations of both the source and destination areas. To comprehend this pattern of limited agricultural development linked to poverty and resource degradation, the problem of population pressure and inappropriate institutions must be explicitly incorporated in the assessment framework.

The framework for policy reform follows this assessment. First, a conventional economic reform effort should remove price and tax current policy biases that lead to overexploitation and inefficient use of resources. Examples include timber underpricing (Repetto and Gillis, World Bank 1989b), and implicit subsidies for extensive or inefficient use of land and water resources (Binswanger, Repetto).

Beyond conventional economic reform, institutional change needs to be considered. Resource management agencies will have to recognize that, given the magnitude of the resource degradation problem, central administration is not appropriate. Management efforts will have to be supported by collective action from communities of resource users. For example, legislation in 1977 officially put much of the control of Nepal's forests under the village panchayats, the local political leaders. But these leaders were not democratically elected, did not represent individual villages, and did not correspond to the user groups who had previously managed the forests as common property. More recently the government has recognized the need for effective local management and is attempting to transfer forest management to direct user groups.

In the Philippines, the government has not made the necessary transition from a regulation- and enforcement-oriented approach to one that focuses on establishing tenure and providing extension support. A social forestry program initiated in the early 1980s allocated long-term use-rights to upland farmers, but coverage is limited to a small fraction of public lands that can sustain agriculture. A more promising effort to change the open-access situation in some areas has been to call for the recognition of ancestral rights for an estimated 6 million indigenous peoples in the uplands (Lynch and Talbott). However, in spite of support from many non-governmental organizations, the bill that would accomplish this is not progressing in the legislature.

Finally, the economic development strategy itself will have to incorporate resource management objectives. Direct focus on reducing population growth is, at best, a long-term proposition. Thus, in the near-term, general economic development strategies will have to carry the burden of reducing population pressure and resource depletion. This will mean added emphasis on employment generation versus industrial policies that promote capital and intermediate input use. In addition, the traditional view of extracting resources to finance development must be supplanted by the recognition that disinvestment in natural capital, unless accompanied by productive investment elsewhere, reduces a country's capacity for sustainable growth.

Natural Resource Management in the Third World: A Policy and Research Agenda

Jeremy J. Warford and Zeinab Partow

That proper stewardship of natural resources is of central importance to agricultural and economic development has become indisputable. This is especially true for developing countries where natural resource depletion is of immediate economic and social consequence. Poor countries are typically dependent on agrarian and pastoral activities and are thus often most vulnerable to the effects of environmental degradation. This vulnerability results in part from shortages of human and financial capital that severely limit countries' abilities to turn to other economic activities when the resource base can no longer sustain them.

In many developing countries, the combination of poverty, unequal distribution of land and other resources, and population growth is creating incentives for people to overexploit existing resources in order to survive. Exacerbating this is the fact that economic systems do not always contain the automatic self-regulating mechanisms for ensuring the perpetual environmental sustainability of current economic development paths. Under such conditions, it is no longer possible to address systemic problems through piecemeal actions.

Although the dependence of sustainable economic development on sound environmental management is increasingly recognized, to date, economists' attention to the macroeconomic implications of environmental matters has been somewhat fragmentary. The traditional approach to environmental management has been to invest in discrete projects with environmental objectives or to ensure that project components contain elements to mitigate adverse environmental impacts. Although this emphasis on individual projects is important and will undoubtedly continue, it is clearly inadequate alone and should be supplemented by a strategy that integrates environmental and natural resource management directly into economic and social policy. A trend along these lines can already be observed in the recent evolution of policies in development institutions, notably those of the World Bank.

In attempting this integration of environmental issues into the core of economic policy making, a number of central issues for further work arise. This paper will outline some of these issues in an effort to present a series of promising research avenues for the future.

The Valuation of Natural Resources and Cost-Benefit Analysis

Conventional economics has undoubtedly made a significant contribution to the understanding of natural resource issues, yet it is often unable to address a host of emerging concerns. A major limitation of conventional approaches to natural resource economics is their concern with only those resources which directly provide economically valuable productive services, to the exclusion of environmental services such as waste absorption and ecological and life-support mechansims.

In response, alternative views have emerged that see resource depletion and waste generation by the economic system as integral to the whole rather than relegated to the margins under the umbrella term "externalities." By demonstrating the physical dependence of economic activity on the sustainability of crucial natural-resource systems and ecological functions, alternative views seek to highlight the economic costs resulting from the failure to preserve sustainability and environmental quality.

Both authors are staff members of the Environment Department, World Bank.

The views and interpretations in this article are those of the authors and do not necessarily represent the views and policies of the World Bank or of its executive directors or the countries they represent.

The authors wish to acknowledge the comments and contributions to this paper made by colleagues in the Environment Department and in other parts of the World Bank.

Nevertheless, a bias against sound environmental management has been encouraged by the difficulty of assessing the monetary values of environmental goods and services. Although the contribution of conventional economics to these challenges has been important in promoting the use of a systematic means of addressing resource allocation decisions, the available analytical means have not been very effective in addressing some of the more intangible services provided by the environment, or in handling specific problems in real-world cost-benefit studies.

The desire to assign monetary values to environmental consequences of project and policies has so far resulted in either trivial exercises in which easily identifiable monetary values are assigned to cost or benefit streams or in the inability to establish adequate criteria for valuation—as has been the case in the failure to place values upon the welfare of future generations or on the extinction of species. The challenge which faces economists is to devise a more comprehensive approach to cost-benefit analysis in which rigorous attention is paid to the nonmonetary consequences of investments.

Although there is a growing recognition that efforts in these areas are important and need to be expanded, cost-benefit analysis and valuation of resources are relatively well-trodden fields with as yet unresolved questions that do not promise substantial advances in knowledge in the near future. More significant improvements in environmental management are likely to result from efforts to integrate environmental concerns into macroeconomic and other government policies.

Macroeconomic Policy

Large-scale development projects are typically subjected to cost-benefit analysis and environmental assessment by concerned public agencies. In contrast, the impacts of the vast number of small-scale individual resource users, each of whom has only a small effect on the environment, can rarely be subjected to analysis at the individual level. The combined consequences of such activities have to be managed at the broader policy level. The individual resource user can be reached effectively only by the use of macrolevel policies and incentive systems such as price policies, subsidies or taxes, or land reform.

No single policy or set of policies is correct or always applicable. Some policies require direct intervention to implement, while others rely on market signals. Indeed, the pendulum, which over the past decades has swung from a position favoring government intervention to one supporting complete reliance on free-market mechanisms, appears now to be in mid-path, with research focusing on providing a balanced prescription between the two extremes. The centrality of macroeconomic policy to environmental management has nevertheless remained clear.

In altering the level or rate of change of economic activity, macroeconomic policy inevitably impacts upon the environment, although often in ways that are unanticipated. Many developing countries, for example, maintain overvalued exchange protection to home market producers. The discrimination against exports in an economy based on agriculture, for example, can be expected to influence the types of crops that are grown. The implications for sustainability may be beneficial or adverse, but they have traditionally not been considered in establishing macroeconomic policies.

Existing studies on the relationship between government policies and environmental management only serve to underline the importance of the linkages. Binswanger and Mahar, in separate studies, describe how massive private investment in the expansion of beef-cattle production in fragile ecological conditions in the Brazilian Amazon has been supported by domestic governments in the form of tax concessions and provision of infrastructure.

The plans to construct 15,000 kilometers of roads in the region have perhaps been the most visible of the government's interventions, not least for the environmental damage they generated. The impact of government fiscal and tax incentives has been perhaps less readily identifiable though not necessarily less dramatic. Some of the most powerful of the incentives have allowed Brazilian corporations to take up to a 50% credit against their federal income tax liabilities under certain conditions, or have provided access to subsidized credit lines for cattle ranching and other activities. Livestock projects approved in this way have probably been the single most important source of deforestation, accounting for up to two-thirds of the deforestation in Amazonia. Not only have these projects been environmentally damaging, but they have largely been unjustified in social cost-benefit terms, although they may have yielded considerable private profits.

Since 1980, the volume of official rural credit has been drastically reduced and the subsidy element was eliminated in mid-1987. The approval of livestock projects in rain forest areas has also been officially prohibited since 1979, but this rule has been difficult to enforce. In the long run, reversal of long-standing policies will surely have beneficial macroeconomic, sectoral, and environmental effects.

Similarly, in Indonesia, Barbier shows how government agricultural pricing and subsidy policies encourage inappropriate land-use and thus contribute to environmental degradation. Rigid import controls and a heavily protected domestic pricing structure may provide indirect disincentives to soil conservation. As the average returns to highly commercialized and input-intensive crops such as vegetables increase, share tenancy and absentee ownership become more common. This can reduce the incentive for long-term investments in improved land management if tenancy arrangements are insecure and if the objective of absentee owners is short-term profit maximization or land speculation. The increased profitability of vegetable crops also encourages farmers to cultivate on steeply sloped volcanic soils, where water run-off, and therefore soil erosion, are greater.

The lack of adequate marketing facilities is another key factor that contributes to environmental degradation and low productivity on marginal uplands in Indonesia. The ability of farmers to undertake improvements and investments in agroforestry and livestock-based systems relies in part on the returns to their marketing efforts. Government policies regarding subsidies to agricultural inputs have resulted in the overuse of fertilizers, particularly in lowland irrigated areas. Fertilizer subsidies may discourage farmers from facing the full economic costs of declining soil fertility and from responding with sound land conservation measures.

In view of the potential environmental impact of policy reforms at the macroeconomic level, one of the major instruments used by the World Bank to address the policy-environment link is policy based, structural, and sectoral adjustment lending. Adjustment lending has recently begun consciously to incorporate measures to protect natural resources and to improve their management. In addition to institutional and economic reforms, adjustment loans contain a number of conditions that may benefit the environment. These include elimination or reduction of subsidies for pesticides, full cost recovery in pricing energy or water services, and improved land distribution policies and tenure arrangements.

It must, however, be added that generalizing about the effect of economic adjustment on the environment is difficult. Policy interventions that have a benign effect in one country may have exactly the opposite effect in another. Reforms such as the elimination or reduction of subsidies or the substitution of cash crops for food crops can result in either positive or negative environmental consequences.

Better understanding is therefore required of the chain of causality leading to severe environmental problems in order that remedial policies can be identified. The difficulties arise because of the complex interactions between natural events and human activities that characterize the environmental problem. To improve its knowledge in this area, the World Bank is investigating the relationships between geographic data, including remote sensing, and various kinds of socioeconomic data. The purpose is to see if recent advances in the processing of geographic information can be used to identify the impact of changes in key economic and social variables in order to improve the basis for policy intervention. Research needs in this area are massive: they include a better understanding of the impact on the various forms of environmental degradation of a range of variables, including fiscal and trade liberalization policies, income distribution and poverty, and population growth.

Awareness of the macroeconomic importance of environmental problems has not been facilitated by the well-known shortcomings of national income accounts. It is increasingly recognized that conventional measures of national income give misleadingly favorable estimates of economic well-being and growth. Prudent accounting of national income should reflect sustainable income as closely as possible. Under the current conventions, however, no account is taken of the reduction in national wealth through the depletion and degradation of natural resources. In addition, expenditures incurred in protecting society against unwanted environmental side effects are counted as income rather than as intermediate expenditures needed to sustain actual income. Growth built on resource depletion is clearly very different from that obtained from productive efforts and may be quite unsustainable. If compensating investment is not made, growth based on such a process is not sustainable and will send false signals to policy makers. The World Bank is conducting a series of country studies in this area to create an

awareness of environmental issues at the macroeconomic level, and equally important, to identify areas where sound policies require more information.

Population, Poverty, and Environment

Ultimately, many of the environmental problems in developing countries harken back to the fundamental issues of income distribution and poverty and include concerns regarding equity within and between generations. While the poor and disadvantaged certainly tend to suffer disproportionately from environmental degradation, and while poverty is an obstacle to bringing about environmental improvement, it is difficult to generalize about the extent to which poverty is itself responsible for environmental problems. Indeed, some of the most pressing environmental problems facing the planet are those that originate in the wealthy countries.

While the link between poverty, population, and degradation of natural resources in many countries is certainly important, the complex factors that make environmental abuse the most logical short-term strategy for people to pursue need to be better understood. Examined as cumulative regional phenomena, deforestation in Haiti and desertification in the Sahel are much more than the result of poverty-stricken people trying to eke out a living. Invariably, deeply rooted political and administrative structures and economic incentives induce the poor, and the not-so-poor, to cut trees or to abuse the earth's soil. Corrupt officials, bureaucracies, inequitable land tenure patterns, or pressures for short-term successes and projects may make reckless use of the land quite rational and often lucrative. Future research faces the challenge of clarifying the linkages between poverty, population, and environmental management and shedding light on the intervening variables in the equation. A clarification of the impact of environmental degradation on equity over time is another promising research avenue.

Avenues for Research and Policy

There continues to be a pressing need, in both industrial and developing countries, to use increasingly scarce natural resources more efficiently. The means of so doing will depend on a vastly improved understanding of the long-term consequences and the underlying causes of environmental degradaton. Increased effort is needed to identify appropriate social, economic, and other policy measures for sound environmental management. Tracing through the chain of causality is important but often difficult—as in the case of unravelling the effects of population and poverty on the environment—and environmental work aimed at developing this understanding is a priority.

The greatest research needs lie in the application of existing knowledge rather than in searching for new concepts and theories. Although additional research in areas such as the valuation of environmental goods and services may be required, deficiencies in information should not be an obstacle to action. There are already economic techniques that make substantial improvements possible to the way in which environmental degradation is handled in economic planning. On the other hand, the difficulty of generalizing about the impact of policies has made the reliance on multidisciplinary, country-specific inquiry a necessity. Multidisciplinary analysis is becoming increasingly important at both the project and the macroeconomic policy levels. In addition to issues well within an economist's range of expertise, such considerations as improved institutional analysis and policy incentives need to be addressed.

Experience shows that good economics is typically good for the environment. There are innumerable opportunities for investments and policy reforms that meet both environmental and economic objectives, and this fact is consistent with the growing evidence that environmental degradation is undermining sustainable development in many countries. However, there will always be important instances in which economic and environmental objectives conflict to some extent. For example, limits may exist to the environmental benefits that can be derived from trade liberalization. Market mechanisms will not cover the full environmental agenda unless they are supplemented by government interventions of various kinds. In particular, the role of "green taxes," possibly substituting taxes on income or capital, should be carefully considered.

Finally, institutional problems in their many forms, including inefficient public agencies, inadequate legislation, and cultural factors are another area of special concern. Research is needed to uncover means of better understanding how local institutional structures help or hinder environmental management and to help in the de-

sign of institutions that respond to local needs.

The range of researchable activities is massive. However, the areas in which knowledge needs to be improved tend to be more empirical than conceptual; the division between environmental research and more policy-oriented or operational work should thus become increasingly blurred. This holds great promise for the applicability and contributions of future research to the resolution of today's pressing environmental problems.

Arresting Renewable Resource Degradation in the Third World: Discussion

Daniel W. Bromley

The three papers approach the problem of resource degradation from similar angles. Rather than comment upon any one of them in detail, the brief space calls for general comments that would seem to apply to each. I will make four points. First, I will argue that the blame for resource degradation that is laid on population growth is largely misplaced. Second, I will remind the reader that policy reform is precisely the essence of institutional change. Third, I want to emphasize the role of property regimes in natural resource policy. Finally, I will close with a few observations on the relevance of our concepts and maintained hypotheses about development, sustainable development, and wise natural resource use in the tropics.

On Population Growth

Population growth figures prominently in all three papers, as well as in the common perception of important causes of resource degradation. While I certainly do not wish to suggest that population growth is unimportant, it is my view that this issue has been overdone (Bromley 1989b). Blaming population growth allows inept or corrupt governments to shift the blame for their behavior—or their inaction, as the case may be—to promiscuous peasants. It further allows governments to appear helpless in the face of forces beyond their control. And it allows them to attract international assistance for projects to correct certain resource insults, the better to appear more beneficent to their citizenry.

The very essence of the state, and its sole justification one might argue, is to design institutional arrangements to address new contingencies and new scarcities faced by its citizens. To blame the masses, to plead helplessness, and yet to engage in—or to promote—many of the resource-use patterns we observe, is disengenuous at best. Resource policy in the developing world would do well to move beyond the bedroom.

Policy Reform and Institutional Change

The papers variously talk of policy reform and institutional change as if to suggest that these are fundamentally different things. In fact, institutional change, by altering rules, conventions, and entitlements, is the very essence of policy reform. It is institutional arrangements that map (transform) policy pronouncements into choice sets from which individual maximizing agents will select preferred actions (Bromley 1989a). One cannot talk of policy reform without addressing institutional change, and I would have been happier had the three papers been more clear on this.

Property Regimes and Natural Resources

The papers offer welcome relief from the mischief that holds open access regimes (*res nullius*) to be indistinguishable from common property regimes (*res communes*). There are really three general classes of property regimes in natural resource management: (*a*) state property regimes, (*b*) common property regimes (private property for a group), and (*c*) individual property regimes. Open-access regimes, or what has unhappily been confused with common property, is in a class apart from these three property regimes for the simple reason that there are no property rights in open access (Bromley and Cernea). Common property and individual property share the trait that the users (or managers) are also the owners; in state property regimes (such as a national forest), neither the users nor the managers are the owners. Common

The author is Anderson-Bascom Professor in the Department of Agricultural Economics, University of Wisconsin.

property and state property share the trait that the number of users (or managers) is often large. By definition, group size in individual property regimes is usually thought of as being one. But of course much "individual" private property (personal dwellings and automobiles) is co-owned by spouses.

Given these aspects of property regimes, I suggest that natural resource policy would benefit if we were to pay more attention to the literature focusing on the separation of ownership and control (Cheung, Fama, Grossman and Hart, Jensen and Meckling). In this regard, much of the resource problem in the developing countries arises because national governments have created an ownership structure (state property regimes) without the attendant capacity to control individual user behavior. As a result, many natural resources are characterized as open access available to any and all claimants. It is natural resource management by proclamation, and it does not work.

The Conceptual View

Much natural resource activity in the developing world is still driven by the colonial (and precolonial) view that resources are for extractive purposes to earn revenue for the state. We must begin to recognize that not all national leaders are as interested as we in "development" and wise natural resource use. I note that the recent fascination with "sustainable development" misses the point by asking about the meaning of sustainability while ignoring the meaning of development. Recall that development means change, and that all change threatens some vested interests. However, many governments view their country rather like family-owned firms with the objective of maximizing revenue in Miami, Zurich, or Singapore bank accounts. Improved modeling of natural resource policies awaits the incorporation of this unfortunate objective function into our work. I urge that we not continue with the idealistic view that governments are innocent bystanders in the process of squandering natural capital. Otherwise, our models are behaviorally naive and little progress will occur.

Arresting Renewable Resource Degradation in the Third World: Discussion

Pierre Crosson

Concern about degradation of renewable resources in developing countries is deep and widespread in the countries themselves, in development agencies such as the World Bank and the U.S. Agency for International Development, in the world environmental community, and among academics interested in economic development. I share this concern. But I note that the evidence of resource degradation on which it is based is fragmentary and anecdotal. Soil erosion is widely believed to be a major threat to agricultural productivity and water quality in the developing countries. The fact is, however, that we have very little reliable information about the amount of soil erosion in these countries and even less about its productivity and water quality effects. Aquifers are being mined in many developing countries and crop productivity is lost to saline and water-logged soils in irrigated areas, but the economic significance of these situations on a country or global scale is obscure. Tropical deforestation is troubling largely because of fears that the associated loss of biological diversity will in time impose high social costs. But with great uncertainty about how much tropical deforestation is occurring, and estimates of the total number of species in the world varying between 4 and 30 million, we have only the vaguest notion of the magnitude of the threat to biological diversity and not a clue as to the social costs of possible losses.

Despite the skimpy information about renewable resource degradation in developing countries, it has become virtually an article of faith among the interested groups and institutions mentioned above that the degradation is severe and demanding strong and quick public action to deal with it. The papers here under discussion reflect this view, and I wish it were not so.

Pierre Crosson is a senior fellow, Resources for the Future, Washington, D.C.

Southgate, Sanders, and Ehui begin their paper with the assertion that "degradation of renewable natural resources in the developing countries is taking a serious toll," and in various places they use "excessive" to describe, e.g., encroachments of farmland on forests in Amazonia and damage to the environment in that region. Nowhere, however, do the authors attempt to give any sense of the magnitude of the various threats they perceive nor do they provide any standard by which to judge whether damages are "excessive."

Cruz and Gibbs introduce their paper with the statement that "the degradation of renewable resources in the developing world now threatens not only the economic prospects of future generations but the livelihoods of current users as well." Elsewhere they assert that cleared forest lands have been turned to "nonsustainable agricultural uses, causing severe erosion impacts. On-site production potential is reduced, and downstream sedimentation and siltation of waterways and agricultural land is increased." We are given no basis for judging the severity of these impacts, however, nor are we told the meaning of "nonsustainable agricultural uses."

Partow and Warford are less concerned with specific instances of resource degradation than the authors of the other two papers, but their paper reflects the same implicit acceptance of the conventional wisdom that degradation is general and severe throughout the developing world.

My point here is not to deny that natural resource management currently imposes high social costs in many developing countries. Nor is it to argue that the authors of these papers should have produced quantitative evidence for the various damages they identify. My concern, instead, is that if we are to make progress in understanding and dealing with the problems the authors discuss, we must find criteria for distinguishing among the problems according to their

social importance and susceptibility to treatment through public action. Making such distinctions is the essence of analysis aimed at ameliorating conditions of the sort the authors deal with. The conventional wisdom ignores such distinctions. This is understandable where the "wisdom" is used to mobilize political support for action to address problems of resource degradation. But the intellectual effort needed to understand and deal with the problems requires that distinctions be made. I would be happier with the papers presented here if their respective authors had recognized the importance of this point and had devoted some attention to it. What I am asking for is acknowledgement of how little we know about the present and future social costs of renewable resource degradation in the developing countries and some discussion of how we might use the little knowledge we have to devise workable strategies of research and policies for dealing with the problems of degradation. Such material could be fit quite neatly with the real substance of the papers presented here.

Despite these rather negative comments, the papers do, in fact, contain much of real substance. Space precludes a full account, so I emphasize some high points. Both the Southgate, Sanders, and Ehui and Cruz-Gibbs papers make an important point which, in my judgment, generally gets insufficient attention: attempts to eliminate overuse of open-access resources by bringing them under state ownership or privatizing them often flounder because governments lack the administrative capacity to enforce the newly established property rights. Economists—I have been guilty of this myself—routinely prescribe secure property rights as the solution to the open-access problem, taking the security of the rights for granted. But where government administrative capacity is the limiting resource, security is not guaranteed, thus undermining an otherwise promising attack on the open-access problem. Southgate, Sanders, and Ehui and Cruz-Gibbs do valuable service in emphasizing this important point.

That national fiscal, monetary, and foreign trade policies can have unintended, and undesirable, effects on renewable resource management is not a new idea, but too often it gets insufficient attention in discussion of these policies. The Partow-Warford paper thus is on target in featuring the idea and giving examples of adverse resource and environmental effects where it has been ignored.

I come away from a reading of the three papers asking myself, what are the conditions for achieving patterns of renewable resource management in the developing countries which are sustainable in the sense of indefinitely providing adequate income to the people using the resources? None of the papers directly address this question, but they provide some clues to an answer. Southgate, Sanders, and Ehui and Cruz-Gibbs suggest that easing population pressure on the resource base is a necessary, although not sufficient, condition for sustainability in the above sense. Southgate, Sanders, and Ehui imply that research to develop technologies suitable for the soil and water endowments of the developing countries is critical; and Cruz-Gibbs, also by implication, indicate that in extraordinarily land-scarce countries such as Nepal, expansion of off-farm job opportunities is the only way to maintain, or increase, the incomes of those who remain in farming. Finally, all three papers emphasize the too often perverse effects of government policies on incentives of renewable resource managers. The papers make clear that correcting this is much more complex than "getting the prices right," important though that is. Governments must look also to the resource management consequences of fiscal, monetary, and trade policies, and they must contrive institutional reforms to establish and enforce clear property rights in open-access resources. These papers succeed in conveying some of the flavor of this most formidable set of tasks.

International Competitiveness: Usefulness of Cost of Production and Productivity Measures in Evaluation
(B. F. Stanton, Cornell University, presiding)

Cost of Production and Productivity in Analyzing Trade and Competitiveness

Jerry A. Sharples

Agricultural economists for many years have calculated costs of producing agricultural commodities and measures of productivity (output per unit of input). Early research focused on farm management extension needs; then came the data demands of linear programming models of representative farms. More recently, estimates of costs of production have been used for setting price supports. Similar stories of the growth in demand for cost data and productivity measures could be told for Canada, Western Europe, Japan, and other countries.

The growth of agricultural trade and the more recent increase in trade conflicts have generated interest in issues of competitiveness. One set of issues is concerned about basic comparative advantage. Would the home country's agriculture still be competitive if government support were removed at home and abroad? A second set of issues is concerned about how changes at home or abroad in policy, technical efficiency, or input prices would affect international competitiveness.

On the surface, it seems quite appropriate to apply our accumulated research skills and data on costs of production and productivity to these questions of international competitiveness. What we have found from early attempts to do this in agriculture, however, is that the comparisons have not always been very helpful in understanding competitiveness. For evaluating global competitiveness, some revisions of old measurement methods may be required.[1]

The purpose of this session is to improve our measures of agricultural costs and productivity to provide a better understanding of international competitiveness. My purpose is to present several basic concepts of trade and competitiveness that can be used as guides to refine these measures in order to make useful cross-country comparisons. The analysis begins with a simple model that illustrates basic links between measures of costs and competitiveness. The focus is on costs, but some of the implications may be extended to measures of productivity.

International Competitiveness: Basic Concepts

Assume country A and country B are two of many countries that produce and export wheat. To simplify, assume that the two exporting countries do not consume wheat, wheat is a small part of their total economic activity, and there are no transportation charges between countries. Several important concepts relating to cost of production, productivity, trade, and competitiveness can be shown with this simple model.

Let the curves F_A and F_B in figure 1 represent export supply curves, at farmgate prices, for countries A and B, respectively. They represent the quantity that would leave the farm for export at alternative farm prices. Because there is no domestic use, curves F_A and F_B are also domestic supply curves. Let the curves XS_A and XS_B represent excess supply curves at the port of exit from the country. The vertical difference between the XS and F curves represents variable domestic "marketing," costs (e.g., storage, transportation, handling, including any marketing and export taxes or subsidies). The world market in figure 1 clears at price P_W, with country A producing and exporting quantity Q_A and

Jerry A. Sharples is an agricultural economist with the Economic Research Service, U.S. Department of Agriculture.

[1] For a detailed example of an intercountry comparison of costs of producing cereals, see Stanton. Capalbo and Denny provide a rigorous example of comparisons of aggregate agricultural productivity measures for the U.S. and Canada.

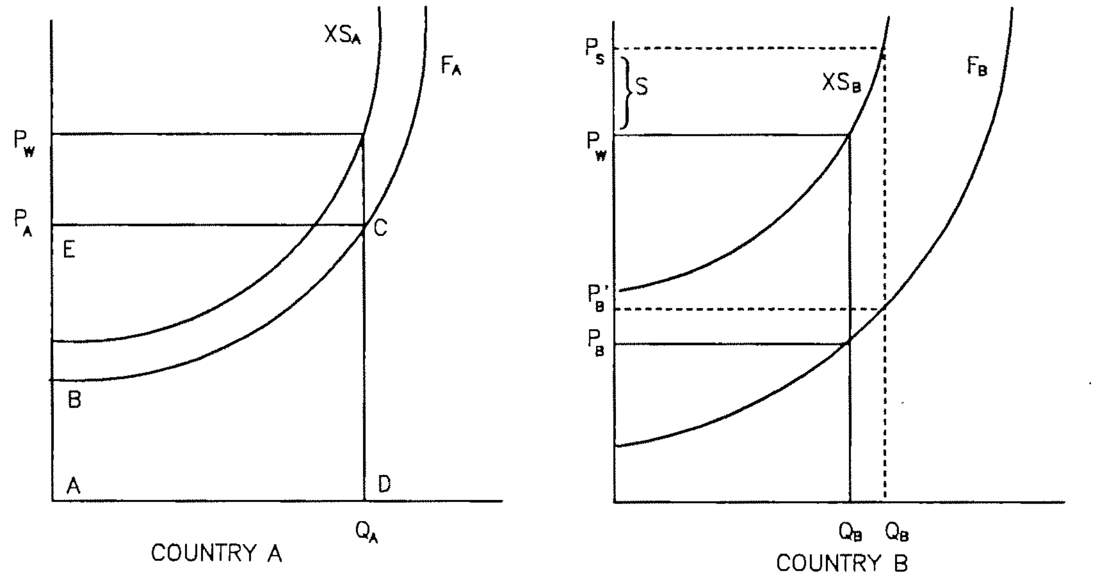

Figure 1. Wheat supply in two countries

country B producing and exporting Q_B.[2] The supply curves show that country A has high variable production costs and low variable marketing costs relative to costs in country B. Thus, the farmgate price in country A, P_A, is higher than the farmgate price in country B, P_B.

Suppose these costs curves were unknown but economists had accurately measured the average cost of producing and marketing wheat in countries A and B. After adjusting for year-to-year variability, they likely would find in country A that the average total unit cost for producing Q_A units was P_A.[3] The average variable production cost per unit would equal area *ABCD* in figure 1 divided by Q_A, and the per-unit residual returns to fixed production factors would equal area *BEC* divided by Q_A. Total marketing costs per unit would equal the difference between P_W and P_A. Equivalent cost estimates could be obtained for country B.

Competitiveness

Concepts of competitiveness may be introduced with this simple model. "Competitiveness" does not have a definition in neoclassical economic theory; it is a political concept. It is becoming conventional, however, for economists and others to perceive of competitivness as the result of the combined effect of market distortions and comparative advantage. For examples, see Amstutz; Barkema, Drabenstott, and Tweeten; and Sharples. "Market distortions" usually implies distortions caused by policy, but it also could include distortions caused by imperfect competition.

Comparative advantage is theoretical, explaining trade and optimal welfare in an undistorted world. Competitiveness, on the other hand, relates to the observable. If firms and industries cannot survive by selling at the going price, they are not competitive. If they are able to survive and increase market share, they have become more competitive. Note, however, that an increase in competitiveness of an industry, possibly the result of government support, does not necessarily imply an increase in national welfare.

In the context of figure 1, a country over time can become more internationally competitive in exporting wheat by doing things that shift its wheat export supply curve right (or down). Examples include (*a*) increasing the stock of fixed resources in wheat production and marketing, (*b*) increasing efficiency (productivity), (*c*) reducing input prices, (*d*) reducing interest rates, (*e*) changing policies to lower taxes or raise subsidies on wheat production and marketing, and (*f*) depreciating the home currency, discussed below.

---

[2] This model represents an intermediate-run equilibrium where production and input use respond to price changes that persist for several years. For individual commodities, most inputs would be considered variable. For example, land would be a variable input to production of one crop on a diversified farm. Its opportunity cost would be its return from alternative crops.

[3] These curves represent private costs. Additional social costs of private production and marketing, such as pollution or soil erosion, are not included unless reflected in taxes or other costs imposed on private firms by public policy.

Analyses of the forces listed above help to explain changes in past competitiveness and help to evaluate alternative futures. The rest of the paper addresses how international comparisons of production costs can help to better understand competitiveness.

Cost Estimates and the Supply Curve

In order to address global wheat competitiveness, in the context of figure 1, we need to have (*a*) estimates of the intermediate run wheat supply and export supply curves and (*b*) estimates of how the forces listed above would shift the supply curves. Estimates of costs of production and marketing tell us little about the supply curves, but cost estimates can help to estimate shifts in the supply curves. Cost estimates also provide a more detailed picture of how differing competitive forces uniquely shaped agriculture in different countries at the time the costs were estimated.

Economists generally agree that agriculture is an increasing-cost industry, as represented by the upward-sloping supply curves in figure 1. The supply curve shows the cost of producing the marginal unit over a range of output prices. A cost survey typically provides information on average variable and average fixed costs at one point in time (i.e., for one output price). Thus, an estimate of average unit cost tells little about the supply function.

Furthermore, knowing the distribution of costs across all firms in the industry may not tell much about the supply curve because that distribution does not represent marginal costs. Suppose, based on a survey of costs of all firms, that production is arrayed from lowest variable cost to highest variable cost. This distribution shows how all firms at one point in time react to one set of expected market conditions. The industry supply curve, on the other hand, shows how all firms in the industry would react to a range of alternative expected output prices. Firms would be expected to change their production methods and input mix in response to expected changes in output price.

Getting Cost Comparisons Right

Even though cost estimates do not help much in defining the supply curve, those data are still useful for answering questions about competitiveness. To do this, however, the comparisons must be consistent with trade theory. The remainder of the paper focuses on issues associated with comparing costs across countries.

Suppose economists decide to compare wheat costs in countries A and B. They would face many conceptual and technical problems, problems that are discussed in the other papers in this session. The focus here is on three important issues specifically associated with making international cost comparisons: (*a*) to include marketing costs, (*b*) to include the impacts on costs of taxes and subsidies, and (*c*) to get the exchange rate right. These are discussed below.

Include Marketing Costs

Figure 1 shows that in order to evaluate international competitiveness, marketing costs as well as production costs need to be examined. Comparisons of costs of production tell us little about competitiveness. As presented in figure 1, both wheat exporting countries successfully compete in the global wheat market. It would be misleading to conclude, based only on country B's lower average variable production costs, that country B has a basic competitive advantage in wheat exports relative to country A. In international trade, it is the cost of production plus all the additional costs to get the commodity to the foreign buyer that determine competitiveness.

Account for Public Policy Effects

In order to understand competitiveness, one needs to account for policy measures that influence the price signals faced by producers and marketers. These include input and output taxes or subsidies and border tariffs, taxes, and quotas. For example, suppose country B provides a subsidy on exports of wheat (fig. 1). Although the export price remains at P_W, an export subsidy of S is equivalent to raising the border price to P_S for exporting firms. As a result, producers would receive price $P_{\hat{B}}$ and country B would produce and export quantity $Q_{\hat{B}}$. Because of the higher price and added production, marginal and average variable costs of production and marketing per ton of wheat would increase as shown in figure 1. Land rents and land values would increase because of their larger residual returns. An accurate accounting would show total costs

equal to P_S in country B, while in country A they would equal P_W. The subsidy raised costs.[4] Likewise, removing the subsidy would be expected to lower costs.

Consider Exchange Rates

Comparisons of production and marketing costs among countries inevitably involve using exchange rates to convert costs to a common currency. Recent history shows that exchange rates are among the most volatile parameters in the whole process of estimating and comparing costs.

For example, during the nine-month period between June 1989 and March 1990, the real value of the U.S. dollar dropped over 25% relative to the currencies of other countries who export corn and soybeans (USDA, p. 55). That depreciation of the dollar implies that in nine months the U.S. costs of producing and marketing corn and soybeans dropped over 25% relative to costs of competitors. No change in domestic agriculture likely would ever have such a large impact on intercountry cost comparisons in such a short time. Movements of real exchange rates imply that forces outside of agriculture have a very large impact on short-run and longer-run cost comparisons.

The effect on cost estimates of the volatility of real exchange rates may be reduced by computing an average over several years. This procedure would be consistent with the intermediate-run assumptions generally used for evaluating competitiveness issues.

Usefulness of Cost Comparisons

Assume that wheat costs in countries A and B of our example have been estimated. Appropriate attention has been paid to marketing costs, taxes and subsidies, and the exchange rate. What do we learn about competitiveness from the comparisons? We likely find that when averaged over several years, total costs approximate incentive prices (observed prices plus taxes and subsidies) in each country. Thus, the estimate of total cost, taken alone, is not very useful because price and, by extension, total cost are already known.

Further, intercountry comparisons of costs gives little insight into basic forces of comparative advantage. The cost structure of an export industry such as wheat is shaped by policy distortions as well as by the forces of comparative advantage. A different, unknown, cost structure would emerge in each country if distortions were removed and the market were only subject to forces of comparative advantage.

Knowledge of the components of cost, however, are useful for a better understanding of competitiveness. A comparison of cost components across countries show the net effect on input use and factor payments of the existing forces shaping competitiveness in each country.

Cost components may also be used to approximate shifts in supply curves. For example, suppose that we are interested in evaluating the impact of a 50% increase in pesticide costs (resulting from an environmental tax?) in country A on country A's competitiveness in the world wheat market. By knowing the ratio of pesticide cost to total variable and fixed cost of production and marketing, and assuming that there would be no significant change in the input mix, one has an approximation of how much country A's supply curve and export supply curve would shift left (up). The change in costs could be used to shift a supply curve in a world trade model. Then the impact on world trade and competitiveness could be estimated. Care must be taken, however, in using cost data to evaluate how production or exports might respond to major changes in input or output price ratios. Producers facing a major change in price ratios likely would reorganize production, so a new cost structure would emerge.

Conclusions

International comparisons of estimates of agricultural costs (*a*) need to be consistent with trade theory, (*b*) tell little about comparative advantage, (*c*) are useful for showing how differing competitive market forces within countries have influenced input use and payments to fixed factors, and (*d*) are useful to a limited extent for estimating how future incremental changes in input prices, technical efficiency, and policy might shift agricultural supply curves. Thus, by incorporating basic concepts of trade theory,

[4] ERS estimates of production costs omit direct effects of government programs because the estimates are used for policy purposes. A recent study by Salassi et al. shows that in 1988 the ERS estimate of residual returns to management for U.S. rice production was $-105 per acre if policy effects were excluded, and $49 per acre if included.

analysis of intercountry comparisons of costs and productivity should provide useful information about how domestic competitiveness forces have affected resource use and costs.

Usefulness and Limitations of COP Estimates for Evaluating International Competitiveness: A Comparison of Canadian and U.S. Wheat

Mary Ahearn, David Culver, and Richard Schoney

With the current negotiations under the General Agreement on Tariffs and Trade (GATT), the potential exists for a reduction in agricultural subsidies and trade barriers. This has led to an increased emphasis on the part of the major exporters of agricultural commodities to understand their relative competitive position in a reformed international trading environment. In addition to the GATT, interest in competitiveness has been heightened in Canada and the United States by the recent bilateral reductions in trade barriers under the Canadian-U.S. Trade Agreement. A number of papers by agricultural economists have compared the cost of production of certain major North American crops with the costs of major competitors (Ortman, Stulp, and Rask; Seecharan; Stanton). These comparisons have often been quoted in the popular press and by farm organizations as a means of illustrating the competitive position of North American farmers. However, there has been very little discussion among agricultural economists on the role of cost-of-production estimates in determining the international competitive position of exporting countries.

This paper examines the usefulness and limitations of cost-of-production estimates in the analysis of international competitiveness. First, the role of cost of production in the concept of competitiveness is discussed. The common uses for which cost-of-production estimates are constructed, the general implications of how those uses might affect estimation methods, and the elements of typical cost-of-production estimates are then discussed. Comparisons of wheat produced in Canada and the United States are used for illustration in the remainder of the paper. We begin the comparison by reviewing the structure of wheat production and the export positions of the two countries. Finally, we compare approaches to estimating costs and cost estimates for two regions and then draw conclusions regarding the usefulness of cost comparisons in the analysis of international competitiveness.

Cost of Production and Competitiveness

There is no general economic theory of competitiveness because it is not strictly an economic term. However, the basic economic trade concept, comparative advantage, is a key element in competitiveness. A country is said to have a comparative advantage in producing a particular agriculture commodity if it has the highest return per unit of fixed resource. The implications of comparative advantage are that each country should produce those commodities for which it has a relatively abundant supply of fixed factors, such as land or labor. The industry marginal costs of production which underlie the industry supply curve, in addition to the costs of delivering the product to the market, then serve as the basis for measuring the comparative advantage concept.

There are two major reasons cost of production estimates as they are commonly constructed and published by countries are not directly applicable in the analysis of competitiveness. First, the implications of comparative advantage con-

Mary Ahearn is Leader, Farm Income Research and Forecasting, Economic Research Services, U.S. Department of Agriculture; David Culver is Head, Western Crops, Production Analysis Division, Agriculture Canada; and Richard Schoney is an associate professor, Department of Agricultural Economics, University of Saskatchewan. Senior authorship is not assigned.

The views expressed in this paper are solely the views of the authors and do not represent the views of Agriculture Canada, USDA, or the University of Saskatchewan.

cepts are only applicable under a certain set of assumptions, in this case, when international markets are well-functioning and undistorted by domestic policies. Because international agricultural markets are far from being undistorted, the cost and production relationships underlying comparative advantage are only one of the determinants of a country's competitive position. Domestic agricultural and nonagricultural policies have major impacts on competitiveness. But there are other factors which affect a country's competitive position, as well. These include product quality, costs associated with adding value to the commodity, market niches, exchange rates, and perceived reliability as a trading partner.

The second reason cost of production estimates, as they are commonly reported, are not very useful in the analysis of competitive position is they are reported as average costs per acre or hectare or per unit of output for a spatially defined area. These estimates are the average of costs for firms of varying sizes and with varying technologies at one point in time facing a single output price. As such, they represent the average of single points on each firm's average cost curve. These cost data contrast with the cost data underlying the industry supply curve, the relevant concept; these latter data are the horizontal sum of each firm's marginal cost curve.

Uses of Cost of Production Estimates

Cost of production estimates are generally constructed with a single or multiple end-uses in mind which affect how they are measured. Use in analysis of international competitive positions is rarely one of the primary purposes for constructing the estimates. There are three common purposes of commodity cost estimates: as financial planning tools for producers, as policy and program instruments, and for economic analysis of production decisions.

Extension Guidelines

One of the most common uses of commodity cost of production (COP) estimates is as production guidelines published by university and provincial extension agencies. These guidelines are intended to be used by farm operators for planning their enterprise mix and their cash flow position for the coming production cycle. They are frequently referred to as "budgets" because of this forward-looking aspect. In addition, they are oftentimes based on the assumption of best management practices and then viewed as goals to be achieved during the upcoming year. Accordingly, management practices are often formulated by production specialists and are not based on actual farm usage data.

Domestic Program Instruments

The United States has income and price support programs for wheat, feed grains (corn, sorghum, barley, oats), cotton, and rice. Under income support programs, the government makes deficiency payments to eligible farmers and share landlords based on established target prices. Under price support programs, the government offers eligible producers the right to place their commodities in a nonrecourse loan program with an established loan rate. Currently, cost of production estimates are not used directly to set income supports for any commodities. They are, however, used in the setting of price supports for sugar, tobacco, and peanuts. Under the current legislation, cost of production estimates are to be used to set loan rates and target prices for wheat if a wheat-marketing quota is established. Because no such quota has been established, cost of production estimates have not been used to set wheat support levels.

In the past, cost-of-production estimates made by the U.S. Department of Agriculture's (USDA) Economic Research Service were used in setting U.S. target prices for wheat, corn, cotton, and rice under the 1977 farm bill. That provision was later removed with the 1981 and subsequent bills. Nevertheless, cost-of-production estimates are still reviewed and discussed in the political arena. Commodity interest groups show continued interest in the levels of the cost-of-production estimates because they believe that, even if they are not used by law to set target prices, policy makers likely use the estimates as guidelines for support levels.

By law, the USDA is mandated to produce estimates of the national weighted average of the costs of producing major commodities. This mandate directly influences the concept and estimation methods used to construct the USDA estimates. In particular, the policy use of the USDA estimates has led to efforts to provide cost estimates which are based on the actual, historical costs of a statistically representative group of the nation's producers. It has also meant

that estimates are constructed which exclude the direct effects of commodity programs.[1] Most important, this translates into excluding the returns from the programs on the gross returns side and valuing production shares paid to share rent landlords at market prices, rather than target prices, on the gross expense side. Eliminating the indirect effects of the programs on other components of costs and returns is virtually impossible.

In Canada, two major ongoing programs have been used to stablilize the incomes of wheat producers: the Western Grain Stabilization Act (WGSA) for the Prairie region and the Agricultural Stabilization Act (ASA) for the other wheat regions. Under the WGSA, producers pay a premium to participate in the program. The WGSA guarantees net cash flow at 100% of the previous five-year average level. The net cash flow estimates are based on the whole-farm National Farm Survey undertaken by Statistics Canada. Individual producers participating in the program are able to enroll up to $60,000 worth of grain in the WGSA each year.

Under the ASA, all wheat producers are eligible for payments if a pay-out is triggered. The pay-out is triggered if wheat price is below 90% of the previous five-year average wheat price with adjustments based on changes in the cash cost of producing wheat. Although the Canadian government does not have an official program for estimating costs of production on an annual basis, cost-of-production data are collected when needed to administer the ASA program. In addition, several universities and provincial governments estimate the costs and returns associated with commodities of importance in their areas.

Economic Analysis

Although they are usually not constructed for the primary purpose of conducting purely economic inquiries, cost-of-production estimates are used in a variety of economic analyses. Of special interest in this paper is evaluating comparative advantage and competitiveness, but other examples abound, for example, economies-of-size analysis. Estimates of long-run costs of production are generally the most useful for economic analysis. In particular, these estimates include a complete costing for all inputs, including owned inputs which are valued at an opportunity cost.

Problems in Comparing Cost-of-Production Estimates from Multiple Sources

Ideally, commodity cost and return data that are being compared should be generated under identical procedures. This is rarely the case in practice if the estimates are not of the same source because commodity cost estimation is not a straightforward accounting operation, in contrast to whole-farm accounting. Operators generally do not keep their records on a commodity-by-commodity basis, and if they do, they are forced to make some simplifying assumptions about allocating some costs.

No matter what the purpose of comparison, secondary users of cost and returns estimates from multiple sources need to consider the variation in assumptions and approaches across sources. Much of the variation results from the different primary end uses described above. Other differences are simply the result of a value judgment on the part of an economist on how best to construct an estimate given production theory and the resource constraints. This is especially an issue for the imputed returns to owned inputs. Economic theory provides the guide that an opportunity cost should be measured, but a great deal of variation exists in the assumptions involved in specifying and then measuring the appropriate rate of return to inputs. Moreover, imputed costs are generally not a small component of total economic costs. The most straightforward costs to allocate among commodity enterprises are the cash variable costs. In 1988, cash variable costs among the major field crops varied from 30% to 60% of total economic costs (USDA). Furthermore, even some of the cash variable expenses, such as fuel, lube, and repairs, are based on the actual acres covered by specific machines as reported by operators, in conjunction with the use of some assumed engineering relationships. Klemme, Schoney, and Finner found, through a comparison of farmers' estimates of the total time spent in machine use for all farm enterprises with the sum of estimated machine use as generated by typical cost of production estimation techniques, that standard procedures underestimated machine use and, hence, machine-related costs.

The potential for variation in estimates from multiple sources resulting from differences in

[1] The 1990 farm bill has specified that the direct effects of commodity programs are to be included in cost and return estimates.

estimation methods, rather than actual cost levels, is too extensive to elaborate in this paper. However, a data user should consider the following set of questions regarding consistency in measurement approaches when comparing cost and return estimates from multiple sources: What cost concept is being measured, for example, a net cash flow or an economic cost? Are the underlying data representative of the population of interest? Are the estimates intended to be a reflection of actual costs or of best-management costs? Do the cost estimates include landlord as well as operator costs? How often are the production technology data collected; are they for the year in which comparisons are being made? How are the effects of government policies treated? What portion of costs are out-of-pocket costs and what portion are imputed? What are the imputation procedures? Is a "budget-generator" used with implicit engineering relationships, or are operators asked to allocate all their costs among the commodity enterprises? Is depreciation measured on a replacement basis or an historical basis? How are shared inputs of multioutput firms allocated, for example, machinery costs? How are cash fixed costs allocated, for example, interest charges? Are real or nominal interest rates used to impute returns to capital?

Wheat Production and Exports in North America

Wheat is an important crop for both the United States and Canada. In terms of value of crop receipts, it is the most important crop grown in Canada and the fourth most important crop grown in the United States. The 1986 Canadian Census of Agriculture reported that 119,718 farms produced wheat, representing 40.8% of all census farms. Saskatchewan is the largest Canadian wheat producing province with 55,202 farms producing wheat. In the United States, 352,237 farms produced wheat in 1987 according to the U.S. Census of Agriculture; these farms represented 17% of all U.S. farms. North Dakota, Kansas, and Oklahoma are the top three wheat-producing states and account for approximately 30% of U.S. production. Wheat-producing farms are more specialized in Canada than in the United States. Specialized wheat farms (50% or more of farm sales from wheat) accounted for 18% of the farms producing wheat in the United States and 40% in Canada. Small farms with farm revenues of less than $50,000 account for approximately 50% of the farms growing wheat in both United States and Canada, but only about one-quarter of the wheat acres. More than half of the wheat acres in each country, however, were on farms with revenue of between $50,000 and $250,000.

Compared to most other agricultural commodities, wheat is not a homogenous commodity. There are five major classes of wheat, each with different final uses which affect demand on the international market. Hard Red Spring Wheat (HRSW) is the dominant wheat crop grown in Canada, accounting for 77% of the Census acres in 1986. High protein wheats in the United States are less dominant than in Canada. In the United States, HRSW accounts for approximately 20% of U.S. production; and hard red winter wheat, with a somewhat lower protein level, accounts for about half of production. The United States also produces and exports wheat in the other three classes: soft red winter, white, and durum wheat.

The United States and Canada compete in the world market for sales of wheat with similar characteristics. In the United States, over half of the wheat crop is exported, accounting for some 30%–40% of the world wheat trade. Over three-quarters of the Canadian wheat crop is exported giving Canada a 15%–20% share of the world wheat trade.

Comparison of Saskatchewan and Northern Plains

We will compare estimates of wheat production costs for two similar regions in the United States and Canada for 1987 and 1988 to illustrate the issues regarding comparability of approaches. We view this comparison as one based on as close to a consistent approach as an international trade analyst could realistically expect to find in today's agricultural data system. For this reason, and because environmental growing conditions are very similar, we would a priori expect cost estimates to be very similar.

The U.S. estimates are for all classes of wheat in the Northern Plains region, which includes Minnesota, Montana, North Dakota, and South Dakota (USDA). The USDA estimates use three general approaches to estimating costs: wheat production costs are reported by the operator, wheat input quantities are reported by the operator and valued at a state average price, and input costs are estimated with a budget generator system. The budget generator system is used to estimate machinery-related costs and relies on

operators' reports of actual machinery used and times over or hours of use in conjunction with established engineering relationships of machine efficiency (USDA). USDA collects data on production technology every four to five years and updates quantities of output and prices of inputs every year. The production technology underlying the estimates for 1987 and 1988 reported here are based on the 1986 wheat version of the Farm Costs and Returns Survey. The wheat survey is designed to be representative of all wheat production in the region and has a sample size of 255 farms which represent approximately 55,000 wheat-producing farms.

The Canadian estimates are based on Top Management Workshops data for Saskatchewan (Schoney). The Saskatchewan workshops require a high level of time input from participants and are not based on a representative sample of farms. Because large, possibly more efficient, farms are overrepresented in the sample, one might expect to find costs lower for Saskatchewan than those for the neighboring U.S. Northern Plains region, whose costs are based on a representative sample of all wheat producers. However, it is unlikely that the lack of representativeness of the Saskatchewan sample would have a large impact on the average cost level because small farms account for a disproportionately small share of wheat acres and wheat production.[2] The Saskatchewan sample size was 78 farms for 1987 and 115 farms in 1988. The general procedures are similar to the USDA system with two exceptions: (*a*) complete data, including data on underlying production technologies, are available every year and (*b*) because cost data are collected on every enterprise on the farming operation, the system has a built-in check to ensure that the sum of enterprise costs as estimated by standard procedures does not exceed the whole-farm costs.

The methods that are used to calculate the various cash cost items from the USDA and University of Saskatchewan are summarized in table 1 and provided in detail in Schoney and USDA. The methods of calculating cash costs are generally similar. Not surprisingly, methods to estimate fixed cash costs and imputations for owned inputs between the two systems do differ. For example, returns to nonoperating capital under the USDA system are based on a real rate of interest and are based on a nominal rate of interest under the University of Saskatchewan system.

[2] A comparison of farms participating in a similar, nonrepresentative farm-record-keeping system in North Dakota to a representative sample of farms found that the characteristics of farms were significantly different between the two groups (Gustafson, Neilson, and Morehart).

Results and Discussion

The wheat cost and return estimates for Saskatchewan and the U.S. Northern Plains are reported in table 2 for 1987 and 1988. In 1987, growing conditions were relatively normal, but both areas experienced a severe drought in 1988. The yields on average and total revenue (excluding government payments) were very similar in Saskatchewan and the U.S. Northern Plains.

In terms of variable cash expenses per acre, wheat production costs were also similar. In 1987, variable cash costs in the U.S. Northern Plains were $36.23, compared to Saskatchewan's $33.43. Although the sum of variable cash costs were similar, significant differences exist for individual expense items. For example, chemical expenses are higher in Saskatchewan, whereas fertilizer expenses are higher in the Northern Plains. Because of the relative consistency in estimation methods between the two systems for these inputs, we can confidently assume cost differences are real and draw relevant conclusions. For example, policy reforms or new technologies which may affect chemical quantities applied and/or price would probably have relatively more impact on Saskatchewan producers than producers in the Northern Plains.

Fixed cash costs per acre were similar between the two regions in 1987 but much less so in 1988. The $2.54 difference widened to $4.76 in 1988. This can be explained only by the methods. USDA allocates fixed cash costs based on the proportion wheat value of production is to total value of production versus the University of Saskatchewan's approach of allocating fixed cash costs based on the proportion cash variable wheat costs are of total farm cash variable costs. With the extreme drought conditions of 1988, total value of production was down and, moreover, wheat was more adversely affected than other commodities produced on farms in the region.

Estimates of capital replacement and returns to operating and nonoperating capital are all significantly different between the two regions in both years. However, so are the estimation methods used to calculate them. The important point for purposes of this paper is not how the

Table 1. Comparison between USDA and University of Saskatchewan Methods of Calculation

Cash Expenses	USDA	University of Saskatchewan
Seed	Multiplies farmer-reported seeding quantities by state average seed prices.	Multiplies farmer-reported seeding quantities and prices.
Fertilizer	Multiplies state average prices per pound of primary nutrients by farmer-reported pounds of nutrients applied.	Multiplies farmer-reported price of fertilizer by quantities applied per acre.
Chemicals	Producers report their chemical expenses for a particular crop.	Multiplies quantities of individual chemicals applied by farmer-reported price of the pesticide.
Custom Operations	Producers report custom operation expenses for a particular crop.	Same as USDA.
Fuel, lube, and electric	Producers report data on machine size, age, and acres covered. These data are combined with engineering specifications of speed and field efficiency to arrive at hours per acre. The hours per acre are multiplied by fuel consumption per hour and fuel price to determine fuel expense per acre. Lubrication costs are calculated at 15% of fuel expenses. Electricity for irrigation is estimated from farmers' reported equipment specifications and hours that water is pumped.	Same as USDA except for pick-up trucks, except a calibration procedure is used to ensure that individual commodity estimates for all commodities produced equals the whole-farm estimate. For pick-up trucks, costs are included as general overhead.
Repairs	A repair rate per machine is calculated based on engineering relationships for each machine which is divided by the number of hours the machine is used on a particular crop.	Same as USDA except for pick-up trucks, except a calibration procedure is used to ensure that individual commodity estimates for all commodities produced equals the whole-farm estimate. For pick-up trucks, costs are included as general overhead.
Hired labor	First, total hours of both unpaid and paid labor are calculated. Hours of machine-related labor requirements are estimated based on reported field operations. Hours of hand labor requirements are estimated based on the type of irrigation system and the hours water is pumped plus the hours of other hand labor reported by farmers for other purposes. Total hours are then designated as paid or unpaid based on the proportion of labor paid a cash wage on all crop farms. Estimated paid hours are then multiplied by the state wage rate for farm labor to give the hired labor expense.	Hired labor expenses are the sum of paid machine-related labor hours and expenses for salaried labor. Hours of machine-related labor are calculated in a manner similar to the USDA procedure. Salaried labor expenses are allocated to the commodity based on the proportion cash variable expenses of the commodity are all cash variable expenses. Salaried paid to spouses are excluded.
Technical services, other	Costs reported by farmers for such items as soil testing, scouting and land surveying.	Same as USDA, except it also includes crop insurance premiums.
General farm overhead	Farm overhead is the sum of non-crop-specific activities, such as utilities and blanket insurance policies. Overhead costs are allocated to the commodity based on the proportion value of production of the commodity is of total farm value of production.	Overhead costs include items similar to the USDA. Overhead costs are allocated to the commodity based on the proportion cash variable expenses of the commodity are of all cash variable expenses.
Taxes and insurance	Taxes equal the sum of personal property tax for machinery plus real estate taxes. Insurance charges for machinery are also included.	Real estate taxes paid are included, but all insurance costs are included in general overhead.
Interest	Data on actual operating and real estate interest paid are collected annually and allocated to the commodity in a similar fashion to general farm overhead.	Interest expenses are the commodity's share of charges actually paid for operating, machinery, and real estate loans. Interest on operating loans are allocated to the commodity based on the proportion of cash variable expenses. Machinery and real estate interest expenses are allocated to the commodity based on the proportion of the value of the machinery and land used for the

Table 1. Continued

Cash Expenses	USDA	University of Saskatchewan
		production of the commodity of the whole farm value of machinery and land.
Capital replacement	Based on a per-hour rate that each piece of depreciable equipment is used and on the hours per acre that each is used in the production process. Hourly capital replacement is calculated based on the current purchase price less salvage value divided by the hours used.	Based on the nominal loss in value of machines, equipment, and buildings between the beginning and ending of the period.
Charge to operating capital	Calculated based on the product of the value of cash variable expenses and the time between their use and harvest as a proportion of a year and the average interest rate on 6-month Treasury bills.	Calculated as the product of cash variable expenses and a 6% interest rate.
Charge to other nonland capital	Calculated based on the product of the current value of machinery and equipment used for the commodity by the real rate of return to agricultural assets over the previous 10-year period.	Calculated as the product of the beginning investment value of machines, equipment and buildings and a nominal 12% rate of interest.
Net land return	The rental rate is a composite rate based on cash rental rates and the value of share rental agreements. The production under share agreements is valued at the market price. All land, whether owned or rented, is charged a return.	Calculated as a blended charge of cash rent paid, the value of share rents, and an imputed charge for owned land. The charge for owned land is equal to the beginning value of land times 5% interest rate.
Unpaid labor	Calculated as the product of unpaid labor hours times the state average wage rate for hired labor. See hired labor for a description of how hours of unpaid labor are calculated.	Calculated as the product of unpaid hours and a wage rate of $7 (CAN). See hired labor for a description of how hours of unpaid labor are calculated.

procedures are different and which approach might be preferred, but that they are different and may, in fact, be responsible for the different levels of cost reported by the two sources. Methods for estimating costs of land are similar, however, and based on information on rental markets for wheat land. Again, we find that cost levels in the two regions are comparable when methods are similar.

Costs of production vary considerably across individual farms (Ahearn et al.). The analysis of cost of production throughout the range of cost levels can be useful for analysis of competitive position in two ways. First, the assessment can provide an indication of various quantities which could be supplied at certain levels at least in a shorter-run period. In the longer run, firms, could be expected to adjust to relative price changes and the cost curve may have a different shape. Second, assessment of cost variability can be useful in identifying the reasons certain producers are high cost producers and lead to the development of extension programs or policies to improve per unit of output cost levels. Of course, this type of analysis is fraught with the same limitations as are the average cost esti-

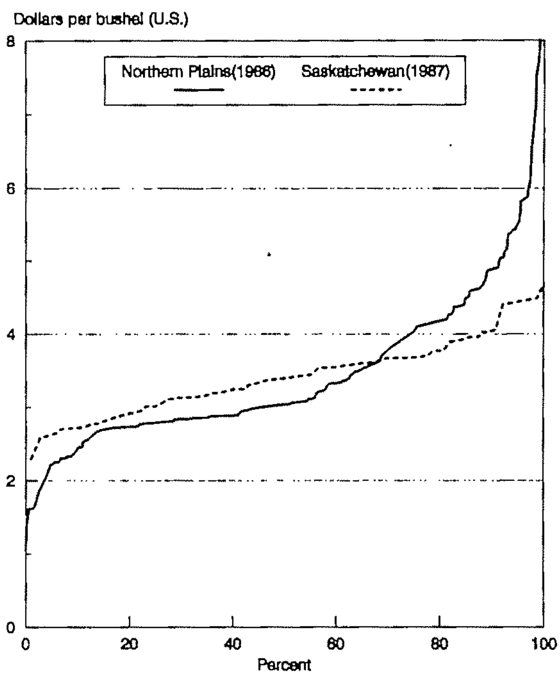

Figure 1. Cumulative distribution of economic production costs for wheat

mates if the underlying estimation methods are incomparable.

Figure 1 shows the cumulative probability distribution of wheat production costs per bushel in Saskatchewan and the U.S. Northern Plains. Two relevant observations can be made about cost distribution information. First, the distributions are quite similar except at the high cost end of the distribution. This is likely because of the low representation of small, generally high-cost producers who account for a small share of the production in the Saskatchewan sample. Second, the average economic cost of production for wheat in Saskatchewan was $4.31 (CAN) and the median was $4.19 (CAN). In 1988, with the severe drought conditions, the difference between the average and median was much greater. Average economic costs for Saskatchewan wheat were $8.51 (CAN) and the median was $6.41 (CAN). This illustrates the importance of analyzing the full range of cost estimates.

Conclusions

The purpose of this paper has been to explore the usefulness of cost of production estimates in the discussion of international competitiveness. Cost-of-production estimates can not be directly used to measure a country's competitive position. However, cost estimates are extremely useful and perhaps a country's leading indicator of competitiveness. In addition, this paper sought to establish that knowledge of the underlying estimation system is critical for evaluating whether comparative costs are real or a result of the estimation system. The most consistency in estimation methods was found to be in the estimation of cash variable costs. This is not surprising, given that these are also the costs that are most easily reported by farm operators.

International Comparisons of Agricultural Productivity: Development and Usefulness

Susan M. Capalbo, V. Eldon Ball, and Michael G. S. Denny

The simultaneous developments in duality theory, in the use of flexible functional forms in economic research, and in the theoretical linkages between index numbers and production technologies have augmented the tools to address productivity measurement.[1] As a result there have been many studies of agricultural productivity growth in the United States and other countries in the past two decades; international comparisons, however, have received considerably less attention.[2] While from a methodological point of view there is no reason to distinguish intertemporal from international productivity comparisons, the latter comparisons involve additional data-related problems. First, reliable information from many countries may be difficult to obtain. Second, each country's data must be measured in the same units. Third, comparability of input and output groups is needed. These groups are often less comparable among countries than over time within one country.

In this paper we provide an overview and critique of methods for comparing agricultural productivity and efficiency among countries that integrate economic production theory with empirical practices and discuss the relationship of these measures to competitiveness. We conclude by relating the methodological needs to ongoing efforts to construct an internationally consistent data set.

Framework for Productivity Analysis

Productivity research encompasses analysis of both changes in rates of growth and changes in levels. In theory, the distinction between growth rates and levels is trivial since one may be derived from the other. In practice, the uses have been quite different. Productivity growth is used as an indicator of how much more output can be obtained from a given set of resources by a given production unit, i.e., a firm, sector, or country. It is often used with time-series data. Productivity levels are often used to compare different production units at a point in time.

Measures of productivity are related to the production technology. They all involve a comparison of the output level produced relative to the inputs used. Output-based indexes measure productivity differences as differences in maximum output conditional on a given level of inputs; input-based indexes define productivity differences as differences in minimum input requirements conditional on a given level of output. Specific productivity indexes imply some assumptions about the underlying production technology.[3] Indexes that use only an incomplete list of inputs or measure output as value-added can be interpreted as implying restrictions on the technology in the latter case (Capalbo and Denny) and implicit assumptions about the role of other inputs in the former case.

There are two basic approaches to productivity measurement: parametric or statistical procedures and accounting or index number meth-

The authors also acknowledge the collaboration with C. E. Overton and A. Hoque.

[1] Antle and Capalbo review topics in modern production theory that relate to the productivity literature.

[2] Capalbo and Vo provide a review of intertemporal productivity rates for the U.S.; Nadiri and Kravis have produced surveys of international comparisons of productivity; Hoque et al. have synthesized the empirical research on international agricultural productivity. Other research includes the FAO report and papers by Behrens and DeHaen, Hayami and Ruttan, Yamada and Ruttan, and Nguyen.

[3] The Laspeyres indexing procedure implies a Leontief production function; the geometric index implies a Cobb-Douglas production technology; the Tornqvist index implies a homogenous translog production function.

ods. Parametric procedures rely on the estimation of the production technology. To illustrate, suppose the production function for each sector is known or can be estimated: $Y_i = f_i(k,l)$ where i indexes the sector, y denotes output, and k and l denote capital and labor, respectively. Select any input bundle (k_0, l_0) and calculate $y_{i0} = (f_i(k_0, l_0))$ for all countries. The sector in a particular country i will be more efficient than in country j if $y_{i0} > y_{j0}$. The proportional difference in output levels between any two sectors may be defined as the relative efficiency level, and an index can be constructed by defining a base sector. In general, the comparative ranking is not independent of the choice of the input bundle (k_0, l_0). This is desirable since it allows some countries to be more efficient than others for some input bundles and not for others. Otherwise, country i's production function would need to lie everywhere above country j's.

To use cost functions for comparing efficiency, a similar procedure is employed. Assuming that the cost functions, $g_i(w_k, w_l, y)$ for each country are known, choose a particular set of input prices, w, and output level, y, and calculate $c_{i0} = g_i(w_{k0}, w_{l0}, y)$ for each country. The lowest cost sector is the most efficient. The remarks made with respect to the nonuniqueness of the ranking to choice of the input bundle also pertain here to the choice of the input prices and output level.

If the data needed to estimate production or cost functions are available, making productivity comparisons utilizing the parametric methodology is straightforward. However, because all of the required information is rarely available, an alternative procedure for making productivity comparisons utilizes accounting methods which extract a measure of relative efficiency without knowing the complete production technology. The economic rationale for using the accounting approach to measure productivity differences among countries or sectors is found in a series of papers by Caves, Christensen, and Diewert (CCD) (1982a, b), and Denny and Fuss (DF) (1983a, b). These papers are, in part, a response to justify the methodology used by Jorgenson and Nishimizu to compare U.S. and Japanese aggregate productivity levels.

The preferred accounting method assumes that the production technology can be approximated by a second-order function.[4] In particular, a second-order approximation in the logarithms of the outputs and inputs will be used for the production function, and in the logarithms of the input prices, output levels and cost for the cost function. The second-order approximation assumption is utilized for several reasons: data limitations are likely to make higher-order approximations infeasible, and more important, use of a quadratic function as the second-order approximation allows direct linkage to the economic measures of productivity and efficiency. If the production function can be approximated by a quadratic function, then the use of Diewert's quadratic lemma implies that the difference in the logarithm of output between two sectors can be expressed exactly as a weighted sum of the differences in the logarithms of the inputs and a term which can be interpreted as the difference in the productivity level between countries.

To illustrate, let the logarithm of the production function $y_i = f_i(k, l)$ be approximated by a quadratic function in the logarithms of the input levels and a variable d which indexes the country, $\log y_i = f(\log k, \log l, d)$. This specification assumes that the production function in each country has some common elements, since f_i is replaced with f; the presence of d allows the zero and first-order terms in the function to differ. To analyze the differences in the level of output in countries i and j, we can apply Diewert's quadratic lemma to obtain

$$(1) \quad \log y_i - \log y_j = \frac{1}{2}(f_d^i + f_d^j)(d^i - d^j) + \frac{1}{2}(f_k^i + f_k^j)(\log k_i - \log k_j) + \frac{1}{2}(f_l^i + f_l^j)(\log l_i - \log l_j)$$

where f_z^i is the partial derivative of the production function with respect to the zth argument evaluated at the ith country's input vector.[5] The output differential in (1) is caused by a spatial (country) effect and an input effect.

Equation (1) states that the difference in the value of the production function can be evaluated only if the first-order derivatives and the data point are known. Using the assumptions of constant returns to scale and competitive markets, the first-order derivatives are the shares of

[4] An alternative accounting method is the axiomatic approach to index numbers (see Diewert 1986).

[5] Denny and Fuss (1983c) provide for a generalization of the quadratic lemma to the case of discrete variables.

the inputs in total cost and (1) can be rewritten as

$$\text{(2)}\quad \log y_i - \log y_j = \theta_{ij} + \frac{1}{2}[s_k^i + s_k^j][\log k_i - \log k_j] + \frac{1}{2}[s_l^i + s_l^j][\log l_i - \log l_j],$$

where s_h^i is the cost share of input h in country i; and θ_{ij} denotes the spatial effect.[6] Solving (2) for θ_{ij} yields an equation which can be used to measure the differences in productivity levels. The expression θ_{ij}, which is the Tornqvist approximation to the divisia index, can be interpreted as the output level in country i relative to that in country j after accounting for differences in the levels of inputs used by the two sectors. It is, in essence, the geometric average of two unobservable measures: how much output sector j would produce relative to sector i at j's observed input levels and at sector i's observed input levels.

Using duality results, θ_{ij} can also be interpreted in an approximate sense as a measure of relative cost efficiency. The methodology parallels the previous discussion for the production function. Let the cost function $C_i = g_i(w_k, w_r, y)$ be approximated by a quadratic function in the logarithms of input prices and output, and d, $\log C_i = g(\log w_k^i, \log w_l^i, y_i, d)$. Applying Diewert's quadratic lemma we obtain an expression similar to (1), which indicates that the cost differential can be broken down into a spatial effect, an input price effect, and an output effect. Constant returns to scale and perfect competition imply that the cost differential can be expressed as

$$\text{(3)}\quad \log C_i - \log C_j = \rho_{ij} - (\log y_i - \log y_j) - \frac{1}{2}(s_k^i + s_k^j)(\log w_k^i - \log w_k^j) - \frac{1}{2}(s_l^i + s_l^j)(\log w_l^i - \log w_l^j),$$

where s denotes cost shares, and ρ_{ij} is defined as the cost efficiency differences between i and j.[7] Using (3), the Tornqvist approximation to the divisia index of cost efficiency between countries i and j is given by

$$\text{(4)}\quad \rho_{ij} = (\log C_i - \log C_j) - (\log y_i - \log y_j) - \frac{1}{2}(s_k^i + s_k^j)(\log w_k^i - \log w_k^j) - \frac{1}{2}(s_l^i + s_l^j)(\log w_l^i - \log w_l^j).$$

Using (4) and (2), DF show that the Tornqvist approximations to the index of relative productivity differences and to the index of cost efficiency differences are equal (in absolute value) except for a term which is of "second-order of smallness," i.e., $\rho_{ij} \approx -\theta_{ij}$.[8]

The CCD papers convey a similar message: under constant returns to scale, the geometric mean of two Malmquist productivity indexes is equivalent to the Tornqvist productivity index, which can be computed using information on prices and quantities only.[9] Furthermore, under decreasing returns to scale one can use observed data on cost and revenue to adjust the Tornqvist productivity index to reflect the scale effect (see theorems 3 and 4 in CCD 1982a).

Limitations and Usefulness

The comments in this section pertain primarily to the index number approach to productivity level comparisons. In assessing the merits, one is reminded that the approach is designed to approximate the spatial and/or time derivatives of the production technology using only data on prices and quantities, and thus some limitations should be expected. The limitations stem from the underlying assumptions. Constant returns to scale is a convenient although not a necessary assumption. It is not possible, however, to relax the assumptions about competitive behavior, since these are required to eliminate the first-order derivatives. Furthermore, it is not possible in the

[6] If nonquadratic approximations are used, then the replacement for (1) will involve terms which include second-order derivatives of the production function. These second-order derivatives are related to the curvature of the production function and consequently to the price elasticities of factor demand. Unless one knows the elasticities it will not be possible to use accounting methods to evaluate (1).

[7] $\rho_{ij} = \frac{1}{2}\left(\frac{\partial g}{\partial d_i}\bigg|_{i=i} + \frac{\partial g}{\partial d_i}\bigg|_{i=j}\right)(d_i - d_j).$

[8] The θ_{ij} and ρ_{ij} can also be defined for the multiple output case using the further assumption of perfect competition in the output markets (see DF 1980).

[9] The country i Malmquist productivity index can be defined as

$$(a)\ m^i(y^i, y^j, x^i, x^j) = d^i(y^i, x^j)/d^i(y^j, x^j),$$

where y^i and x^i are country i's observed output and input vectors, and d^i is country i's output distance or deflation function. Since $d^i(y^i, x^i) \equiv 1$, the right-hand side of (a) is interpreted as the maximum inflation factor for the country j output vector such that the resulting inflated output vector, m^iy^j, and x^j are on the production surface of country i. If country i has a lower productivity than country j, from the perspective of country i's production structure, then $m^i < 1$ and vice versa.

quadratic framework to find a function other than the translog that will allow elimination of the derivatives using only data on prices and quantities; while this is restrictive in theory, it is probably irrelevant in practice. The approach also relies on the sectors having production or cost functions that differ in their zero- and first-order parameters but not in their second-order parameters.

How serious are these limitations? Clearly, no index number scheme will allow production structures to be completely different. Country-specific zero- and first-order parameters allow the intercept and slope of the production technology to vary but not the rates of change of the slope. They also imply that the output-compensated factor demand elasticities will be equivalent if prices and quantities are the same, or alternatively, the slopes of the factor demand functions are equal across countries.

The assumption of competitive markets is more complicated to evaluate because the issues are both conceptual and empirical. Conceptually, government policies are distorting the productivity measures if they are resulting in inefficiencies in production. If the producers are simply operating at a different location on the production possibility surface, then there is no inefficiency in resource use, although social welfare implications are likely. If the government programs constrain producers to be inside the frontier, then inefficiencies in resource use are introduced. A frontier production model would be one way to quantify these inefficiencies and possibly explain productivity differences.

Two possible solutions to obtaining distortion-free prices include calculating implicit and explicit subsidies per commodity and adjusting observed prices accordingly, or econometrically estimating the slope of the production technology and use the estimated marginal cost functions to obtain output prices. The latter, of course, hinges on having enough data to estimate the marginal cost or marginal value product functions. The first suggestion may be more reasonable given recent research on quantifying subsidies.

Another issue involves bilateral versus multilateral comparisons. The DF methodology discussed in the previous section is directly applicable to bilateral comparisons. By computing θ_{ij} or ρ_{ij} for each pair of countries, one has information on the magnitude and rank for each region relative to the others. If one is interested in the specific magnitudes of the relative efficiency levels, then direct bilateral comparisons are needed. However, the bilateral comparisons are in theory not transitive; one cannot derive the bilateral comparison of countries i and k from information on the bilateral comparisons of these two countries with a third country j.

CCD compare productivity levels to a hypothetical country or sector, and as such their approach is base-country invariant as long as the composition and/or number of countries is fixed. The multilateral comparisons, while eliminating the intransitivities of the comparisons, obscure the meaning of the magnitude of the productivity or efficiency differential.[10] If one is interested in summarizing a large number of possible comparisons, and the actual direct comparisons are of little interest, then the CCD approach may be preferred. If the comparisons are motivated by a particular country's interests, or if the number of sectors is small, then the DF approach is in our view preferred since the benchmark is an actual country, and the efficiency differential is easy to interpret cardinally.

Both θ_{ij} and ρ_{ij} are useful as components in understanding the larger notion of competitiveness. More specifically, a gap exists, both conceptually and empirically, between a country's competitiveness at the level of delivered goods and its costs of production, or cost efficiency, at the farmgate. This gap is important in agricultural comparisons because of the presence of government programs and distortions. The importance of the productivity measures as components of competitiveness also depends upon the time perspective. In the short run, exchange rates and trade policies are also major determinants of a country's competitiveness; in the long run, productivity and cost efficiency may become more dominant factors. Holding exchange rates, trade policies, transportation costs, etc., constant, higher efficiency means a country will be more competitive. Under these conditions, θ_{ij} and ρ_{ij} are useful for assessing a country's overall efficiency level *vis-à-vis* its specific competitors.

Finally, the productivity measures and in particular, the econometric measures, may provide a preferred set of information for the competitiveness discussions, because they reflect the economic tradeoffs and the diversity in agricultural production. By contrast, costs of production measures are less reflective of real-world

[10] As DF indicate, intransitivities arise because of "cross-overs": at certain data points, country j may be more efficient than country i and the reverse at other data points. The existence of intransitivities can be of interest in and of themselves.

situations and can be misinterpreted in the sense of lending "false precision" to the cost differences among sectors.

Data Development

The USDA is currently involved in efforts to create a consistent data base for the United States, Canada, United Kingdom, France, Federal Republic of Germany, and Netherlands. The objective is to provide international data on the prices and quantities of inputs and outputs which will be useful for more than simply productivity analysis. While a detailed discussion of these efforts is beyond this paper, we briefly highlight some aspects of the ongoing efforts.

The accounting framework is modeled along the guidelines of the United Nations "System of National Accounts." This system is designed to give a systematic and comparable presentation of the activities of each agricultural sector. The agricultural accounts are based on the concept of a "national farm" that represents a single agricultural holding producing the total output of agricultural products of a country's economy. Output is defined as the quantity sold plus stock changes and own-account fixed capital formation. Stocks consist of goods in progress (e.g., immature animals) and finished products from own production.

Gross capital formation is divided into two categories: (*a*) gross fixed capital formation; and (*b*) changes in stocks. (*a*) includes nonresidential structures, other construction, vehicles and other machinery and equipment. Estimates of capital stock are constructed as weighted sums of all past investment where the weights are the asset's efficiency as of a given age. The efficiency function is approximated by a rectangular hyperbola which incorporates several types of physical depreciation (e.g., straight line, geometric, etc.) as special cases.

Because the efficiency function is applied to a broad type of assets, a distribution of service lives is assumed. This is done by constructing a "cohort" efficiency function which is a weighted average of efficiency functions calculated using various asset ages. The weights are determined by a discard density function. The capital stock estimates reflect a concave physical depreciation pattern with a truncated normal distribution of retirement ages.

Own-account capital formation is not recorded in gross capital expenditure. However, the number of animals added to the fixed capital stock can be derived. These animals are valued at their opportunity costs if prices for replacement animals are not reported. Data have been compiled on the effects of age on productivity, culling rates which allow construction of cumulative survival functions, and genetic trends in certain animal traits such as milk yield, weaning weight, fleece weight, and litter size. The genetic trend measures embodied technical change. This information allows us to construct measures of relative efficiency which are, in turn, used to aggregate past investment.

The stocks of goods held in storage exclude commodities held by intervention authorities such as marketing boards or government held stocks. Animals included as fixed capital are also excluded. The stock estimates are for the beginning of the reference period.

The stock of land is an implicit quantity index of land in farms. It is assumed that farmland within a state (region) is homogenous in quality; hence, aggregation is at the state (regional) level. The measure of labor input reflects the changing composition of the farm work force. Data on hours worked and wage rates are cross-classified by occupational and demographic characteristics. Self-employed farmers are imputed the mean wage of hired workers with the same occupational and demographic characteristics.

Conclusions

In understanding international comparisons and how they relate to a country's competitiveness, both rates of growth and differences in productivity levels are important. Econometric and index number methods are applicable for making international comparisons. The econometric approach is based on estimation of the parameters of the production technology. The economic approach to index numbers generates formulas that are easily computed using price and quantity data and, most important, the indexes mesh with economic production theory. The index number approach reviewed in this paper is based on the assumption of optimizing behavior by producers; constant returns to scale is often assumed (although this is not necessary).

This paper has focused on the economic approach to index number measures of productivity because these measures are capable of being implemented in the near future and do not require extensive time series on outputs and inputs. While the approach provides a relatively easy way of ordering countries by their produc-

tivity levels, it should not be used to replace econometric or other methods of estimation in providing a detailed understanding of relative productivity levels.

European Community Experience in Costs of Producing Wheat

Hervé Le Stum and Denis Camaret

Wheat is a major French and European commodity. There are approximately 400,000 wheat producers in France producing 25 million metric tons of wheat on 4 million hectares. European Economic Community (EEC) wheat production is slightly higher than 70 million metric tons.

French wheat production is very intensive, as in all of the northern plains of Europe. Soft wheat is the main type of wheat produced in these plains, while Durum is cropped in the Mediterranean regions of the EEC. Yields are high in relation to North American standards. France averaged up to 6.4 metric tons per hectare in 1989, but production typically varies from 4 to 9 tons per hectare. These yields require high levels of nitrogen ranging from 150 to 200 units per hectare in three applications, similar to the U.S. corn production.

All French wheat producers belong to the Association générale des Producteurs de blé (AGPB), which is similar to the U.S. National Association of Wheat Growers.

AGPB, which is funded by wheat growers, owns two major organizations. The Institut Technique des Céréales et des Fourrages (ITCF) provides extension information to producers on how to improve production. The second organization is UNIGRAINS, which is a bank, owned and financed by the cereal growers. This bank does not loan to producers but finances the processing of cereal and animal products.

UNIGRAINS estimates the cost of production for wheat, barley, corn, rapeseed, and sunflowers. However, only wheat will be discussed in this paper, as it features the most detailed analysis.

This paper has the following objectives: (*a*) to present information regarding the costs and returns of French wheat production; (*b*) to evaluate the cost of production, study its trends, and compare costs with prices over time; (*c*) to compare the French situation with European and North American competitors (USDA cost-of-production data are available in France since 1979).

General Methodology

UNIGRAINS initiated French cost-of-production data for wheat because neither the Ministry of Agriculture nor research institutions or universities could provide information about this subject. Two methods of assessing cost of production were considered: (*a*) Starting from standards of production, in terms of labor, machinery and prices of inputs, like the USDA approach between 1974 and 1980. But this approach cannot meet the high variability in European actual farm conditions. This method proved unable to deal with the North American situation, and the USDA has modified its approach after 1980. (*b*) Consider the total farm and the total of its costs. Farm costs will likely not be equal to an optimized farm in terms of some inputs such as machinery or labor. But this method reflects the exact conditions of production in Western Europe, and in France.

UNIGRAINS selected the second method but did not have the resources to build a sample of cash grain farms. So, the selection was made using existing data. Three sources are available in France: (*a*) The European Community Network of Farm Accounts, as Réseau d'Information Comptable Agricole, RICA, in France, which is the basis of the so-called "objective method" of price establishment by the Commission, but no longer used for this purpose. But RICA provides no crop enterprise data. (*b*) The National Institute of Agricultural Research, INRA, has a good sample, but is too small (two groups of 25 farms) and located in a very narrow region of the Paris Basin. (*c*) The Institut de gestion et d'économie rurale, IGER, a federation of local accounting centers for farmers and paid by users. IGER has a data bank, which collects farm accounting records all over France, on a regional basis (French departement). This

Hervé Le Stum and Denis Camaret are affiliated with the Association Generale des Producteurs de Ble et Autres Cereales (AGPB), Paris, France.

allows geographical approaches. The problem is that these data are not homogenous across departements. Moreover, departements where cash-crops are relatively unimportant are unable to provide data. From this data bank, UNIGRAINS collects a sample of more than 3,000 farms, located in sixteen departements (fig. 1).

In summary, IGER data do not precisely meet the study data requirements nor are they representative of the total French production because they are somewhat biased toward the northern part of France, which is the specialized area in cash-crop farming. Nevertheless, the samples represent more than half of the French wheat production.

Each farm provides to the IGER data bank its general account and direct costs per crop. The direct costs are the following: seed, fertilizer, pesticide, custom operations with corresponding labor included, and, French and European commodity specific taxes.

These taxes are included in the farmgate price and are paid by the farmers for each ton of wheat sold. French tax calculations include wheat board (ONIC) and professional organizations, general agricultural extension services, and a special added contribution to social security. This tax on the product, which is paid only on cereals and oilseeds, is added to the normal general farm taxes based on the acreage of each farm.

This level of the direct costs is named "vari-

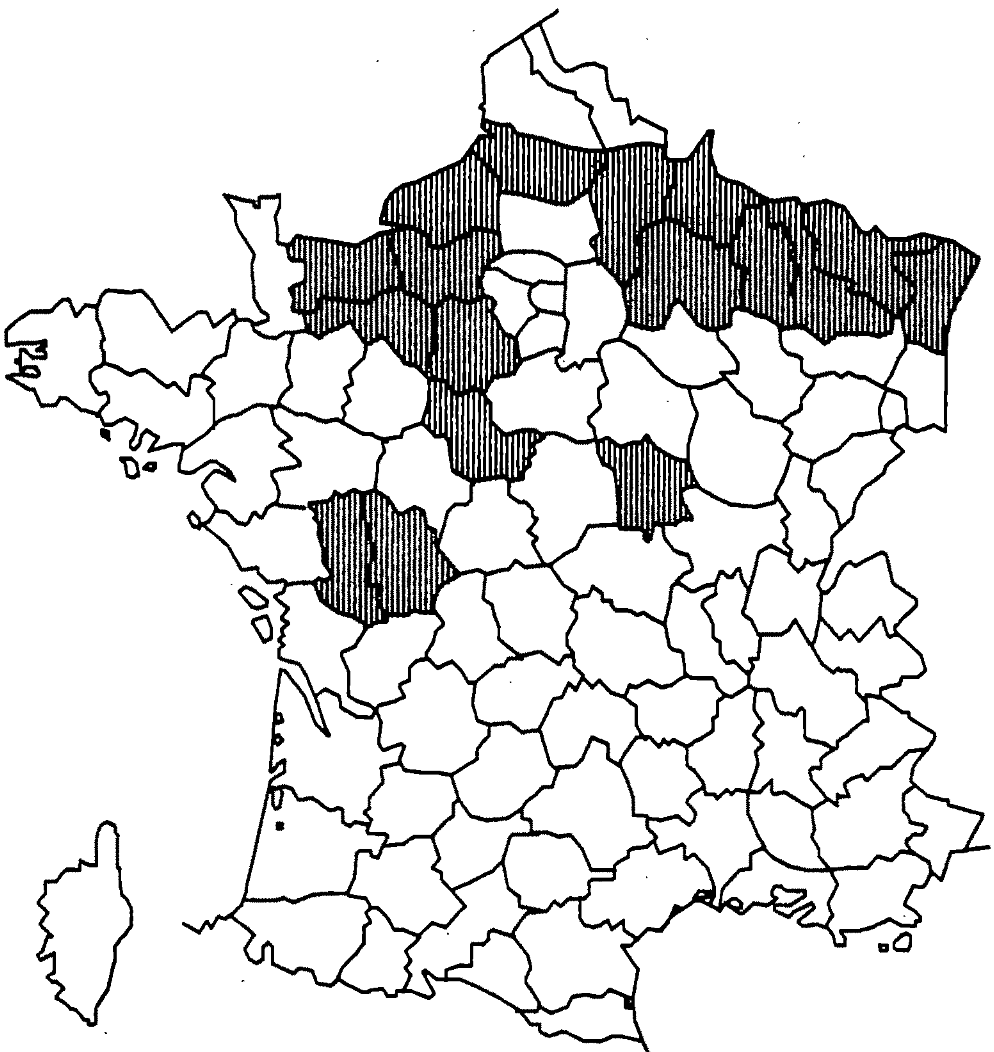

Figure 1. Areas of cost-of-production sample

able expenses." The difference between receipts and variable expenses is gross margin and provides the basis for the choice between crops in the rotation.

Indirect cash costs are repairs; fuel, lube, and electricity; hired labor; social security paid by the enterprise; insurance and general farm taxes; interests on operating loans; and general farm overhead. Allocation of indirect costs is always problematic. Different types of allocation schemes have been tested on real farms where more detailed data were available. But the key has to be a simple system that works for all farms. The results show that, for machinery, the best method is to allocate the cost in proportion of the acreage of the crop in the rotation; for other costs, the best allocation system is the proportion of the gross value of each enterprise of the total receipts of the farm. The sum of these cash costs constitutes the level 1 structural expenses. Returns over these expenses are not usually used by French farm management specialists.

Capital replacement and land costs are the level 2 structural expenses, which are a mix of cash and calculated costs. Capital replacement costs are extracted from the general farm accounts, which are based on French tax accounting rules. These costs are allocated in the same fashion as indirect costs. Machine costs are based on acreage; everything else is based on gross value. For land, no distinction is made between owned and rented land; all land is considered as rented, and in each departement the cost of owned land is calculated in the same manner as rented land.

Return over variable expenses and levels 1 and 2 structural expenses, which is defined as "agricultural income," diagnoses farm business health and is used by both banks and government institutions. Other items are seldom calculated.

Unpaid family labor is estimated from the actual presence of the family on the farm and is considered fixed. Hence, family labor is generally overestimated in comparison to technical requirements, but this reflects the situation of French and European farms, where people are full-time farmers but are not fully employed. Family labor wage rates are set at hired labor rates in the departement. Hence, considerable variability exists between regions.

The last item, the cost of nonland equity, is seldom calculated by accountants. UNIGRAINS values nonland equity at a low rate of interest (6%).

The following results of this research represent a weighted average of French production, the weighting is by the wheat production of each departement.

Main Results

The composition of the cost shows the predominance of the structural expenses (level 1 + level 2), which represents 50% of the total expenses. The variable expenses reach only a third of the cost (table 1).

While the absolute costs levels are important, it is more important to consider how costs have varied over time. UNIGRAINS files began in 1982, but data collection and processing delay the results; in the summer of 1990, only data for 1987 are available. Data for 1988 and 1989 costs are extrapolated by use of indices.

Main conclusions regarding the costs of wheat production in French francs over time are (fig. 2):

(*a*) From 1982 to 1986, the cost of production per hectare has risen 30%, then stabilized in current value.

(*b*) The variable expenses have slightly decreased after 1986, but it is difficult to stabilize structural expenses.

(*c*) The cost per metric ton displays different patterns than costs per hectare because of variations in yields: costs per ton were stable from 1982 to 1984 (1984 yields were very high), increased substantially in 1985 to 1987 (bad yields), decreased in 1988, and finally stabilized in 1989.

(*d*) Gross value of production per hectare has increased at an annual rate of 4% from 1982 to 1986. The decrease and stabilization in the following years were caused by the European Common Agricultural Policy with the scheme of Maximum Guarantee Quantities which pro-

Table 1. Cost of Wheat Production in France, by Item (Crop Year 1987)

Item	French Francs per Hectare	US$ (1987) per Hectare	Rounded %
Variable expenses	2,255	375	28
Specific taxes	515	86	6
Structural expenses (Level 1)	2,235	371	28
Structural expenses (Level 2)	1,880	312	24
Family labor	845	140	11
Cost of owned capital	265	44	3

Source: UNIGRAINS.

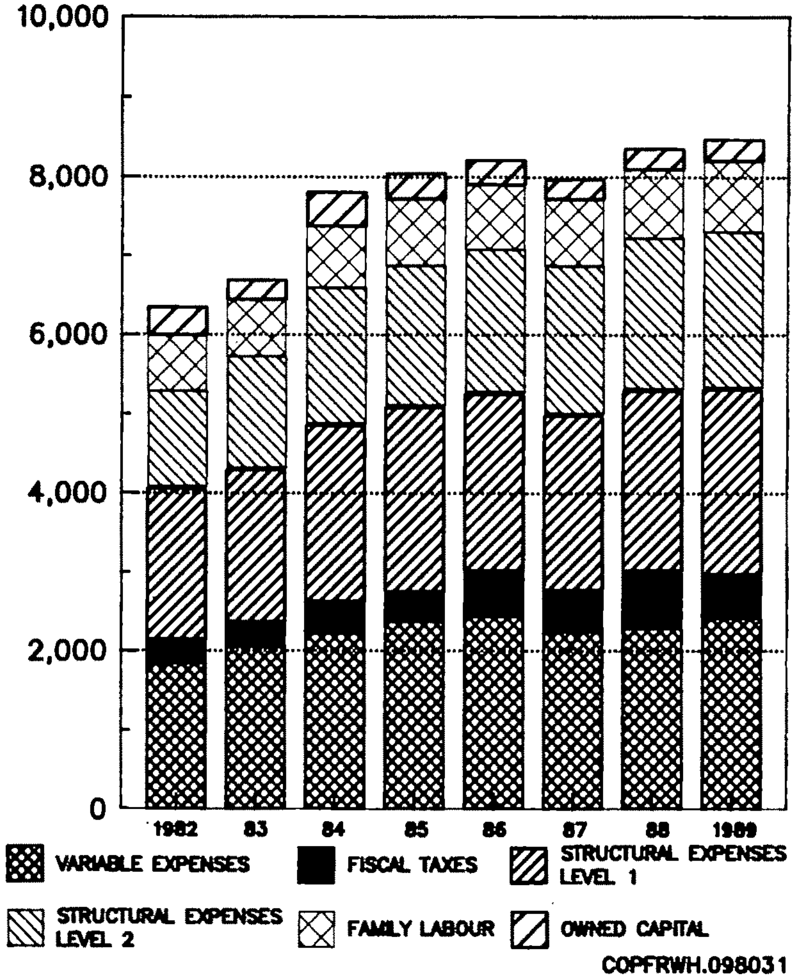

Figure 2. Cost of production of French wheat (FF/ha)

vides, as a result, a decrease in cereal prices of 3% per year.

(*e*) The net return to management and risk per hectare was positive the first years (1,000 FF/ha—143 to 124 US$/ha following year value of US$), null in 1985, very negative (−700 to −800 FF/ha = −54 to −150 US$/ha) in 1986 and 1987 and negative but near zero the last years.

Interestingly, trends in wheat production costs are considerably different when expressed in U.S. dollars (fig. 3). The value of the U.S. dollar increased by 37% between 1982 and 1985, then decreased by 33% from 1985 to 1987. The increase of the French cost per hectare in francs from 1982 to 1986 is turned into a slight decrease in U.S. dollars. The stabilization of the cost in francs after 1986 appears as an increase in dollars.

From a European point of view, wheat production has not been profitable since 1985. As a result, the cost per hectare has stabilized as farmers adapted to a changing, less profitable environment. Other indicators, as the index of income of French cash grain crops, show the same trend. In Francs, the decline reached 35% in five years in real value. Moreover, the disparity between the French farmers which are significantly larger than southern French farmers who have lower yields and incur more drought risks, is increasing over time. Unfortunately, our data cannot precisely measure the differences.

Comparisons in the EEC

UNIGRAINS has begun comparing the costs of production between different EEC countries. The costs of wheat production are compared based on 1988 data.

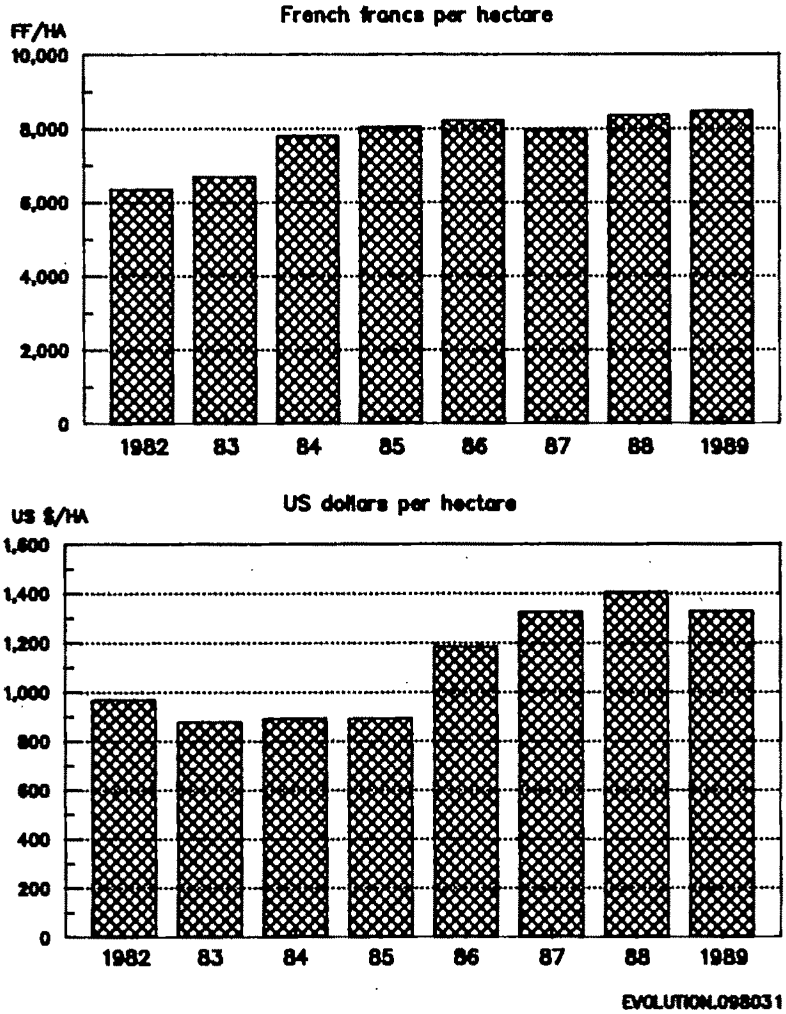

Figure 3. Evolution of the cost of production of wheat

In all countries, except the United Kingdom, it is difficult, as in France, to find good data. This task is made more difficult when the country has many small farms and is located in southern Europe. Data exist in Germany but are not easily available. In Italy and Spain, farm accounts often simply do not exist, even for large farms. Hence, research is limited to specialized grain areas with full-time farming.

Inside the EEC, problems of currencies, government programs, taxes, and price distortions exist in the same way as between EEC and USA or Australia. Hence, the comparisons are not easily made, and the analysis had to be simplified. The general scheme of analysis is the same as in the first part of this paper but COP for France in table 2, even price per ton, cannot be directly compared with those of table 1. Nevertheless, a number of rough comparisons can be made based on 1988 crop year data.

In terms of cost per hectare, the lowest COP is in Castilla-Leon in Spain. Because of the low input intensity, it generates per hectare cost of only half of the European average. Cost per hectare in East Anglia in United Kingdom and Paris Basin in France are at the same level, approximately twice as high. The Pô Valley in Italy is 10%–15% higher than France and the United Kingdom. Fionna in Denmark and Lower Saxen in Germany are 30% higher.

In terms of cost of production per metric ton, the results are not similar. The lowest costs are observed in East Anglia and Paris Basin, around 145 ECU per metric ton, 145 US$ per ton for an exchange rate of 1 for 1 (which seems to be the long-term rate), 169 US$ for 1988 exchange

Table 2. Costs of Production for Wheat in the EEC, 1988 Crop Year (commercial ECU)

	Fionna Denmark	Lower Saxen Germany	East Anglia U.K.	Paris Basin France	Pô Valley Italy	Castilla Leon Spain
Yield (t/ha)	7.2	7.2	6.9	7.3	6.7	2.7
Price per tonne	183	179	163	154	177	186
Cost per hectare	1,343	1,314	1,000	1,029	1,186 to 1,100	443
Cost per tonne	186	183	144	143	176 to 164	166
Net return per hectare after taxes	−31	+67	+83	+76	+1 to +85	+41

Source: UNIGRAINS.

rate and 178 US$ for the exchange rate of July 1990. COP per tonne in the Pô Valley and Castilla Leon are 15% higher and Fionna and Lower Saxen, 30%. So, in the European context, intensive production seems to be more competitive than extensive production.

But, in the Common Market, prices are not equalized because of monetary disparities. Prices are higher in countries where costs are high, and the differences of competitiveness are restrained a first time.

In some countries, general taxation and government policies can cancel a handicap of competitiveness and reverse profitability patterns, as in Germany (table 2).

Conclusion

The following conclusions can be made from this analysis. A large number of difficulties are encountered in both intracountry and intercountry comparisons. Intracountry results can be improved by the establishment of a series of COP. Nevertheless, the following problems must be addressed: (*a*) The sample should be extended to the southern regions of France, in order to have a more representative sample of French wheat production; this will be possible with time. (*b*) Comparisons with optimized costs should occur to allow a better appreciation of progress in production costs. (*c*) The study should include an examination of COP variability and its underlying causes. (*d*) The work with other European countries requires the building of a network of cooperation, but it will always suffer from the lack of data for some countries.

Food Insecurity
(Mark Newman, Abt Associates, Inc., presiding)

Optimal Control of Food Insecurity: A Conceptual Framework

Truman P. Phillips and Daphne S. Taylor

During the past three decades, the focus of food security research has evolved from an examination of concepts such as nutrition, food production, and pricing policies to an examination of household and national level food security systems and mechanisms.[1] In the 1960s, research focused on expanding agricultural production and supply. In the early 1970s, the variability in food supplies led to research on buffer stocks, balance of payments stabilization, trade, and food aid policies and programs. In the 1980s, if measured by the degree to which global food supply and food stocks increased, national and international food security efforts would appear to have been successful. However, as we enter the 1990s, problems of household and individual food insecurity persist.

It is estimated that in 1989, 550 million people did not have enough to eat, and many more lacked both adequate quality and quantity of food to meet specific nutritional requirements (WFC 1990). Regionally, 60% of the undernourished live in Asia, 30% in Sub-Saharan Africa, and 10% in Latin America, with the absolute number of undernourished growing fastest in Africa. Although the vast majority of hungry people live in countries with very low average per capita incomes, food insecurity is not restricted to those countries. In the United States, it is estimated that 20 million people do not have access to sufficient food (WFC 1990).

Researchers now accept the fact that the causes of food insecurity have still not been properly addressed. In particular, it is realized that many of the earlier studies of food security failed to recognize that national food security did not imply household or individual food security, and that food security today does not imply food security tomorrow. The following quote from Simon Maxwell highlights the need for continued research at a disaggregated level while the quote from the World Food Council indicates the need to understand food insecurity as a dynamic concept.

> It ought to be axiomatic that food security planning must begin with an analysis of "who is food insecure and why": only by combining a taxonomy of food insecurity with an analysis of why it occurs can appropriate interventions be planned and their effect predicted. The identification of food insecure groups is required at different levels of aggregation: in broad socio-economic and geographical aggregates for national policy making: in more detail for the allocation of resources at regional or district level; and in enough detail to allow discrimination between individuals when it comes to implementing targeted programmes such as emergency relief or supplementary feeding. Despite the surge of interest in food security, especially in sub-Saharan Africa, these issues of description and analysis remain neglected. The gap has certainly been felt in Sudan, where the IDS review of food security issues in 1988 concluded that better understanding of food insecurity was the single greatest priority in improved food security planning. (Maxwell, p. 1)
>
> Food security implies two things. First, it implies that food is available, accessible, affordable—when and where needed—in sufficient quantity and quality. Second, it implies an assurance that this state of affairs can reasonably be expected to continue; or, in other words, that it can be sustained. To put it simply, food security exists when adequate food is available to all people on a regular basis. (WFC 1988, p. 2)

In this paper a conceptual framework of food insecurity is presented which highlights both the importance of the household and the dynamic nature of food insecurity. The purpose of the paper is to describe the conceptual framework

Truman P. Phillips is director, and Daphne S. Taylor is an associate, Centre for Food Security, University of Guelph.

The authors would like to thank Alfons Weersink, Wayne Howard, and Kene Ezemenari for their helpful comments.

[1] The literature in this area is extensive. An excellent collection of research articles may be found in *Food Security: Integrating Supply, Distribution and Consumption*, by Gittinger, Leslie, and Hoisington. Other books include *Food Security for Developing Countries*, by Valdes; *World Food Security: Selected Themes and Issues*, by the FAO; *Coping with Hunger*, by Bigman; to name just a few.

and to illustrate that when expressed as an optimal control problem, it can assist in the planning and targeting of appropriate food security interventions. The next section presents the conceptual framework of food insecurity. The third section demonstrates food insecurity as a control problem for a single household and multiple households. We then provide a discussion of data implications and, finally, a summary.

A Conceptual Framework of Food Insecurity

The definition of food insecurity adopted in this paper is: A state of food insecurity exists when members of a household have an inadequate diet for part or all of the year or face the possibility of an inadequate diet in the future.

The two fundamental concepts implicit in the above definiton are that food insecurity is defined in terms of the household, and that food insecurity relates to both the current and future adequacy of the household diet.

Following from this definition, our concept of household food insecurity can be expressed mathematically as

$$FS = CS + f(R, I, HT).$$

This equation states that the determination of the future state of household food insecurity (FS) entails an assessment of the current state of household food insecurity (CS) and the likelihood of deviation from this state ($f()$). This deviation is a function of food insecurity risks (R), food insecurity insurances (I) and household types (HT). The following paragraphs define these variables.

Current State of Household Food Insecurity (CS)

This refers to the adequacy of the household's present food consumption. An assessment of the current state of household food insecurity should be based on both the quantity and quality of the household's diet and should indicate if the household is in a state of food security (all members of the household have an adequate diet throughout the year) or a state of food insecurity. States of food insecurity may be defined in terms of types of food insecurity (e.g., temporary, cyclical, chronic), levels of food insecurity (e.g., dietary intake as a percentage of an acceptable standard), or a combination of both.

Deviation from the Current State f(R, I, HT)

Deviation from the current state refers to the likelihood of deviation from the household's current state of food insecurity and is based on an assessment of food insecurity risks, insurances, and household types.

Food Insecurity Risks (R)

These refer to events which increase food insecurity, or, in other words, lessen household food consumption. Food insecurity risks can be measured both by the damage caused by these events and by the likelihood that these events will occur. Risks may emanate from natural or manmade causes and they may impact on the entire population or be restricted to selected households. Examples of risks include food shortages prior to harvest, temporary marketing problems, seasonal or unforeseen unemployment, exceptional increases in prices, civil strife, chronic poverty.

Food Insecurity Insurances (I)

These refer to actions which decrease the likelihood that risky events happen and/or their resulting damage. Food insecurity insurances may be actions taken by households, communities, or nations. Insurances may address the root causes of food insecurity or they may address the symptoms of food insecurity, namely hunger. Examples of insurances which address the root causes of food insecurity include increasing employment opportunities, land reform, and use of improved agricultural production techniques. Examples of insurances which address symptoms include local charity, supplementary feeding programs, and emergency food aid. As these examples indicate, many food insecurity insurances are provided through government policy interventions and programs.

Household Type (HT)

Household type refers to a taxonomy of household types which reflect such things as the means and methods by which households acquire food for consumption. Two broad household types are the market-food-oriented household and the nonmarket-food-oriented household. A market-food-oriented household may be defined as any

household that acquires the bulk of its food through the exchange of resources such as cash, services, or goods. A non-market-food-oriented household may be defined as any household that acquires the bulk of its food supplies through home food production. These household types may be further refined by grouping households by sources of income, by percentage of market dependence, resource base, or location such as urban or rural.

A breakdown by household type is important because food insecurity risks and insurances do not affect all households equally. For example, a risk such as a downturn in the economy or an increase in unemployment could increase the food insecurity of a market-food-oriented household but would not necessarily change the food insecurity state of a non-market-food-oriented household. Similarly, insurances which increase agricultural resources or provide new agricultural technologies could benefit the non-market-food-oriented household but would do nothing, in the short run, for an urban market-food-oriented household.

To summarize, the household in this conceptual framework is the basic building block for food insecurity analyses. By using the concepts defined in the framework to synthesize household-level data, an initial assessment may be made of the number of households (or population) that are food insecure, the severity of the insecurity, the risk factors that are contributing to food insecurity, and the insurance measures needed to combat food insecurity.[2] For policy purposes, this means that household aggregations can be used for community and national level food security planning, monitoring, and evaluation.

To further illustrate the usefulness of our conceptual framework, the following section demonstrates how our conceptual framework may be cast as an optimal control problem which may assist in the planning and targeting of appropriate food security interventions.

Food Insecurity as a Control Problem

A food security planner's ideal objective might be to provide an adequate supply of food to all people on a regular basis (WFC 1988). The challenge for the planner is to efficiently use resources (physical, monetary, or human) towards this end. In economics, this objective and challenge can be referred to as an optimal control problem: i.e., the optimal allocation of scarce resources among competing ends over an interval of time to satisfy a stated objective. An optimal control problem consists of time, an objective functional, state variables, control variables, and equations of motion (Intriligator, p. 292). Assuming that the variables of the framework can be expressed in numerical units, the following paragraphs illustrate how the components of the conceptual framework may be formalized as an optimal control problem.[3]

Time

In general, control problems require the specification of initial time and terminal time.[4] In terms of our conceptual framework, initial time, t_0, corresponds to the time when the current state of household food insecurity is evaluated. Terminal time, t_1, corresponds to the time when the future state of household food insecurity is evaluated. From a planner's point of view, the terminal time may be dictated by budgetary and political factors and is probably in the range of three to five years into the future.

States of Household Food Insecurity

Such states are represented in the control problem by state variables, $x(t)$, which characterize the system at any point in time, t. Current state (CS) is equivalent to the state of household food insecurity at the initial time, $x(t_0)$. Future state (FS) is equivalent to the state of household food insecurity at the terminal time, $x(t_1)$. For discussion purposes, it will be assumed that the state of household food insecurity ranges from 0, extreme insecurity, to 1, food security [equation (1)].

$$(1) \qquad 0 \le x(t) \le 1,$$

where $x(t)$ is a state of household food insecurity at time, t.

[2] An example of this type of analysis may be found in *Food Security: an Analysis of the SEARCA/Guelph Survey*, by Phillips and Taylor.

[3] For example, the components of the framework may be expressed in ordinal units such as months of inadequate or adequate diet or in scalar units ranging from 0 to 1.

[4] The terminal time may be undefined if transversality conditions hold; the terminal time is bounded or if it is defined by a known function (Kamien and Schwartz).

Deviations from the Current State

Deviations from the current state are represented in the control problem by equations of motion which are differential equations describing the time rate of change of state variables. Based on the conceptual framework, equations of motion describing the time rate of change in states of food insecurity may be expressed as functions of insurances,[5] risks and household types.[6]

In the discussion of the conceptual framework, it was suggested that changes in the state of household food insecurity are negatively affected by risks and positively affected by insurances.[7] It may also be assumed that the amount of food insecurity insurance required to change the state of household food insecurity is positively correlated to the severity of the insecurity. That is, to render a given change in household insecurity requires more insurance for a highly food insecure household than for a moderately food insecure household. Taking these factors into consideration, the following equation of motion is specified [equation (2)] which states that the change in a household's state of food insecurity in a given time period is equal to the amount of insurance that is provided to the household, adjusted for its state of food insecurity, minus the amount of risk faced by the household.

$$(2) \qquad \dot{x} = [\beta U(t) - \gamma(1 - x(t))] - \sigma\frac{dz}{dt},$$

where $\dot{x}$ is the time rate of change of the state of household food insecurity; β is the change in the state of household food insecurity per unit of insurance; $U(t)$, the number of units of insurance provided to the household at time t; $(1 - x(t))$, the severity of the state of food insecurity at time t; γ, the insurance penalty associated with the severity of food insecurity; $\gamma(1 - x(t))$, the additional insurance needed given the severity of the state of food insecurity at time t; $\sigma(dz/dt)$, risk, the stochastic disturbance which renders the movement of state variables undeterministic; σ, the standard deviation of the risk; and dz is the incremental of the stochastic process that obeys Brownian motion (Kamien, p. 243).

The above discussion outlines one approach to formalizing the variables of the conceptual framework into optimal control problem terminology.[8] The following sections illustrate how this specification of the conceptual model can be used as a food security planning tool for problems facing single and multiple households.

A Single-Household Problem

For the conceptual framework to be used as a food security planning tool, an objective functional must be specified. While many objective functions can be defined, for purposes of exposition, a planner's objective for a single household could be to select appropriate food insecurity insurances which result in the greatest reduction in household food insecurity within a specific time interval.[9] This objective functional is expressed as

$$(3) \qquad \text{Maximize } x(t_1) - x(t_0),$$

which states that the objective is to maximize the improvement in the household's food security within the time interval $t_1 - t_0$. Furthermore, it can be assumed that the planner is constrained by a budget which limits the amount which can be spent on food insecurity insurances and the planner requires that household food insecurity not worsen from its initial state.

Thus, the planner's optimal control problem for the single household can be expressed as

$$\text{Maximize } x(t_1) - x(t_0),$$

subject to

$$\dot{x} = [\beta U(t) - \gamma(1 - x(t))] - \sigma\frac{dz}{dt}$$

$$x(t) \geq x(t_0)$$

$$C(t)U(t) \leq B(t) \quad \text{for} \quad t = 1, 2, \ldots, t_1$$

$$0 \leq x(t) \leq 1,$$

[5] Food insecurity insurances are analogous to control variables in the control problem literature.

[6] Household types will be introduced in the section entitled "A Multiple Household Problem."

[7] Insurances may address the root causes of food insecurity or the symptoms of food insecurity. The former type of insurances contribute to a change in the state of household food insecurity, while the latter may not contribute to changes in states of household food insecurity in the long term. For this paper it will be assumed that all insurances address the root causes of food insecurity.

[8] Alternative, more realistic, and thus more complicated specifications of the model are also possible, although they are not illustrated here.

[9] Alternative objective functionals could be to minimize the time required to make a household food secure, minimize the cost of insurances required to bring about a specific change in food security, minimize the amount of insurance required to maintain current states of food security, etc.

where $C(t)$ is the cost of a unit of insurance in time t, and $B(t)$ is the total insurance budget available to the household in time t.

The maximum principle technique can be used to solve the planner's problem for the final state, $x(t_1)$, interim states, $x(t)$, as well as the timing and amount of food insecurity insurances, $U(t)$ for $t_0 < t < t_1$, given that the following variables are known: t_1; $x(t_0)$; $C(t)$; β; γ; σ; $B(t)$.

The maximum principle technique can be considered an extension of the use of Lagrange multipliers to optimal control problems and is often the most useful since in "contrast with classical calculus of variations, it can cope directly with general constraints on the control variables and, by contrast to dynamic programming, it usually suggests the nature of the solution" (Intriligator, p. 344).

For purposes of exposition, and in an attempt to highlight the substantive points of the conceptual framework rather than small complexities of the model, a more general Hamiltonian will be specified than that implied by the above statement of the single-household optimal control problem. Specifically, the constraint on the range of state variables, $0 \le x(t) \le 1$, and the constraint that the state of food insecurity can not worsen from its initial state, $x(t) \ge x(t_0)$, were not included in the Hamiltonian. In addition, the probability of a risk occurring was assumed to be 100%, reducing the risk term in the equation of motion, $\sigma(dz/dt)$, to zero. This additional assumption means that it is not necessary to utilize Itô's calculus.

Adopting the above simplifications, the generalized Hamiltonian is

$$H = x(t_1) - x(t_0) + \lambda_1(\beta U(t) - \gamma(1 - x(t))) + \lambda_2(B(t) - C(t)U(t)),$$

where λ's are costate variables.

Applying the maximum principle, assuming that $t_0 = 0$ and the insurance budget is constant through time, leads to the following solution:

$$\frac{\lambda_1}{\lambda_2} = \frac{C(t)}{\beta}$$

$$x(t) = x(t_0)e^{\gamma t} + (1 - e^{\gamma t})\left[1 - \frac{\beta}{\gamma}U(t)\right],$$

where λ_1 is the costate variable of the equation of motion, and λ_2 is the costate variable of the budget constraint.

This solution states that the change in the state of household food insecurity per unit of insurance equals the marginal cost of providing that insurance. From this general solution, it can be shown that if the state of household food insecurity is not allowed to worsen, $\dot{x} \ge 0$, then the amount of insurance offered the household is defined by the following equation:

$$U(t) \ge \frac{\gamma(1 - x(t))}{\beta}.$$

This result combined with the constraint that the state of food insecurity ranges from 0 to 1, indicates that the amount of insurance applied to the household ranges from 0 when the household is food secure, $x(t) = 1$, to γ/β when the household has extreme food insecurity. This solution is only possible if there is sufficient budget to provide the necessary insurance. That is,

$$C(t)\frac{\gamma(1 - x(t))}{\beta} \le B(t).$$

The solution to this single-household problem is as expected, namely that the marginal benefits of lessening food insecurity will equal the marginal cost of the insurance required to bring about this change. Furthermore, the reduction in food insecurity will be within budgetary constraints and will happen as quickly as possible.

A Multiple Household Problem

Expanding on the previous example, the control problem is specified again to include multiple households. While many objectives can be defined, for purposes of exposition, the objective functional for the multiple household optimal control problem will be to select appropriate food insecurity insurances over time which result in the greatest reduction in household food insecurity.

As noted in the discussion of the conceptual framework, food insecurity risks and insurances do not affect all households equally. Therefore, it is necessary to define state variables for groups of households. Such household groupings may be based on household types and states of current food insecurity. This means that the state of household food insecurity at any time t is written as $X_{hs}(t)$, where the subscripts h and s identify all possible combinations of household type and states of food insecurity at t_0. The implicit assumption is that all households of type h and current state of food insecurity s are considered homogenous, facing the same risks and responding equally to the same insurances. The

planner's objective is to determine the optimal allocation and scheduling of targeted insurances to these *hs* household groupings. State variables are still restricted to values between 0 and 1.

Thus the planner's optimal control problem for multiple households can be expressed as:

$$\text{Maximize} \sum_{h=1}^{N} \sum_{s=0}^{1} n_{hs} X_{hs}(t_1) - \sum_{h=1}^{N} \sum_{s=0}^{1} n_{hs} X_{hs}(t_0),$$

subject to

$$\dot{X}_{hs} = [\beta_{hs} U_{hs}(t) - \gamma_{hs}(1 - X_{hs}(t))] - \sigma_{hs} \frac{dz}{dt}$$

$$X_{hs}(t) \geq X_{hs}(t_0)$$

$$C(t) \sum_{h=1}^{N} \sum_{s=0}^{1} U_{hs}(t) n_{hs} \leq B(t)$$

$$0 \leq X_{hs}(t) \leq 1.$$

The subscripts are defined as follows: h is the household type, ranging from 1 to N, at t_0; s is the state of household food insecurity, ranging from 0 to 1, at t_0. The variables are defined as follows:

$X_{hs}(t)$ is the state of food insecurity for each household in the *hs*th group at time t;

$X_{hs}(t_0)$, the state of food insecurity for each household in the *hs*th group at time t_0;

$X_{hs}(t_1)$, the terminal state of food insecurity for each household in the *hs*th group at time t_1;

n_{hs}, the number of households in the *hs*th group;

$\dot{X}_{hs}$, the time rate of change of the state of food insecurity for each household in the *hs*th group;

$U_{hs}(t)$, the number of units of insurance provided to each household in the *hs*th group at time t;

$\sigma_{hs}(dz/dt)$, the amount of risk facing each household in the *hs*th group;

σ_{hs}, the standard deviation of the risk facing each household in the *hs*th group;

dz, the incremental of the stochastic process that obeys Brownian motion (Kamien, p. 243);

$C(t)$, the cost of a unit of insurance at time t;

$B(t)$, the total insurance budget available in time t;

N, the number of defined household types.

The definitions of the parameters are: β_{hs} is the change in the state of food insecurity per unit of insurance for the *hs*th household group, and γ_{hs} is the insurance penalty associated with the severity of food insecurity for the *hs*th household group.

The problem is solved for the states of food insecurity for each *hs* household group at terminal time, $X_{hs}(t_1)$, and interim time, $X_{hs}(t)$, and the amount and timing of food insecurity insurance available to each household in each *hs* group, $U_{hs}(t)$ for $t_0 < t < t_1$, given that the following variables are known: t_1; $X_{hs}(t_0)$; N; n_{hs}; β_{hs}; γ_{hs}; σ_{hs}; $C(t)$; $B(t)$.

Utilizing the same simplifications as were used to solve the single-household problem, the generalized Hamiltonian for the multiple household problem is specified as

$$H = \sum_{h=1}^{N} \sum_{s=0}^{1} n_{hs} X_{hs}(t_1) - \sum_{h=1}^{N} \sum_{s=0}^{1} n_{hs} X_{hs}(t_0) + \lambda_1(\beta_{hs} U_{hs}(t) - \gamma_{hs}(1 - X_{hs}(t))) + \lambda_2\left(B(t) - C(t) \sum_{h=1}^{N} \sum_{s=0}^{1} U(t)_{hs} n_{hs}\right).$$

And this leads to the following solution:

$$\frac{\lambda_1}{\lambda_2} = \frac{C(t) n_{hs}}{\beta_{hs}}$$

$$X_{hs}(t) = X_{hs}(t_0) e^{\gamma_{hs} t} + (1 - e^{\gamma_{hs} t})\left[1 - \frac{\beta_{hs}}{\gamma_{hs}} U_{hs}(t)\right],$$

where λ_1 is the costate variable of the equation of motion, and λ_2 is the costate variable of the budget constraint.

Again, from this general solution, it can be shown that if the state of household food insecurity is not allowed to worsen, $\dot{X}_{hs} \geq 0$, then the amount of insurance offered the *hs*th household is defined by the following equation:

$$U_{hs}(t) \geq \frac{\gamma_{hs}(1 - X_{hs}(t))}{\beta_{hs}}.$$

This result combined with the constraint that the state of food insecurity ranges from 0 to 1 indicates that the amount of insurance applied to a household ranges from 0 when the household is food secure, $X_{hs}(t) = 1$, to γ_{hs}/β_{hs} when the household has extreme food insecurity and is only possible if there is sufficient budget to provide the necessary insurances. That is,

$$C(t) \sum_{h=1}^{N} \sum_{s=0}^{1} n_{hs} \frac{\gamma_{hs}(1 - X_{hs}(t))}{\beta_{hs}} \leq B(t).$$

The solution to the multiple household problem thus suggests how different groups of households should be targeted for food insecur-

ity insurances so as to bring about the greatest reduction of food insecurity.

Data Implications

The data requirements to undertake the above analysis include household-level data for the identification of household types, the assessment of current states of household food insecurity, and the identification of risks and insurances. Community and national level data are required for the identification of risks and insurances which do not originate at the household level. Current research and surveys in food security are now providing this type of data (Phillips and Taylor).

The area of greatest data paucity is that required to develop the equations of motion, specifically the estimates of β and γ. While estimates of β and γ are limited, it is possible to use expert opinion to find reasonable proxies of the changes that can be expected in household food insecurity per unit of risks and insurances. Previous studies related to nutrition, production, price analysis, etc., can be used to provide additional estimates of these parameters.

Summary

Briefly, our conceptual framework embraces the following components: states of food insecurity (both current and future), risks, insurances, and household types. It contributes to the understanding of food insecurity in a number of ways. It focuses on the household where the problem of food insecurity exists. It recognizes that there are different types and levels of food insecurity and can accommodate alternative definitions. It identifies causes of and possible solutions to food insecurity by examining the impact of risks and insurances on households. It recognizes that these causes and solutions vary for different household types, and it captures the dynamic nature of food insecurity by examining both the current and future adequacy of household diets.

Furthermore, the paper illustrates that the conceptual framework may be quantified when expressed as an optimal control problem. The optimal control problem allows for dynamic optimization which can assist with the planning and targeting of food insecurity interventions. While the optimal control problem specification of our conceptual model was simplistic, it is hoped that the reader can appreciate how the concept can be used to address the problem of food insecurity in a holistic manner, and that the model can be refined to reflect more complicated situations.

To fully realize this potential, there is need for further research. There is need for analysis which quantifies the linkages between risks, insurances, and states of food insecurity. There is also need to develop a taxonomy of household types which captures the behavioral attitudes of households and governments toward food insecurity and its alleviation. Further research, of course, is contingent on the collection of household-level data, relating to the concepts defined in our conceptual framework of food insecurity.

Measuring Food Security in Africa: Conceptual, Empirical, and Policy Issues

John M. Staatz, Victoire C. D'Agostino, and Shelly Sundberg

"Food security is access by all people at all times to enough food for an active and healthy life."—World Bank

The definition of food security has broadened since the term first came to prominence at the 1975 World Food Conference. Discussions of food security in the mid- and late 1970s were strongly influenced by the shortfall in world food production and run-up in prices early in that decade. Initially, food security meant avoiding transitory shortfalls in the aggregate supply of food. By the early 1980s, however, the world food supply situation had evolved markedly. The famines striking Africa took place in a world awash in grain. Clearly, inadequate levels of global food supply were not the cause of hunger. Sen's work focused attention on the lack of access by households and individuals to food because of low incomes (entitlements) as a cause of food insecurity, and other research has shown that for most of the hungry in the world, this lack of access is chronic, not transitory. Thus, the conceptual understanding of food insecurity has gradually evolved over the past fifteen years to include not only transitory problems of inadequate supply at the national level but also chronic problems of inadequate access and unequal distribution at the household level.

Despite a broader understanding of the complexity of food insecurity, policy makers must still look for easily measured indicators to design programs to reach the food insecure. Often, these indicators are measures of regional or national food supply or its correlates (such as rainfall), as current information on household or individual entitlements to food is usually lacking. Some policy makers may think of supply shortfalls or the lack of domestic food self-sufficiency as the "true" food insecurity problem.[1] More commonly, they may simply believe that the supply indicators they use are highly correlated with the true but unmeasured indicators of household or individual access to food.

A critical question then becomes to what degree are commonly used indicators of food security, as measured at one level of aggregation such as the nation or region, correlated with indicators of access to food at other levels, such as the household or the individual?[2] This paper addresses these issues, drawing on preliminary findings from research carried out in the OHV zone of southern Mali. The sample included approximately ninety rural households in eight villages, for which coarse grain (millet, sorghum, and maize) production and transactions data were collected over the period 1985–88 and food

This paper is based on research undertaken under the "Food Security in Africa Cooperative Agreement" between the U.S. Agency for International Development (Bureau of Science and Technology and Africa Bureau) and the Department of Agricultural Economics, Michigan State University. In Mali, the research was conducted under the auspices of the Malian National Food Strategy Commission (CESA).

In no case should the paper be taken to reflect the official position of USAID or CESA.

The authors thank Bruno Henry de Frahan, Lawrence Rubey, Jennifer Wohl, and Michael Weber for comments on earlier versions of this paper but accept sole responsibility for the material presented here.

[1] Shortfalls in domestic supplies of grain, resulting in massive commercial or food aid imports, may represent real food insecurity to those decision makers concerned about the overall foreign exchange position of the importing country or its ability to retain its sovereignty in the face of pressure from its food suppliers (Staatz and Wohl). Because of space limitations, this type of insecurity is not addressed here, but it is important to bear in mind when considering why some policy makers give such emphasis to domestic food self-sufficiency even though it is well known that such self-sufficiency is no guarantee against hunger among the population.

[2] The term region, as used in this paper, refers to a subnational area, such as a province, not a regional grouping of countries, such as the Sahel.

consumption, expenditure, and anthropometric data were collected in 1988 and 1989.[3]

National versus Regional Food Security

Following the trauma of the great Sahelian drought of the early 1970s, most Sahelian states, including Mali, made attaining food self-sufficiency a central pillar of their food strategies (Staatz and Wohl). Hence, the degree to which domestic consumption of basic staples was covered by national production became a key measure of food security for national policy makers. Yet, attainment of national food self-sufficiency does not guarantee adequate access to food in each region of the country. Indeed, the restrictions on private marketing of grain that most Sahelian countries imposed until the 1980s (especially the interdiction of inter-regional grain trade) helped assure that national self-sufficiency did not translate into adequate regional food supplies. However, even with the removal of restrictions on the private trade, inadequate transportation infrastructure and weak effective demand may result in gluts in one region not being translated into adequate access to food in another.

In addition, policies designed to alleviate national problems of food surpluses or shortages can exacerbate regional entitlement disparities, particularly when markets are poorly integrated and regional income inequalities are great. For example, as a result of a record coarse grain harvest in Mali in 1989, the government emphasized export promotion to boost farm-level prices and hence the incomes of those farm households (mainly in the CMDT zone of southeastern Mali) that are net sellers of grain. Some local officials in the grain-deficit zones of the West through which the exports pass, however, have attempted to block them to prevent higher prices in this very poor region. This highlights the food-price dilemma inherent in food policy, that is, the difficulty of reconciling the conflicting interests of net buyers and sellers of food (both as individuals and as regions). This dilemma is severe in many African countries, even though most of the population is rural, because many small farmers are net purchasers of basic staples (Weber et al.).

Regional versus Household Food Security

In Mali, as in many other Sahelian states, policy makers rely heavily on regional indicators of food production and prices to target food aid and general development assistance. For example, all the districts (*arrondissements*) monitored for potential food shortages in Mali (the "at risk" zones) are located north of the fourteenth parallel, in the lower rainfall areas of the country (Staatz et al.). Yet, many households in the "surplus zones" south of the 14th parallel lack adequate access to food. Even in the southern CMDT zone, the most productive agricultural region of the country, where per capita coarse grain production in 1987 averaged 311 kilograms (kg) (compared with an estimated consumption requirement of 188 kg), only 43% of households that cultivated manually (27% of total households) had production above the consumption requirement. In contrast, 89% of households having at least some animal traction equipment met that norm.

Northern areas of Mali are generally perceived as being more prone to food insecurity than southern areas because of their lower and more erratic rainfall levels. Over the 1970–85 period, the annual rainfall in northern OHV ranged between 550 and 760 millimeters, compared to a 850–1,000 millimeter range in southern OHV (D'Agostino, p. 48). According to CESA-MSU survey results, average per capita grain production during the 1985–87 period was 16% to 65% higher in southern OHV than in the north (D'Agostino, Dioné, and Staatz). Yet, when sample households were ranked in terms of their food consumption security in 1988, there was no significant difference between north and south (table 1).[4]

The main reason that differences in regional agricultural production potential were not correlated with differences in consumption security is that households in the northern, more arid area, have more diverse income sources and rely more on the market for their food supply than their southern counterparts. In 1987–88, sample

[3] OHV stands for *Opération Haute Vallée*, or Upper Niger River Valley Development Authority. The OHV households were part of a larger survey of farm households in southern Mali, which also included the CMDT zone (*Compagnie Malienne du Développement des Textiles*). The CMDT zone is the main cotton-producing area of the country and also the area that produces the bulk of Mali's marketed surplus of coarse grains. For details, see Dioné.

[4] The consumption ranking was based on a scale that took account of the following indicators for each household: number of meals eaten per day, number of meals which included meat or fish, number of ingredients in the sauce served with the main staple (a measure of dietary diversity), and number of times per day a nutrient-poor gruel was prepared as the main meal.

Table 1. Household Consumption Security Rankings, Northern and Southern OHV Zone, Southern Mali, 1988 (percentage of households by category)

Consumption Security Ranking	South	North	Total
High	8.9	7.8	16.7
Average	25.6	26.7	52.2
Low	17.8	13.3	31.1
Total	52.2	47.8	100.0
Chi-squared (df = 2) = .79			

Source: D'Agostino and Sundberg, forthcoming.
Note: The consumption ranking was based on evaluation of the following indicators for each household: number of meals eaten per day, number of meals which included meat or fish, number of ingredients in the sauce served with the main staple (a measure of dietary diversity) and number of times per day a nutrient-poor gruel was prepared as the main meal.

households in northern OHV obtained 39% of their household grain supplies from the market, compared to only 8% in the south. The market becomes particularly important late in the crop year. In the period just before harvest in 1988, grain from the market served as the base for 67% of the meals in northern OHV, compared with 28% in the south.

The importance of reliance on the market in the north is reflected in how market purchases influenced household consumption security, as measured in table 1. Whereas the level of market purchases is negatively correlated with a household's consumption security in the south, it is positively correlated with it in the north (table 2). In other words, southern households attempt to assure household food security through own production and tend to purchase grain only when this strategy fails. Northern households, in contrast, develop more diverse income sources that are less directly dependent on rainfall levels (table 3) and use revenues from those activities to purchase food. The northern households, living in a more risky environment, have evolved strategies that allow them to mitigate the effects on consumption security of fluctuations in household crop production to a greater extent than their southern counterparts, who have developed strategies to exploit the (normally) higher agricultural production potential of their area. These findings are similar to those observed in northern and southern areas of neighboring Burkina Faso (Reardon, Matlon, and Delgado).

Table 3. Distribution of Major Income Sources in the OHV by Subregion (% of men and women's responses, aggregated over three seasons), 1988–89

Income Sources	OHV-South (N = 706)	OHV-North (N = 363)
Agriculture and wild products	55.1	29.4
Commerce	15.0	10.4
Artisans' activities	7.9	20.1
Livestock	6.1	16.5
Prepared foods	4.1	16.8
Labor and migration remittances	6.0	4.1
Gifts	4.8	1.1
Other	1.0	1.6

Table 2. Correlates of Household Food Security in the OHV by Subregion, 1987–88

	OHV-South		OHV-North	
Indicator	t-ratio	signif.	t-ratio	signif.
Coarse grain production per household	2.32	.03	2.62	.02
Coarse grain production per capita	.23	.82	2.49	.02
Coarse grain availability per household	1.96	.06	2.57	.02
Coarse grain availability per capita	−.31	.76	2.03	.06
Coarse grain purchases per household	−2.24	.04	2.17	.05
Coarse grain sales per household	1.49	.15	−1.30	.21
Number of farm household workers	2.21	.04	1.48	.16
Number of revenue sources per household	2.31	.03	0.36	.72
Household size	1.66	.11	1.45	.17
Ownership of animal traction equipment	chi square = 9.23	.06	chi square = 7.00	.14

Source: D'Agostino and Sundberg, forthcoming.
Note: Unless otherwise stated, the statistics presented in this table are t-values from tests of the equivalence of the population means for consumption-secure and consumption-insecure households. A significant positive t-ratio indicates that consumption-secure households measured significantly higher on this variable than consumption-insecure households. For animal traction equipment ownership, three levels of ownership were measured (nonequipped, semi-equipped, and fully equipped). The chi-square test measures whether the distribution of ownership was different between consumption-secure and consumption-insecure households.

The findings suggest that the functioning of rural product and factor markets in grain deficit zones plays an extremely important role in determining household food security. In particular, the ability of rural distribution markets to deliver grain reliably to grain-deficit rural households at low cost is central to the ability of these households to assure adequate levels of consumption. Yet, many of these rural distribution markets are thin, and prices are consequently volatile.[5] Price volatility hits hardest those poor households that sell grain early in the season to meet pressing cash needs (especially tax payments) and repurchase grain late in the season to meet consumption needs (D'Agostino and Staatz).

The ability of rural households to obtain income to purchase the grain depends critically on the functioning of the markets for the goods and services these households sell (table 3). In addition, the capacity of these households to weather short-term fluctuations of real income depends on the functioning of rural capital markets. In the long run, the goal of policy should be to decouple a household's food consumption status from short-term fluctuations in agricultural production by improving both rural capital markets and the markets for the goods and services the households sell (von Braun).

If differences in per capita grain production levels across geographic zones are not good predictors of household food consumption security, what are? Table 2 summarizes the factors that were significantly different between consumption-secure and consumption-insecure households within northern and southern OHV. A few indicators, such as coarse grain production and availability per household, are positively correlated with consumption security within both subzones, indicating that even though the northern households are more market oriented, own production continues to play an important role in their food strategies. In both subzones, larger households (which have more diverse income sources) tend to be more consumption secure than small households. But what is striking in table 2 is that many indicators are valid for one subregion but not the other. For example, size of the farm labor force and ownership of animal traction equipment are more significantly correlated with household consumption security in the south than in the north because in the south agriculture contributes more to family income. Most striking, the level of grain purchases is negatively correlated with household consumption security in the south but positively correlated with it in the north, for reasons explained above.

This diversity in the subregional correlates of household food security suggests that any attempt to develop indicators to monitor household consumption security needs to be area specific. Few easy-to-monitor indicators are robust across all subzones. One possible method to obtain indicators is to use local village informants. The two enumerators employed by the consumption survey (women with 9th grade educations) were asked to give their subjective rankings of the household consumption security of all the sample households. The correlation between these rankings and those based on the scale described in footnote 4 was .87, suggesting that local informants may be a cost-effective way of monitoring household food security. A major challenge, however, would be to assure the objectivity of their rankings if such rankings served as the basis for the distribution of benefits, such as food aid, to food-insecure households.

Regional versus Individual Food Security

If aggregate measures of regional food production are not good indicators of household food security, it is even less likely they will be reliable guides to individual nutritional status as measured, for example, by anthropometrics. In order to evaluate children's nutritional status, children aged 0–7 years from the sample households were weighed and measured in three different seasons to evaluate their degree of protein-energy malnutrition (PEM): early November 1988 (just before the main grain harvest), early February 1989 (immediate post-harvest period), and late August 1989 (peak of the hungry season).[6] Aggregating across the three rounds, the overall rate of short-term PEM, or wasting, as measured by weight-for-height, was 4.2%. The prevalence of chronic PEM, or stunting, as measured by height-for-age, was 37.0%.

The fact that northern households were at least

[5] Between October 1987 and August 1988, the prices paid by sample households in northern OHV for millet and sorghum more than quadrupled, from under 29 CFA.F/kg to slightly over 130 CFA.F/kg. (D'Agostino and Staatz).

[6] Sample sizes for the 3 rounds were 268, 277, and 256, respectively. A child was considered wasted if her weight-for-height fell at least two standard deviations below the median NCHS/WHO growth reference curves. Similarly, a child was considered stunted if her height-for-age fell at least two standard deviations below the NCHS/WHO median curves. For details, see Sundberg 1989b.

as consumption-secure as their southern counterparts is borne out in the anthropometric measures. Children in the northern areas had significantly lower levels of chronic PEM than children in the south, 23% versus 43% ($t = 4.73$, $p < .01$). There was no significant difference in the prevalence of wasting between north and south, although mean weight-for-height is significantly lower in the south ($t = 2.96$, $p = .003$). One possible explanation for the substantially lower incidence of growth stunting in the north is that health and sanitation problems (particularly the incidence of malaria) are likely to be greater in the more humid south. Given the strong synergies between disease and malnutrition, the disease problems may have been manifested in more growth stunting in the south.[7] Cultural differences between the two subzones, such as child feeding practices, may also have been a factor, although the vast majority of the sample in both areas were of the same ethnic group. (The issue of child-feeding practices will be explored in future analysis).

Household versus Individual Food Security

Poor health and sanitation and inappropriate child feeding practices may prevent adequate levels of household consumption security from translating into satisfactory nutritional status for the most nutritionally vulnerable members of the households, such as preschool children or pregnant and lactating women. Indeed, for the OHV zone as a whole as well as for each subzone, the data indicate no correlation between the household consumption security ranking reported in table 1 and either of the anthropometric measures (the prevalence of wasting and stunting within the household). This is a striking finding: it implies that even if one could accurately assess household food security as measured by the frequency of meals and indicators of dietary diversity used in the consumption-security scale, this alone would not be a reliable guide to the nutritional status of the children in the household. The household consumption ranking derived by the enumerator, however, was positively correlated with long-term nutritional status ($r = .43$, $p < .01$) in northern OHV, thus suggesting that the use of local informants may be an effective tool for monitoring both household food security and individual nutritional status.

For both the northern and southern subzones, there are very few significant correlations between the anthropometric measures and the household-level economic and demographic indicators shown in table 2. In the south, there are no significant correlations between long-term nutritional status and household-level indicators. Short-term status, however, is negatively correlated with two variables: coarse grain purchases per household ($r = -.40$, $p < .01$) and the degree to which the products from women's individual fields were sold ($r = .49$, $p < .001$). On average, the more grain purchases a household made, the worse off its children were nutritionally. This finding parallels the negative correlation between purchases and household food security in the south (see table 2). This underscores the conclusion that, in the south, higher purchases reflect a failure of the agricultural production strategy, which renders the household more vulnerable to consumption and nutritional deficiencies. Second, in households where women sold a greater part of the products from their individual fields, children were more likly to be wasted. A possible explanation is that women who retained their own production for home consumption increased the diversity of their children's diet, thus contributing to a better nutritional outcome. This hypothesis will be explored in further analysis of the food consumption data.[8]

In the north, short-term nutritional status is negatively correlated with household size ($r = -.48$, $p < .01$), number of farm workers ($r = -.43$, $p < .01$), household grain sales ($r = -.53$, $p < .001$), and gifts of grain received by the household ($r = -.39$, $p < .01$). The direction of correlation between household size and farm workers, on the one hand, and nutritional status, on the other, is the opposite of that between these same demographic variables and household food security (although the latter correlates are not statistically significant—see table 2). Nutritional status may decline as household size increases because, although staple grain quantities may increase commensurately with the number of consumers, typically sauce ingredients are not

[7] The village with by far the worst anthropometric rankings was the only village in the sample surrounded by low-lying wet areas, suggesting that the incidence of mosquito-borne diseases may have been higher there. This village was also one of the most isolated of the sample villages from surrounding markets, thereby hindering the ability of households to diversify their incomes.

[8] Sales from women's individual fields are not correlated with the overall level of grain sales of a household or with the number of nonagricultural enterprises. Thus, it does not appear that women who sold a high proportion of the output from their fields did so because their households had fewer alternative income-earning opportunities than their neighbors.

augmented by a similar ratio and are therefore stretched thinner in larger families, thus lowering the per capita intake of protein, vitamins, and minerals. Households in the north with higher total grain sales are likely to have more wasted children, perhaps because these transactions represent distress sales of grain, which is not truly surplus but is sold only to meet pressing cash needs. Finally, it is intuitive that households with more malnourished children received a larger quantity of gifts of grain.

Long-term nutritional status in the north is positively correlated with only a single variable, grain production per capita ($r = .44$, $p < .01$). Thus, in spite of the importance of nonfarm activities in the northern households' income strategy, agricultural production remains vital to both the overall food security of the household (table 2) and the nutritional status of its vulnerable members.

These findings suggest that a number of factors intervene in the OHV to prevent adequate levels of household food availability from translating into satisfactory child nutritional status. Poor health and lack of adequate nutrition education are likely to be among the most important of these variables. Policy therefore needs to focus on developing mechanisms to address these variables. Work in Guatemala has highlighted the importance of community-level health and nutrition investments in improving the link between higher rural incomes and the nutritional status of children (Von Braun, Hotchkiss, and Immink). In the OHV, short-term and long-term malnutrition rates varied widely by village. While by far the highest rates were found in one of the most isolated villages with poor health facilities (see footnote 6), among the other seven villages, the incidence of malnutrition did not seem to vary systematically with the level of village infrastructure, as measured by the presence of dispensaries, maternal health clinics, and schools. Just because a village had such infrastructure, however, does not mean it was effective, as lack of supplies and poorly trained and poorly motivated staff often impede the facilities' effectiveness. Such facilities probably also need to focus their activities more closely on nutritional issues to have a strong impact.

One should be cautious in interpreting and generalizing from these preliminary results. The OHV zone has poorly developed markets, a low degree of cash-cropping, and weak village infrastructure. One important area for further research is to replicate this type of study in areas such as the cotton-producing CMDT zone, where cash-cropping, off-farm income earning opportunities, and the degree of village-level health infrastructure are higher to see if the lack of correlation between indicators of household food security and child nutritional status holds up.

Conclusions

The analysis has shown that for Mali, commonly used indicators of food security at the regional and national level are often poor predictors of household and especially individual food security. Hence, they may be poor guides to interventions to help the hungry. This poses three challenges for policy makers. One is to develop more accurate, area-specific indicators and cost-effective means to monitor individual and household food security.

The second is to decouple household and individual food security from the vagaries of local agricultural production. Reforms and infrastructure improvements aimed at improving the ability of private traders to move food at low cost among regions and improving the functioning of product, service, and factor markets to allow the food insecure to earn reliable income streams are crucial. Such improvements must be tied to improvements in productivity in cereals cultivation in order to help drive down the real cost of food to rural consumers. Over the long run, strengthening rural capital markets to allow households to bridge temporary shortfalls in income also is important. In designing reforms, it is important to have information on the degree, timing, and conditions of participation of the food insecure in these various markets in order to maximize the impacts of such reforms on the hungry (for examples, see Staatz). The third challenge for both researchers and policy makers is to develop a better understanding of how disease, intrahousehold food distribution, and nutrition education mediate the relationship between household food availability and individual food security. The goal should be to develop mechanisms to strengthen the currently weak relationship in Mali between higher rural incomes and improved nutrition of vulnerable groups.

Finally, it is important not to misinterpret these findings. Although rural households in northern OHV rely heavily on the cereals market and on nonagricultural enterprises to assure their food security, one should not conclude that increasing agricultural productivity is unimportant to them. Even within the north, household consumption security and long-term child nutri-

tional status are correlated with labor productivity in grain production, demonstrating that own production continues to play an important role in these households' food strategies. Even more important, the success of a strategy of relying on the market depends critically on the ability of the food system to produce and deliver grain to these rural households at low price. Given Mali's landlocked position, a large part of this grain will continue to be produced domestically, at least in the medium term. Thus, improvements in productivity in cereal farming as well as marketing are needed.

Poverty, Food Intake, and Malnutrition: Implications for Food Security in Developing Countries

Maurice Schiff and Alberto Valdés

The focus of this paper is on the relation between household income, food intake, and nutritional status in less developed countries (LDCs). This article presents a framework which relates explicitly household behavior patterns with the public policy options designed to improve the nutritional status of the poor in rural and urban households.

Nutrition and Income: The Statistical Evidence

Recent literature on the interaction between nutritional status, nutrient intake, and household income has made recommendations on how to improve nutrition based on parameters from empirical studies of food expenditure systems (Behrman and Deolalikar 1988, Alderman, Schiff and Valdés 1990a). However, the policy recommendations derived from the analysis depend critically on the definition of nutrition and, more broadly, on the conceptual framework used. In particular, critical elements of the pathway from changes in income to its effect on nutritional status are still questioned.

It is useful to highlight some fundamental findings on which there is a fair degree of agreement. Estimates from food expenditure systems yield income elasticities of nutrients (ϵ_{ny}) somewhat smaller than, but not significantly different from, 1.0. These are derived indirectly by estimating the income elasticities of food expenditures (also close to 1.0) and by assuming constant nutrient-to-food conversion factors.

More recently, for rural South India, Behrman and Deolalikar (1988) find that the expenditure income elasticity of food for the (6) food aggregates is close to one. However, for the major nine nutrients, the income elasticities (ϵ_{ny}) are not significantly different from zero. As income increases, a larger proportion of food expenditures is spent on non-nutrient food attributes such as diversity of products consumed, freshness, taste, convenience foods which save time in their preparation, and others. Similar results are found for low-income households in Pakistan by McCarthy and in several other studies. Based on this evidence Behrman and Deolakikar (1987) conclude that nutrition is unlikely to improve with income. However, if it can be shown that nutrition is not identified exclusively with nutrient intake, then the policy implications might be strikingly different. This is a major objective of this paper.

The Framework

The starting point is that the nutrition level or status (N) of a household depends only in part on its nutrient intake (n). It also depends on other privately and publicly provided goods and services.[1]

At the household level, we can think of a process of "producing" nutrition (a nutrition production function), where N is a function of the current as well as lagged values of (a) the nutrient intake (calories, protein, vitamins, etc.) which we call n, (b) the input of non-nutrient food attributes which affect N, such as freshness of the foods purchased, their cleanliness, and their storability, which we call q, (c) the privately provided inputs which may affect N, such as the time and care to prepare food including cleaning, cooking, boiling water, and other inputs (refrigeration) that ensure that the food does

Maurice Schiff is with the World Bank, and Alberto Valdés is with International Food Policy Research Institute, Washington D.C.

The views expressed in this paper are the sole responsibility of the authors and should not be attributed to the World Bank or to IFPRI.

[1] A formal development of this framework is found in Schiff and Valdés (1990a).

not become contaminated or spoiled, which we call p, (d) the publicly provided inputs which would include potable water, sewerage, electricity, nutritional information, etc., which we call k. The production of N is also partly determined by the individuals' health status, age, sex, and location (rural or urban). A fall in health resulting from causes other than a fall in n, q, p, or k above—say, because of a reduction in medical services—will result in a fall in N.

Only in the extreme case of famine (i.e., as nutrient intake approaches zero), would all food expenditures be allocated to nutrients n, the impact on N of the other variables, particularly q, would tend to zero and only an increase in nutrients would have a significant impact on N. In that case, ϵ_{ny} would be close to one. However, the vast majority of the population in developing countries does not fall under this extreme case of famine.

In a broader sense, the variable of concern is household's welfare, an important component of which is the health status (H) of its members, which depends in part on their nutritional status. As with nutrition, at the household level we can think of a health production function, H, which is a function of (a) nutritional status referred to above, (b) privately provided inputs (p), (c) publicly provided inputs (k), and (d) a variable (m) of current and lagged values of additional inputs affecting health. In fact, the variable m consists of both privately provided inputs (amount and quality of child care, hygiene, etc.), and of publicly provided inputs (medical services, information on hygiene and child care, and other). Finally, the production of health is also a function of age, sex, and location (rural or urban) of the individual. Thus, health depends on privately and publicly provided inputs directly, as well as indirectly through their effect on nutrition.

Because the functions N and H may vary according to sex, age, location, and other individual characteristics, the impact on N and H of changes in each determinant n, q, p, k, and m also may vary according to those characteristics.

This framework allows us to further elucidate the question of whether income gains in low-income communities could reduce malnutrition (raise N), even when they have only a very marginal effect on nutrient intake at the household level. How these two variables, N and H, respond when income gains occur among low-income households is then the central concern in this paper.

From the production function of nutrition (N) defined above, we can derive the income elasticity of nutrition (See appendix for details.):

$$\epsilon_{Ny} \equiv A + \epsilon_{NH}\epsilon_{Hy},$$

where N is level of nutrition, H is level of health, y is the household's income, ϵ is the income elasticity, and A is the partial elasticity of N with respect to income (for a given health status) and includes the impact of income on n, k, q, and p.

Similarly with health status, given the production function of health described above, we derive the income elasticities, namely

$$\epsilon_{Hy} \equiv \epsilon_{HN}\epsilon_{Ny} + B,$$

where B is the partial income elasticity of H (for a given N). Variable B includes the income elasticities of privately provided inputs ϵ_{py} of publicly provided inputs ϵ_{ky} and of the other variable ϵ_{my} affecting health (such as medical services, information on hygiene and child care, and others). Solving for ϵ_{Ny} and ϵ_{Hy}, we obtain

$$\epsilon_{Ny} = \frac{A + B\epsilon_{NH}}{1 - \epsilon_{NH}\epsilon_{HN}}, \text{ and}$$

$$\epsilon_{Hy} = \frac{B + \epsilon_{HN}A}{1 - \epsilon_{NH}\epsilon_{HN}}.$$

We postulate that $\epsilon_{qy}, \epsilon_{py}, \epsilon_{ky}, \epsilon_{my} > 0$; that is, increases in household's income will be accompanied by an increase in the demand for food "quality"—e.g., freshness, cleanliness, level of processing, and taste of purchased foods (q)—in the care in preparing food, and in the use of household appliances such as refrigerators (p), and in more income spent on potable water, electricity, and sewerage systems (k). Also, richer households will use more medical and other health-related services, and may provide health-related child care (m). The positive income elasticities for q, p, k, and m imply that $A > 0$ and $B > 0$, which in turn implies that $\epsilon_{Ny} > 0$ and $\epsilon_{Hy} > 0$. Consequently, the impact of income on N may be significant, even though nutrient intake remains unchanged or increases only slightly with income.

What we are trying to emphasize here is that to assess the impact of income on nutrition, one should not simply examine the impact on the input n but should look at the entire production function N. Furthermore, if the ultimate concern is with improving the health status H (N being one input in the production of H), then again the impact of income on health status H may be quite important. The fact that the nutrient in-

come elasticity is close to zero ($\epsilon_{ny} = 0$) and the food expenditure elasticities are close to 1.0 ($\epsilon_{Fy} = 1$) implies that the demand for non-nutrient food attributes (variety, storability, cleanliness) is high at those low income levels ($\epsilon_{qy} > 1$).

This framework is consistent with the finding, for example by Shah in rural India, and more recently Behrman and Deolalikar (1987), that even at such a low level of family income, as income increases, household's demand a wider variety of food products with a larger quantity of non-nutritive attributes (freshness, taste, processing, etc.). At the same time, however, the actual increase in nutrient intake associated with increases in the household's income is not significantly different from zero. Thus, families have a choice of spending increments in food expenditures on nutrients n but choose to spend their additional income on non-nutrient food attributes (q). And this choice, depending on which element of q is selected (say, freshness rather than taste), might even lead to an increase in nutrition or health.

Thus, the common practice of estimating the number of hungry and undernourished by comparing calorie and other nutrient intake with requirement standards implies that, in addition to ignoring the impact of intputs of non-nutrient attributes (q) and privately provided inputs (p) on nutrition, no weight is given to household preference. No matter how closely related, food adequacy (measured by nutrient intake) and nutrition level are not the same thing. The problem of food adequacy may or may not reveal itself as a nutrition problem; and a nutrition problem may or may not be the result of an inadequate supply of food.[2]

Policy Implications

Considering that the policy objective is to raise the level of nutrition or health, the approach developed above suggests that, except in the case of famines, a variety of alternative policy instruments is available and their relative merits may change according to location (rural or urban), initial conditions of infrastructure, etc. It also suggests that income will affect nutrition (and health) through its impact on q, p, and H (and m), even if it has little or no impact on nutrient intake n.[3]

Education undoubtedly plays an important role; one might expect the nutrition and health-related child care to improve with the level of the mother's education. In his study for India, Padmanabha finds that infant mortality falls both in rural and urban areas as the literacy and formal educational level of the mother increases. The evidence may not be entirely conclusive, as income may be positively correlated with the mother's education and was not controlled. García and Pinstrup-Andersen, in their study on the Philippines, find that the mother's education strongly affects the food consumption and nutritional status of preschoolers.

If the concern is with the production of health, and taking infant mortality as one indicator of health, Padmanabha argues that in rural areas in India, the main causes of death are tetanus, pneumonia, dysentery, and typhoid. These diseases are mainly conditioned by the absence or availability of basic facilities such as reliable water supply, sanitation (k), and basic child care services (m), so that nutrient intake does not seem to be the major factor. This confirms the results obtained by Castañeda for Chile, where the most important variable explaining the remarkable reduction of infant mortality in Chile from 107 per 1,000 in 1965 to 19.4 per 1,000 in 1986 was the increase in urban coverage of potable water and sewerage. Differences in such coverage were statistically more important than the positive impact of the available nutritional programs addressed to mothers. Thus, governments may have to increase the level and quality of publicly provided inputs (k and m above) in order to have a lasting impact on nutrition and health.

Providing information and education on hygiene and child care may also be effective ways of raising nutrition and health. Direct demonstration in the rural areas like in the Iringa Integrated Nutrition Program in Tanzania, or provision of information via television, which has been very successful in raising privately pro-

[2] Of course, in the extreme case of famine, malnutrition is the result of inadequate food supply.

[3] If, alternatively, nutritional status is measured as (n), then N is not responsive to y, given that nutrient consumption has been found to be rather unresponsive to changes in income. Thus, transfer programs will be ineffective means to improve nutrition. Similarly, as argued by Alderman, a weak link between income and nutrition implies that nutrition is to some degree buffered from the downswings in the local economy. Under such scenario, and given that definition of N, for income to have an impact on nutrition, policies must be designed to raise the income elasticity of nutrient intake (ϵ_{ny}); some analysts have argued that raising the mother's education could be another way to do it.

vided inputs (p) and (m) in Chile, are logical approaches to exploit the complementarities in the production of health and nutrition. Here, we refer to the private component of m, but, as mentioned earlier, there is also a public component of m. Also, policies designed to raise the nutrient content of some food ingredients, such as food fortification programs, lead to an increase in the level of nutrition by raising n.

Conceptually, the framework presented above can help in the evaluation of public investment programs to raise health and nutrition for the poorer households. However, in order to devise effective policies to raise H and N, research efforts should be directed at the empirical estimation of (a) the technological production functions of N and H, to know the impact of p, q, k, and m on N and H; and (b) the behavioral relationships to estimate ϵ_{py}, ϵ_{qy}, ϵ_{ky}, and ϵ_{my}, so as to compare the effectiveness of raising N and H through y, and through k and m (public components)—or a combination of both; and (c) the costs of providing the services, so as to identify and select cheaper and more efficient programs designed to raise the nutritional and health status of the poorer households.

One would expect that the parameters of these functions N and H differ according to age, sex, income class, and rural and urban characteristics. The estimation of these parameters should be part of the research agenda.

The Distinction between Urban and Rural Populations

The distinction between urban and rural households could raise a particularly complex issue. For governments to provide medical services and drinking water and sewers in urban areas is probably considerably less expensive than to provide it for rural areas. Given the lower population density in the latter, the cost per household scattered over large areas would be considerably higher. On the benefits side, they are probably lower in rural areas, considering that the lower population densities in rural areas would reduce the need for publicly provided sewers, drinking water and other such service.

Thus, if the low levels of N and H are the social concern, raising those levels in urban areas by increasing expenditures on k and on public components of m may be an efficient public policy. However, this may very well not be the case for rural areas because of higher costs and lower benefits of providing k and the public components of m.

What then is the prescription for rural areas? One important implication is that nutritional and health status in rural areas will then largely depend on the levels of inputs (p, q, and the private components of m), which are provided by the households. These levels depend on income, so that raising rural household's income can raise their nutritional and health status. For example, it may be easier to make a significant impact on incomes in a rural community through a variety of agricultural programs and policies than it is to appreciably increase the provision of sewerage or of health care delivery.

We are back then to the long-debated question on how to best raise farm income. One way would be to reduce the taxation of agricultural production caused by sector-specific and economy-wide policies in LDCs.[4] Another would be to increase public expenditure in those factors which raise land and labor productivity. In principle both are necessary and the right balance between them is an empirical question to be addressed on a country-by-country basis.

Concluding Comments

While food is continuously referred to in this paper, little is said about agriculture. There is, however, a strong link with agriculture because, as the analysis suggests, in rural areas the nutritional and health status will largely depend on the levels of private inputs (p, q, and the private components of m), which are provided by the households. These levels depend on income, so that raising rural income can raise their nutritional and health status.

The evidence suggests that the development strategies since World War II in most developing countries grossly undervalued the potential contribution of agriculture to economic development. Preliminary estimates for eighteen LDCs show that in most of these eighteen countries, the agricultural sector lost approximately one-fourth of agricultural GDP during 1960–84, as a result of the sectoral and economy-wide price interventions (Schiff and Valdés 1990b). The cumulative effect over time of such a transfer of income out of agriculture must have had a significant repercussion in aggravating poverty in

[4] An analysis of the impact of those policies for 18 developing countries during 1960–84 is provided in Krueger, Schiff, and Valdés.

rural areas. According to the conceptual link between income, nutrition, and health developed earlier, this evidence on income transfers suggests that these domestic economic policies probably had very detrimental effects on nutrition and health status of the poorest segments of the population. Policy reform in the developing countries should make an important contribution in alleviating rural poverty in developing countries.

Appendix

Derivations

We propose the following alternative definition for the nutrition production function:

$$(1)\quad N = N(n, q, p, k, H; S, E, L), \qquad \epsilon_{Nn}, \epsilon_{Nq}, \epsilon_{Np}, \epsilon_{Nk}, \epsilon_{NH} > 0,$$

where n is a vector of inputs of nutrients, q is a vector of inputs of non-nutrient food attributes, p is a vector of other privately provided inputs, k is a vector of publicly provided inputs, H is health status, S is sex, E is age, L is urban or rural location, and where n, q, p, and k are lag polynomials in those variables, reflecting the effect of current as well as lagged values of those variables.

A health production function can be defined as

$$(2)\quad H = H(N, p, k, m; S, E, L), \quad \epsilon_{HN}, \epsilon_{Hp}, \epsilon_{Hk}, \epsilon_{Hm} > 0,$$

where m is the vector of current and lagged values of additional inputs affecting health, such as medical services, information on hygiene and child care, and other. Health depends on p and k directly, as well as indirectly through their effect on N.

Because N and H depend positively on current as well as lagged values of their arguments, the long-run elasticities will tend to be larger than the short-run elasticities. Also, the functions N and H may vary according to sex, age, location, and other individual characteristics, so that the elasticities of N and H with respect to their arguments may also vary according to those characteristics.

Finally, in terms of income elasticities:

$$(3)\quad \epsilon_{Ny} = \epsilon'_{Nn}\epsilon_{ny} + \epsilon'_{Nq}\epsilon_{qy} + \epsilon'_{Np}\epsilon_{py} + \epsilon'_{Nk}\epsilon_{ky} + \epsilon_{NH}\epsilon_{Hy} \equiv A + \epsilon_{NH}\epsilon_{Hy},$$

and from equation (2) the income elasticity of health status is

$$(4)\quad \epsilon_{Hy} = \epsilon_{HN}\epsilon_{Ny} + \epsilon'_{Hp}\epsilon_{py} + \epsilon'_{Hk}\epsilon_{ky} + \epsilon'_{Hm}\epsilon_{my} \equiv \epsilon_{HN}\epsilon_{Ny} + B,$$

where ϵ' is a row vector. Solving for ϵ_{NY} and ϵ_{HY} from equations (3) and (4), we obtain

$$(5)\quad \epsilon_{Ny} = \frac{A + \epsilon_{NH}B}{1 - \epsilon_{NH}\epsilon_{HN}}, \text{ and}$$

$$\epsilon_{Hy} = \frac{B + \epsilon_{HN}A}{1 - \epsilon_{NH}\epsilon_{HN}}.$$

We postulate that $\epsilon_{qy}, \epsilon_{py}, \epsilon_{ky}, \epsilon_{my} > 0$; that is, an increase in household's income will tend to be accompanied by an increase in the demand for food "quality," e.g., freshness, cleanliness, and taste of purchased foods (q), in the care in preparing food, and in the use of household appliances such as refrigerators (p), and in more income spent on potable water, electricity, sewerage systems, etc., (k). Also richer households will use more medical and other health-related services and may provide health-related child care (m). Thus, $A > 0$ and $B > 0$. Since, for stability, $1 - \epsilon_{NH}\epsilon_{HN} > 0$, this implies that,

$$\epsilon_{Ny} > 0 \text{ and } \epsilon_{Hy} > 0.$$

Food Insecurity: Discussion

Joachim von Braun

The notion of food security and the research on it has come a long way since the 1973 world food crisis. The three papers reflect the shift from a production orientation to a consumption and health focus and from country-level to household-level analyses. They emphasize disaggregated approaches for the research agenda by proposing disaggregation among and within households, among regions, and over time. The papers do not address, however, the critical issue of seasonality of food security.

Three broad, new issues are emerging from persistent problems which must be kept in perspective: (*a*) the risk of temporary global food shortages, (*b*) the fast disappearance of the easy option of expansion of cropped area to achieve food supply expansion, and (*c*) the increasing emergence of the food security problem as a problem of the urban poor in low income countries.

Household-level analyses risk ignoring these broad challenges to food security and heading toward targeted programs to mitigate food insecurity, even where policies to overcome growth and employment constraints and market failures may be the feasible first-best solutions.

The important point made by the theoretical paper of Schiff and Valdéz is that complex factors, other than income-nutr*ient* relationships, are important for the income-nutr*ition* relationship. Schiff and Valdéz appropriately critique income-pessimism regarding the nutritional improvement effects of income growth as derived from partial analyses which leave out health and other interactions with income. Evidence from household survey analysis has accumulated in support of their point. Also, cross-sectional country-level data for rural malnutrition show a strong relationship to income at low income levels: Between $300 and $600, the income elasticity of nutritional improvement is about 0.4 (fig. 1). Lack of public action for health and sanitation seems to be an important reason undercutting the nutritional benefits of income growth.

Joachim von Braun is program director of the Food Consumption and Nutrition Policy Program of the International Food Policy Research Institute, Washington, D.C.

This paper stimulates thoughts on two broader issues: the type of growth for food security, and the role of public interventions for nutritional improvement.

The Phillips and Taylor paper suggests an innovative approach by casting the food security planning problem in the optimal control framework and emphasizes the dynamic risk problem of food security. While data and empirical problems loom large if the concept were applied, the concept as such may help to sharpen the debate on food security, which frequently suffers from imprecise goals-instruments separations. A basic question, however, arises from the proposed control instruments, "insurances" against food insecurity: Should these "insurances," conceptualized as programs by Phillips and Taylor, not be better dealt with as elements of insurance markets so as to give focus to overcoming failure in these markets?

The paper by Staatz, d'Agostino, and Sundberg is based on a rich primary data set and carries the point that even simple empirical analysis of real-world household food security gives interesting insights which need to enter the feedback to proper conceptualization of the food security program in specific areas. The paper utilizes an ordinal food security index, which is not convincing as food insecurity is defined as a cardinal problem: the probability of falling below some absolute consumption or nutrition cut-off point. The statistical testing of the relationship is partial and cross-sectional, not multivariate and dynamic, as would be desired.

The policy research agenda on food security comprises a growth and policy-instruments perspective. To the extent that employment-expanding growth reduces absolute poverty, food security and nutrition are enhanced. However, even steady growth in well-functioning market environments does not take care of the household food security risk in LDCs in an acceptable time. For rapid reduction of absolute poverty, the set of policy instruments comprised of self-targeting public works, price stabilization, a fresh look at efficient feeding schemes, health and sanitation promotion—tailored to specific country circumstances—needs to be deployed rap-

idly. Institutional capacity to assess and respond to food insecurity (including decentralized institutions to monitor, design, and supervise implementation of food security policy modules) should grow as a consequence of collaborative research.

Abstracts

Symposia

End-User Computing for Agricultural Economics Research: The Promise and the Challenge. James Horsfield (ERS USDA) and Dean T. Chen (Texas A&M University), organizers; Dean Chen, moderator; Bruce McCarl and James McGrann (Texas A&M University), John Okay (Office of Information Resources Management, USDA), Bruce Scheer and Gerald Leeper (Sparks Commodities)
Emerging technologies for end-user computing (EUC) hold the promise of another revolution by expanding the role of computing in ways that may transform both the research process and the nature of research itself. This symposium addressed four major issues regarding the EUC development for agricultural economic research: "Where are we now in the transition to EUC?" "Where do we want to go in the next 3–5 years?" "Managing the Transformation" and "Next Steps." Three presenters explored these questions from the university, government, and business perspectives. McGrann described the evolutionary process, responses and implications as well as the future role of agricultural economists in universities. Okay outlined the strategic plan for USDA and discussed the ways of managing the future environment. Leeper provided a business view on emerging data needs and future directions for decision-support tools. Chen summarized emphasizing user/user interfaces for EUC development.

Sharecropping: Is It a Remnant from a Peasant Economy or a Modern Way to Deal with Information and Risk? Hyunok Lee, moderator (ERS USDA); Avishay Braverman (World Bank), Keijoro Otsuka (Tokyo Metropolitan University), Jeffrey Reidinger (Michigan State University), Robert Chambers (University of Maryland), D. Gale Johnson (University of Chicago)
Despite the long history of share tenancy, there is little consensus in the literature concerning the causes and effects of share tenancy. The symposium reexamined share tenancy from the perspective of recent advances in information economics. Braverman provided an overview on share tenancy issues ranging from the traditional inefficiency argument to various explanations on the existence of share tenancy. Otsuka suggested a framework to integrate the Cheungian notion with imperfect monitoring. Reidinger discussed share tenancy from the social economic viewpoint arising between two social classes, landlord and sharecropper. Chambers discussed share tenancy in U.S. agriculture and emphasized that U.S. share tenancy must be examined as a contract emerging from merging two firms, the landlord and the tenant. Johnson concluded that the share contract may not result in efficiency loss and he stressed the usefulness of short-term share contracts as a way to enforce the contract by the landlord.

Global Grain Distribution Systems: Impediments to Increased Exports Leo C. Polopolus (University of Florida) and Roland R. Robinson (CSRS USDA), moderators; Rodman Kober (Continental Grain) and C. Phillip Baumel (Iowa State University), Robert Hauser (University of Illinois) and Barry Parker (E. D. and F. Man International Futures), Myron R. Laserson (Central Trading System), Steven Fuller (Texas A&M University), Won W. Koo (North Dakota State University), and Lowell D. Hill (University of Illinois)
The primary purpose of this symposium was to identify the transportation and infrastructure barriers in domestic, transoceanic, and foreign distribution sytems that impede the efficient movement and effective marketing of U.S.-produced agricultural commodities. Kober and Baumel argued that a truly national economy cannot operate efficiently without an integrated nationwide transportation system. This could include federal government ownership of rail rights-of-way, which are now privately owned. As impediments to increased exports, Hauser and Parker contended that import-port development is the most important research issue. Laserson and Baumel provided a critique of the Soviet Union's grain distribution system. The Soviet Union has major transportation and distribution problems between production fields and consumer locations, as well as between import ports and points of consumption. Fuller provided a comprehensive outline of grain transportation research needs which included the following areas: rural roads and bridges, ocean freight markets, truck/rail/barge markets, rail/barge capacity, rate determination, and interdependence of modes in grain distribution systems. Koo argued that the United States has a comparative advantage in exporting agricultural products because of not only advanced production technology and farming practices but also because of an excellent transportation system. Hill summarized the discussion by identifying the following impediments to grain transportation and distribution: physical impediments, logistical impediments, and policy impediments and barriers.

Millionaire Farmers and the Equity of Payments. Bernard Stanton (Cornell University), Robert Dubman (ERS USDA), Gregory Hanson (Pennsylvania State University), Terry Hickenbotham (ASCS USDA), Dan Sumner (Deputy Assistant Secretary for Economics, USDA), Gerald Whittaker, moderator (ERS USDA)
The equity of government payments to wealthy farmers became a large issue during the 1990 farm bill debate. The popular press contained contradictory statements about how many farmers were millionaires, the level of payments received, etc. Stanton

discussed several statistical issues including published (but likely reconcilable) differences in USDA reported statistics on payments. He also presented distributional information showing payments highly skewed to the highest decibel of producer recipients. Dubman and Hanson made the key points that only 10% of commercial farmers are millionaires from an equity standpoint, and that only about 1% of the millionaire farmers are financially vulnerable. Millionaire farmers could better withstand tighter payment caps than other commercial farmers. Hickenbotham provided an alternative perspective by pointing out that farm programs may function better in terms of supply control by not limiting payments to the larger, wealthier producers. He also made the point that the development of ASCS data to assist policy makers in evaluating payments levels and their impact would require massive commitments of USDA programming resources that are not readily available. Sumner focused on the political process which included the relatively new element of some environmentalist organizations not opposing payments to the largest, wealthier producers in order to preserve USDA clout on conservation controls. There were several recurring themes: the importance of reliable data with regard to payments distribution, the singular subsidy nature of the peanut and sugar programs, and the persuasive power of special interest groups by commodity and region.

The Sustainable Development of Tropical Rainforests: Economic, Resource, and Environmental Issues. Kenneth Baum (USDA ERS) and Vince Cusumano (ST USAID), organizers; Thurman Grove (Cornell, ST USAID), moderator; Alfredo Sfeir-Younis (World Bank), Michael Nelson (Economic Committee for Latin America), and Douglas Southgate (Ohio State University)

The sustainable development of tropical forests and other complex natural resource systems can be addressed using economic theory and analysis relating complex interactions among ecological, technological, socioeconomic, institutional, and policy objectives. The development of a more comprehensive and coördinated research program within agricultural economics relating to the sustainable development of tropical forest ecosystems needs to be more fully addressed. Agricultural economics can play an important information generating role in several areas: (*a*) formulating alternative policies and programs relating to incentives for sustainable development and management of tropical rainforests; (*b*) evaluating the linkages among economic, ecological, and environmental benefits and costs of tropical forest resource development activities; and (*c*) developing more comprehensive evaluation criteria and analytical methodologies providing policy tradeoff information to supplement rate of return and cost-benefit measures now used by many governments and multilateral institutions. Economic knowledge is an essential element for developing alternative policies and strategies affecting public and private sector investment and development decisions, and introducing and implementing economically efficient and ecologically sound incentives to preserve and manage tropical rainforest ecosystems.

Results from the Social Science Agricultural Agenda Project (SSAAP). Glenn L. Johnson (Michigan State University), organizer and moderator; James Bonnen (Michigan State University), Fred Buttel (Cornell University), William Brown (Central Michigan University), R. James Hildreth (Farm Foundation)

The session opened with a discussion of the background and organization of the Social Science Agricultural Agenda Project (SSAAP) of three years duration. SSAAP originated from dissatisfaction with the funding and administration of the rural social and basic social sciences in the agricultural establishment (AE). SSAAP seeks improved work (research, extension, teaching, advising, consulting, administering, and entrepreneurial) agendas, administration, and funding to increase rural social science (RSS) contributions to the solution of societal problems. Improved partnerships are sought with the technical agricultural sciences and the basic social, physical, and biological sciences including the ancillaries—philosophy, mathematics, and statistics. SSAAP has developed and presents balanced agendas for (*a*) disciplinary as well as multidisciplinary problem solving and subject-matter work; (*b*) the four driving forces for rural improvement—technical advance, human capital formation, institutional and policy improvements, and enhancement of natural and manmade resources; and (*d*) cross-cutting improvements in the supporting basic social sciences, in databases, and in the handling of ethical issues. SSAAP has also developed and presented more traditional agendas to assist farmers, agribusinesses, and consumers both domestically and abroad.

A lively one-hour discussion centered on increasing incentives for doing multidisciplinary problem solving and subject-matter work, administrative problems, funding possibilities, work on problems of disadvantaged rural farm and non-farm groups, and the rural social sciences' need for a standing organization such as SSAAP. Interventions, questions, and comments were from a wide variety of administrators, researchers, teachers, and extension personnel in a standing-room-only crowd of participants.

International Trade and Economic Development. Larry D. Sanders and Mike Woods (Oklahoma State University), organizers; David Henneberry (Oklahoma State University), Fred Ruppel and Michael Mazzocco (Texas A&M University), Parr Rosson (Texas A&M University) and Hal Harris (Clemson University), Warren Trock (Colorado State University)

Existence of a global economy continues to increase in significance. Rural communities tied to export-based farm production are especially insensitive to international forces. Frustration among educators, analysts, and public officials has often led to poorly coordinated educational efforts. This panel provided extension and research program ideas for community leaders, business managers, and public decision makers. Texas survey results showed that small business exports can be enhanced with targeted programs and research. Ways to establish export resource networks for business and public decision makers were discussed. Results of a survey of community leaders were examined to offer program and research opportunities and internationalize community economic development efforts.

1990 Farm Bill—A Discussion of Content and Impacts. Ron Plain (University of Missouri), organizer; Craig Infanger (University of Kentucky), moderator; Harry Baumes (ERS), Robert Young (Senate Agriculture Committee), Abner Womack (University of Missouri), and Ron Knutson (Texas A&M University)

The emerging 1990 farm bill was discussed in this symposia session by four presenters with intimate knowledge and experience with the political and economic forces which are shaping the new legislation. Baumes discussed the highlights of the different commodity programs in the House and Senate versions of the 1990 farm bill. Young explained the political environment in the U.S. Congress and how that has shaped the legislation in the last few months. Womack reviewed the current economic situation and outlook and discussed the impact on the emergence of 1990 farm legislation which reflects the new economic stability in agriculture. Knutson presented several challenges for the research agenda and researchers regarding existing and emerging legislation. Infanger moderated a lively question/answer period which focused primarily on the political options and outcomes including questions and comments from two former USDA assistant secretaries and participants from the U.S., Canada, and other countries.

Economic Policy Liberalization in Latin America: Implications for Agricultural Development. Philip F. Warnken (University of Missouri), organizer; James T. Reorden (MUCIA), moderator; David Franklin (Sigma 1 Corporation), Dale Colyer

Latin American nations are liberalizing trade policies and correcting macroeconomic imbalances. While the pace of policy reform varies from country to country, from the region as a whole, there is a definite movement away from policies that have been counterproductive to economic growth and development, especially for the region's agriculture. In the 1970s, many Latin America nations reduced or eliminated agricultural export taxes and the most negative industrial import substitution policies. But with global recession and inflation, mounting debt loads and balance of payments crises of the 1980s, there was a retrogression. Governments controlled exchange rates, and used import quotas and licenses to offset balance-of-payments difficulties. To contain domestic inflation, price ceilings were often set on basic goods, especially foodstuffs, and food imports were directly or indirectly subsidized. In many nations, export taxes were raised or reimposed and agricultural input subsidies curtailed to reduce fiscal deficits. In the 1980s, pressure from international financial and donor entities compelled policy reform. Recent and current trade and macroeconomic policy liberalizations in the region are significant and pervasive. Nations are lifting foreign exchange and interest rate controls, cutting export taxes, reducing or eliminating trade quotas, licenses and duties, and reducing or eliminating price and marketing margin controls, consumer subsidy programs, and parastatal market interventions.

China, Eastern Europe, and the USSR: Alternative Approaches to Political and Economic Reforms and the Implications for Agriculture. Shwu-Eng Webb and Nancy Cochrane, (USDA ERS) organizers; J. B. Penn (Sparks Commodities), moderator; D. Gale Johnson (University of Chicago), Frederick Crook, Nancy Cochrane (ERS USDA), Karen Brooks (University of Minnesota) and Karl Skold (Quaker Oats)

Johnson contrasted conditions in China, the USSR, and Eastern Europe across three topic areas: changes in ideology relative to private property, the effects of centralization on economic efficiency, and differences in technology levels. His general observations were corroborated by the three subsequent papers. Webb and Crook argued that China must implement genuine marketing reforms to sustain economic growth generated by reforms in rural production systems. The rapid increase in urban subsidy expenditures that has exacerbated inflation and growing concerns with falling grain production has caused China to recentralize its agricultural production. Cochrane noted that the transition to market economies in Eastern Europe will be difficult because of institutional rigidities inherited from the Communists. However, most of the new governments seem firmly committed to making full marketing reforms. Eventually the contradictions arising from only partial marketization should disappear. Brooks observed that Soviet land tenure reforms were ineffective because there has been no reform of price and input policies which favor inefficient firms. Marketing reforms and improvement in transportation systems are imperative for the success of Soviet economic reforms. Skold used Stavropol's experience to illustrate needs for improving technological efficiency and economic information. Penn summarized findings from these four papers and audience discussions.

Agricultural Livestock Outlook Programs: Effective Marketing Tools or Just an Academic Exercise? Mark R. Weimar, organizer; Terry L. Crawford, moderator; Ken E. Nelson (USDA ERS), Scott Irwin (Ohio State University), and Carl W. O'Connor (Oregon State University)
The efficacy of U.S. Department of Agriculture (USDA) and University Extension Outlook Programs were discussed. USDA livestock programs were evaluated graphically and statistically using Theil relative change statistics Ul, Um, Uc, Us, mean percent error, and mean absolute percent error. No attempt was made to characterize whether forecasts were good or bad, but beef and cattle production and price forecasts were obviously biased and reasons for the bias were discussed during the session. The methodology of USDA forecast development was also discussed including the diversity of agencies within the USDA that are on the Interagency Commodity Estimates Committees. One discussant noted the group dynamics involved in determining the official USDA forecast. Another discussant pointed out that by benchmarking USDA 7-market barrow and gilt prices and Omaha Fed Steer prices by the corresponding live animal futures price forecasts, traders could not use the USDA forecasts to make money. He also noted that USDA hog price forecasts were significantly different in bias and variance from the live hogs futures prices; but USDA live cattle price forecasts were biased while futures were not, and the variance of the two series were significantly different. The other discussant noted that even though the forecasts appeared inaccurate that most of his requests for information were for outlook-type information. He also pointed out that he relied on USDA outlook information extensively and adjusted it for his regional seasonality.

The Agricultural Trade Negotiations: What Is Achievable? George E. Rossmiller (NCFAP RFF), moderator; M. Ann Tutwiler (NCAP RFF), Craig Thorn (FAS USDA), Timothy Josling (Stanford University), T. K. Warley (University of Guelph), Fred Sanderson (NCAP RFF), John Schnittker, and Douglas Kelley (Agriculture Canada)
Tutwiler reported that the comprehensive proposals of late 1989 still reflected a wide gap between the U.S. and Cairns Group objective of fundamental policy reform and the more limited Western European and Japanese objectives of restraining the trade-distorting effects of existing policies. Thorn pointed to the June 1990 report of the chairman of the agricultural Negotiating Group as an indication of the EC's isolation in the face of a broad consensus on a rules-based multipronged solution involving cuts in internal support, market-access, and export subsidies. Josling concluded that a broad aggregate measure of support (AMS) would not be acceptable as the only policy commitment, but some version of it would probably be retained to scale down internal supports. Warley saw agreement in principle on a traffic-light approach to internal subsidies, but much work remains to be done on classifying specific policies into three categories: green (non-trade distorting and therefore noncountervailable), amber (subject to surveillance and AMS reduction) and red (to be phased out). Sanderson suggested that waning prospects for adequate cuts in the AMS and for measurable commitments on policy reinstrumentation had led the exporting countries to revert to the traditional focus on border measures. Agreement on partial tariffication was unlikely so long as the EC insisted on simultaneous rebalancing of tariffs and the retention of variable levies and subsidies. Improved market access might be achieved via tariff quotas, and an agreement to limit and reduce export subsidies also seemed possible. Schnittker felt that the U.S. would be able to adjust its policies to comply with the likely results of the negotiations. Grain support levels will be cut in any case because of budget pressures. Sugar, peanut, and milk producers will resist but will not be able to block a successful conclusion of the Uruguay Round. Hedley (Agriculture Canada) said that a fundamental policy review was underway in Canada, focusing on transportation subsidies, decoupled income stabilization accounts, and greater flexibility in the dairy and poultry sectors. He foresaw no major difficulties in adjusting to the likely outcome of the negotiations.

Grades, Standards, Safety, and Quality: Incompatible Bedfellows. Henry Bahn (ES USDA) and Bruce Bainbridge (Colorado State University), moderators; Tom Schotzko (Washington State University), Lowell Hill (University of Illinois), Roberta Cook (University of California, Davis), and Barry Goodwin (Kansas State University)
Coordinated grades and standards with end use properties and food safety are needed. Government standards are used to provide standards for communication but do not necessarily change as rapidly as the market place requires. Schotzko emphasized the ability of high-grades in the Red Delicious apples, which emphasize color and shape and add to product differentiation. Roberta Cook reviewed the impacts of organics and the relatively minor success of organics in the marketplace. Barry Goodwin reviewed research coordinating wheat milling qualities, prices, and the need for improved communication of milling qualities needs to the wheat breeders. Hill emphasized that product segregation based on economic quality characteristics will not occur unless economic advantage exists. Currently, wheat, corn, and soybean standards are based on historic measures of limited use to the processing industry, such as test weight and moisture content. Discussion of the needs for integration of grading standards and needs across commodities, countries, and disciplines from production to assist in legitimate product differentiation.

Foreign Agricultural and Development Assistance: Donor Nation Perspectives on Levels, Trends, Types, Objectives, and Outlook. Fred J. Ruppel (Texas A&M University) and Wade F. Gregory (The Pragma Corporation), coordinators, Gregory also presiding; Duane Acker and Howard Steele (OICD USDA), Barry E. Prentice (University of Manitoba), E. Wesley F. Peterson (University of Nebraska), Chi-Ming Hou and Tain-Jy Chen (Ching-Hua Institute, Taipai)
Foreign agricultural development assistance has recently been a topic of discussion among donor agencies, recipient countries, academics, and policy makers. The panel agreed that agricultural and rural development is important for overall economic growth and that better linkages with international research organizations, private sector entities, and multinationals would enhance effectiveness. U.S. bilateral development assistance should be increased and directed to agricultural and rural development activities in a prioritized (but broader) array of LDCs. Guiding principles for Canadian development assistance include putting poverty first, development as a priority, and working in partnership. About half of Canadian aid is bilaterals with approximately three-fourths going to Africa and Asia. Development assistance programs in European countries differ considerably as a result of different historical relationships with the third world. Humanitarian concerns dominate Swedish and German aid efforts. France emphasizes education in an effort to spread French civilization, while U.K. relations with the third world are largely commercial. Because of events in Eastern Europe, there is much uncertainty concerning the future of European assistance. Taiwan's aid program has a focus on technology transfer, with agricultural experts working directly with farmers in recipient countries. This hands-on approach can be strengthened by incorporating market incentives in the future.

National Farm Financial Standards: The Development and Potential Use by Educators and Researchers in Agricultural Finance. David Kohl (Virginia Polytechnic Institute and State University, moderator; Freddie L. Barnard (Purdue University), James M. McGrann and Danny Klinefelter (Texas A&M University)
The Agricultural Bankers Executive Committee of the American Bankers Association (ABA) organized the Farm Financial Standards Task Force in 1989. This ABA task force of over fifty professionals from all aspects of agricultural finance have prepared, through consensus of opinion, a set of farm financial standards for agriculture. Members of the task force described recommended standards and suggested how they can be used in agricultural finance education and research activity. An effort to develop a national data base was described. Adoption of the standards as well as their incorporation into educational programs by land grant faculty are viewed as keys to success in their use in agriculture. Their use could have a very important long-term impact on financial performance documentation, analysis, and formulation of a national farm financial performance data base.

Agriculture, Technology, and Society. Gene F. Summers (University of Wisconsin, president, Rural Sociological Society [RSS]), organizer; Frederick H. Buttell (Cornell University, RSS president-elect), moderator; Don Dillman (Washington State University), Martin Kenney (University of California, Davis), and Linda Reif Labao (Ohio State University)
Dillman stressed that rural development specialists tend to ignore the opportunities of, and problems posed by, modern information technology for the development of rural regions and communities. Information technology can contribute to rural development by enabling service-information industries to locate far from metropolitan areas, but many rural communities lack access to digital telephone facilities essential to attract these industries. Kenney noted that there is a growing Japanese investment in manufacturing industries and in farm and agribusiness operations in U.S. rural areas and that the technologies and management practices employed in Japanese-owned businesses are already beginning to make a major impact on several U.S. rural regions. Lobao summarized the past several decades of rural sociological scholarship on the impacts of farm structural changes on rural communities and their possible implications for agricultural economics research. She noted that these studies, while conclusive in many respects, have almost totally ignored gender relations as a factor that shapes these effects and which is in itself affectd by shifts in agricultural organization and technology.

Toward Resolution of Data Access Conflicts. Edward I. Reinsel (ERS USDA), organizer; Douglas L. Young (Washington State University), Charles E. Caudill (NASS USDA), George T. Duncan (Carnegie-Mellon University)
The viability of our economy and functioning of our society can be enhanced by sharing available information. To ease replication, foster an attitude of openness, and insure honesty, several social science journals now require access to methods and data underlying reported research. Problems arise when legitimate information needs conflict with values and rules concerning the privacy of individuals. This symposium explored the nature of data access problems and searched for ways to lessen conflict. Young described how the Western Agricultural Economics Association policy on data access has worked and noted unresolved areas of tension. Caudill explained the NASS confidentiality procedures, publication policies, and options for data-sharing access. He discussed means of broadening data use including sta-

tistical or research enclaves, informed consent of survey respondents, artificial or masked microdata sets, and research fellowships. Duncan discussed progress to date on a major panel study by the Committee on National Statistics concerning confidentiality and data access. He discussed earlier work, outlined goals for the study, and described procedures being used.

Critical Economic Issues in Aquaculture Development. David Liao (South Carolina Marine Resources Center), organizer and moderator; Ken Roberts (Louisiana State University), organizer; Alan Kenney (British Columbia Salmon Farmer Association), Wade Griffin (Texas A&M University), Upton Hatch (Auburn University), Ivar Strand (University of Maryland), James Anderson (University of Rhode Island), Richard Johnston (Oregon State University)

The increasing consumer demand for seafood products, particularly in North America, has stimulated the tremendous interest in development of aquaculture industry in recent years. This symposium examined current economic issues related to aquaculture development. Kenney discussed economic issues facing the Canadian salmon-farming industry. Griffin reported that management is the major factor inhibiting the growth of shrimp aquaculture in the United States. According to Hutch, catfish price stability and product image are critical issues in catfish aquaculture. Strand focused on policy issues in oyster aquaculture in Virginia and Maryland. Anderson examined international trade issues related to aquacultural products. Johnston's summary remarks concentrated on future directions for economic research.

Comparability of International Data on Agricultural Outputs and Inputs. Susan Capalbo (Montana State University) and C. Ed Overton (ERS USDA) organizers; Anwarul Hoque (ERS USDA), moderator; Michael Denny (University of Toronto), Klaus Frohberg (OECD), Eldon Ball (ERS USDA), C. Ed Overton (ERS USDA)

The importance of trade to most agricultural sectors and the related issue of competitiveness have highlighted the need for comprehensive and consistent country-level data. The symposium examined the issue of data requirements for international analyses. Basic data—prices and quantities of agricultural outputs and inputs—are either collected in such a manner which does not facilitate intercountry comparisons or is not collected at all. Frohberg and Ball, both users of agricultural data, provided information on data sets. Frohberg focused on the EUROSTAT and SPEL data bases and suggested that information used for calculating PSE's and CSE's should be made public. He also indicated a need for comparable EC data on the level of policy instruments. Ball discussed his efforts to create a U.S./EC data set for econometric uses and productivity accounting. Participants also discussed general collection guidelines which may improve the usefulness of ongoing series, and political and institutional barriers for altering collection procedures. Denny offered suggestions for minor changes drawing on his data-collection experience in other sectors. Overton discussed the need for better communication between users and collectors, noting the costs involved in initiating major changes. He ended on an optimistic note: there is a formal mechanism within the UN and FAO which solicits proposals to initiate new data series or modify existing procedures. Such a mechanism should be exploited!

Comparative Analyses of Food Demand/Consumption and Agricultural Stucture/Supply in the United States and Japan. Rueben C. Buse (University of Wisconsin), moderator; Wen S. Chern (Ohio State University), Naraomi Imamura (University of Tokyo), Hiroyuki Arayama (Nagoya University), Luther Tweeten (Ohio State University), Masaru Morishima (University of Tokyo), Mitsuhiro Nakagawa (National Research Institute of Agricultural Economics, Tokyo), and Benjamin Senauer (University of Minnesota)

The joint U.S.-Japan research project represents a consortium of thirteen universities in the U.S. and seven universities and research institutions in Japan. Chern provided an overview on objectives and research design. Imamura pointed out the difficulties in achieving the structural reform of paddy-rice production because of small farm size and high land price in Japan. Tweeten argued that a rich nation can afford almost any agricultural structure. Public policy is capable of shaping that structure, but costs can exceed benefits of alternatives. Morishima indicated that Japanese food consumption has been shifting toward the diet pattern of western countries, i.e., increasing meat consumption and decreasing grain consumption. Senauer noted that increasing health concerns and changes in demographic variables have had significant impacts on food consumption, notably decreasing consumption of red meat in the United States. The panel also discussed the benefits of the joint project.

Future Directions of Farm Management. Jean-Paul Chavas (University of Wisconsin), moderator; Glenn Johnson (Michigan State University), George Casler (Cornell University), Arne Hallam (Iowa State University), Steve Sonka (University of Illinois)

The American Agricultural Economics Association has its roots in farm management in the early 1900s. Since then, the AAEA has diversified its scope to address economic issues going far beyond the farm-gate. In the process, the relative importance of farm management has greatly diminished over the last few decades. This symposium examined the current state of farm management and tried to anticipate possible directions for future developments. Glenn Johnson

provided an historical review of the evolution of farm management, its mission and its approach to the analysis of decision making. George Casler discussed the role of research, teaching, and extension. He suggested that teaching and extension in farm management outruns what has been done in research. Arne Hallam explored the linkages and the differences between farm management and production economics. Steve Sonka concluded by discussing the future prospects and challenges for farm management.

The Effect of Agriculture on Environmental Quality in Developed Countries: An International Perspective. Stephanie Mercier and Bengt Hyberg (ERS USDA) organizers; Stephanie Mercier, moderator; David Ervin and Bengt Hyberg (ERS USDA), Glenn Fox (University of Guelph), and Sean Pascoe (ABARE)

Recent concern over the environment and the potential contribution of agriculture to its degradation have led to questions on whether the agricultural policy structure in place in major agricultural countries tends to accelerate the degradation process. Pascoe divided U.S. programs into two categories: those that intensify input use and increase production (i.e., input subsidies and price supports), and those that tend to reduce production (ARP and CRP). Hyberg noted that in Australia the population is concentrated in urban centers away from agricultural production to such an extent that agricultural runoff affects mostly farmers. Ervin contrasted EC "green" fever and elaborate plans for conservation policies with the fact that only 6% of the EC agricultural budget is allocated to such activities. Fox found that most Canadian agricultural policies, while not necessarily leading to higher production, contribute to increased specialization both at the farm level and regionally, with unclear implications for the environment. Public awareness of this issue is increasing in developed countries, and the possibility was raised during discussion that environmentalism can be characterized as a luxury good, limited to populations where sufficient income and leisure time exist to permit individuals to notice and protest declines in environmental quality.

The Changing Role of Extension Economists in the 1990s. Gary Fairchild (University of Florida), moderator; Karen Klonsky (University of California, Davis), Damona Doye (Oklahoma State University), Otto Doering and George Patrick, (Purdue University), David Lambert (University of Nevada, Reno), Robert Christensen (University of Massachusetts), Fred Woods (Extension Service USDA), and Tim Wallace (University of California, Berkeley), summarist

Extension economists in the 1990s will be confronted not only with changing problems and issues but also pressure for interdisciplinary involvement, increased applied research, changing and expanding audiences, and potential funding limitations. The symposium focused on the implications of these trends by examining policy and program directions for the decade ahead. Klonsky and Doye discussed the role of extension economists in interdisciplinary and multidisciplinary research by noting the increasing complexity of science and the need to help audiences understand and interpret research results, as well as the impact of issues-based programming on traditional discipline-based programs. Doering and Patrick discussed the role of extension economists in applied research in terms of relationships with research economists, impacts on educational program delivery, and the need to generate additional resources. Lambert outlined challenges associated with incorporation of new problems and issues in extension program delivery in terms of new audiences and new techniques. Christensen and Woods discussed the challenge of funding a changing extension commitment. They noted the changes in federal, state, and county funding for extension and the increasing need for competitive and specialized grants. Wallace admonished the symposium participants for plowing old ground and called for a more futuristic focus.

North-Central Region Survey of Farm Operators and Spouses: Long-Term Adjustments Resulting from the Farm Crisis. Freddie Barnard (Purdue University), organizer; William Saupe (University of Wisconsin), moderator; Peter Korsching (Iowa State University), Larry Leistritz (North Dakota State University), Linda Lobao (Ohio State University), Arlo Biere (Kansas State University), Colletta Moser (Michigan State University), and Kent Olson (University of Minnesota)

Public attention has focused on the severity of the farm crisis at the national and state levels, but until now little scientific inquiry has been directed at the long-term effects of farm financial stress. Little is known about how economic hardship has affected long-term adjustments in farm operations, family functioning and individual well-being and how adjustments may differ in a sparsely populated versus an industrialized state. North-central region researchers collected comparative data on farm operations across the twelve states to determine adjustments as a result of farm financial stress and prospects for further economic and institutional changes. Korsching discussed the organization and implementation of this twelve-state regional study. Leistritz and Lobao compared findings for a sparsely populated state (North Dakota) to findings for an industrialized state (Ohio). Finally, differences in those states and other states in the region were discussed by Biere, Moser, and Olson.

Applications of Input-output Analysis to Agricultural and Rural Research—Problems and Prospects. Ron Shaffer (University of Wisconsin), moderator; Mark Planting (BEA USDC), David Holland (Washington State University), Mark

Henry (Clemson University), and Chinkook Lee (ERS USDA)
The symposium addressed four issues pertinent to using input-output (I-O) analysis in agricultural and rural research. Mark Planting, the economist with final responsibility for constructing the official 1982 U.S. table, addressed table data details and accuracy of the U.S. I-O table. David Holland dealt with using an I-O modeling framework to analyze structural change. He reviewed decomposition models for determining the sources of economic growth and discussed applications of the 1982 data. Mark Henry then addressed the experiences of using national I-O tables for rural and regional analysis. He also discussed constructing regional I-O tables from national tables and the usefulness of 1982 national I-O tables in rural and regional research. Chinkook Lee discussed the incorporation of the agricultural sectors into the U.S. I-O table.

Pitfalls and Rewards of Theoretical and Applied Research: Implications for Young Professionals. Catharine Lemieux (Indiana State University), moderator; Ronald Knutson (Texas A&M University), Cleve Willis (University of Massachusetts), and Kenneth Farrell (University of California)
Changes in funding priorities and an increasing emphasis on problem-oriented research are altering the research climate in the profession. An extension economist, department chair, and system vice-president addressed these issues and offered advice to young professionals. The three agreed that well-conceived and executed research will be rewarded whether it is applied or theoretical. Both Knutson and Willis felt it was important to select real problems and not "tinker at the margins" or become technique oriented in a research program. The need to develop a commodity or functional area expertise was cited as critical by Knutson. Knutson also recommended young professionals collaborate with other successful economists and seek a clientele of support outside the profession. However, both Knutson and Willis cautioned against doing consulting prior to tenure. Willis recommended interdisciplinary research saying, "If done sparingly it can increase funding, productivity, and publishing opportunities." However, Farrell emphasized the necessity of establishing disciplinary credentials and cautioned against engaging in interdisciplinary research prior to tenure. He suggested that new structures such as interdisciplinary research institutes outside the control of individual departments may be needed to address multidisciplinary issues. All agreed that their comments were aimed at describing the situation as it currently exists, not as what is optimal.

Use of Crop Simulation Models for Economic Analysis: Potential and Limitations. Robert O. Burton, Jr. (Kansas State University), moderator; Paul T. Dyke (Texas Agricultural Experiment Station, Temple), William G. Boggess (University of Florida), Ronald D. Lacewell and James W. Mjelde (Texas A&M University)
Numerous analyses performed by agricultural economists require crop production data. Crop simulation may be used to fill data gaps quickly and inexpensively relative to other data-gathering strategies. This symposium brought together agricultural economists who have had a wide range of experiences with crop simulation models to discuss potential and limitations. Dyke summarized their development, operation, and use. Boggess presented numerous uses in policy and nonfarm analyses. Lacewell discussed uses in farm management research. Mjelde focused on multiple models and questions users should consider. Burton summarized: (*a*) crop simulation models are daily (or less) time-step production functions; (*b*) they use climate, soil, plant growth, tillage, and management data to simulate physical, chemical, and biological processes; (*c*) they provide data under conditions that have not been observed; (*d*) they have been widely used. Subsequent discussion focused on validation and revealed the expectation of increasing use of crop simulation models.

Human Capital Topics Demanding Attention: A Canada/U.S. Comparison. Ray Bollman (Statistics Canada), organizer; Robert D. Emerson (University of Florida), moderator; Rich Barichello (University of British Columbia), Dan Sumner (USDA and North Carolina State University)
The primary areas of application of human capital over the past thirty-five years have been on schooling, productivity, and decision making, effects on output mix and quality, and management techniques. Although this research is highly relevant for the problems facing agricultural and rural areas, it was recognized that human capital research is not high on the agenda of any policy makers. Examples of problems toward which a human capital policy could contribute are substituting for farm programs, compensating for adverse trade effects, and facilitating the movement of labor out of agriculture. A number of topics were suggested for research attention on human capital. Among these were (*a*) the supply of human capital to agriculture, (*b*) the role of human capital in economic growth and international competitiveness, (*c*) the effect of human capital on farm size via speeding the adjustment to optimal size, (*d*) mobility out of farm labor markets, and (*e*) greater attention to education rather than just age and experience in explaining the effect of human capital. A necessary prerequisite to improving the human capital research base is improved data sets pertaining to human capital for rural areas.

Alternative Rural Development Perspectives. Ron Shaffer (University of Wisconsin), moderator; Amy Glasmier and Niles Hansen (University of Texas),

William J. Coffey (University of Quebec at Montreal), Susan Christopherson (Cornell University)
Rural development activities by researchers have been challenged by events of the 1980s and the limitation of traditional approaches. Four speakers from outside the association were invited to provide alternative perspectives on prospects for rural areas. Glasmier presented an overview of performance patterns in the rural economy relative to urban areas. Rural area researchers are urged to pay greater attention to international events, industrial structure and analysis, and corporate strategies. Hansen examined central issues in growth center theory relevant to current rural economic development concerns in the United States. The case of peripheral Jutland in Denmark was examined as a recent rural industrialization case study. Central government policies were found to have relatively little impact, while local cultural character played a key role. Coffey presented a framework for the analysis and utilization of a local development approach. Several guiding principles for local economic development were offered. (*a*) High priority should be given to human and information infrastructure. (*b*) Initiatives should respond more to market opportunities. (*c*) A diverse array of projects should be pursued. Christopherson examined rural development implications of flexibly specialized firms, industrial districts, new work patterns, and restructuring of service industries for rural areas. Trends in each of these areas are expected to present challenges for economic development efforts in rural areas.

Innovative Extension Education Delivery Methods—The Issues. Dean Baldwin (Ohio State University), Gerry Campbell (University of Wisconsin), and Lee Meyer (University of Kentucky), organizers; Dean Baldwin, moderator; Gerry Campbell, Terry Gibson (University of Wisconsin), Henry Bahn (ES USDA), Lee Meyer
Innovative technologies can complement extension education programs. The symposium provided an opportunity for the discussion of issues including educational effectiveness, parochialism, funding, training, and support needs. Campbell focused on the impacts on curricula and support. Gibson (participating via teleconference) discussed approaches to distance education and the learners' needs. Bahn discussed the implications for national programs. Meyer summarized evaluation approaches and results of distance education efforts among nonagricultural student groups. As part of the symposium, surveys were conducted before the conference among ag. economists and during the symposium among those attending. The same three topics were of highest interest to both groups: (*a*) concern about actual effectiveness, (*b*) the impact of parochialism on adoption and use of the delivery methods, and (*c*) interest in evaluation techniques, results, and use. Discussion focused on these three points, although there was also considerable debate about extension programs meeting "the market test" and the need for investment in human capital.

The Canadian Agricultural Policy Review: An Update. Ray Bollman (Statistics Canada), organizer; Garth Coffin (McGill University), moderator; Doug Hedley (Agriculture Canada), Ken Rosaasen (University of Saskatchewan), and Roger Hughes (British Columbia Ministry of Agriculture and Fisheries)
The Canadian government is in the midst of the most comprehensive review of agricultural policy in at least twenty years. Some fourteen task forces, involving more than 300 farm and industry leaders, academics and government officials, are preparing recommendations for the Minister of Agriculture on issues relating to market and trade development, farm finance and management, income safety nets, supply management in dairy and poultry, transportation policy, food quality, sustainable agriculture, and other topics. Hedley presented the background and rationale for the policy review and the process underway. The need for review is driven by changing consumer demands, increasingly competitive world trade, rapid technological change, increasing environmental concerns, and the need to maintain Canada's reputation as a supplier of safe and nutritious food. The "four pillars" or principles guiding this review are (*a*) increased market orientation, (*b*) increased self-reliance of farmers, (*c*) national policy which recognizes regional diversity and (*d*) environmental sustainability.

The process responds to long-standing demands of farm and industry groups to have more involvement in policy decisions. Rosaasen noted the division of regional interests between domestic and export market orientation and questioned where adjustment should occur and whether this process could be expected to recommend major change. Hughes reinforced the skepticism of process by questioning the consistency of an apparent emphasis on income safety nets on one hand with the need for change on the other.

Rural Governments in Financial Crisis. David Zimet, presiding (University of Florida), Susan White (National Association of Counties), Michael Hattery (Cornell University), David Chicoine (University of Illinois), Bruce Weber (Oregon State University)
Recent changes in federal aid, termination of revenue sharing, unfunded federal and state mandates, and declining tax bases have created financial burdens on local governments. Zimet and White reviewed the history of federal tax codes affecting tax-exempt bonds and how the federal fiscal crisis adversely affects that market. They contended that trends toward bond pooling by rural governments and lease financing will accelerate. Hattery stated ways to improve local efficiency include yielding greater fiscal and institutional flexibility to local governments, increased use

of technology to improve links among local governments and between them, and technical expertise. Chicoine noted that rural governments spend 25% more per capita on operating expenses than do urban governments. He stated that county governments act as agents for higher levels of government to constituents and as independent governments responding to constituent needs. Weber described the decline in federal support. He indicated local governments have lost proportionately more in funding than state governments. He noted that special districts have been created to support specific activities.

Undergraduate Curriculum Review: Translating Review into Curriculum Change in Agricultural Economics. Carl Zulauf, (Ohio State University), moderator; Dale Dahl (University of Minnesota), Larry Conner (Michigan State University), Bernard Erven, (Ohio State University)

The University of Minnesota, Michigan State University, and Ohio State University have reviewed and revised their undergraduate programs in light of continuing national concern about undergraduate education. Similarities and differences in the experiences of these three departments were presented in this symposium. Implications for the profession were also drawn. Key similarities among the three departments were a clearly defined mission for undergraduate education, an opportunistic approach to review which led to reform in curricula rather than just minor changes, careful attention to both process and content in curricular revision, no major called agricultural economics, and the importance of relationships with colleges of business. Key differences included the number and content of new majors, role of service courses, use of the core course concept, and business school-type courses in agricultural economics. Implications for the profession included the need for clarification of the mission for undergraduate education, distinguishing between professional and disciplinary education, role of business courses, job descriptions for new faculty positions, and the need for teaching materials to support the new curricula.

Initiatives and the Funding Process for Rural Social Science and Extension. Ronald C. Wimberley (North Carolina State University), organizer; James J. Zuiches (Washington State University), Kenneth R. Farrell (University of California), and Russell C. Youmans (Western Rural Development Center)

This panel provided information and updates on the social science research and funding initiatives that have been advanced in the past year. The panelists served this effort through ESCOP and National Association of State Universities and Land Grant Colleges' (NASULGC) Division of Agriculture. Efforts through USDA and NASULGC continue to unfold during this congressional session. These include work on the farm bill plus research and extension appropriations, which await a Senate-House compromise, for rural research in the National Research Initiative for Research in Agriculture, Food, and Environment. Farrell explained how research initiatives develop through regional experiment station directors in NASULGC. He challenged social scientists to influence this process at various stages. Youmans pointed out a difference in the experiment station agenda, which concentrates more on physical agricultural issues, and the extension agenda, which concentrates on the broader issues facing farm and rural people. Someone added that social scientists should take issues and findings to research administrators to show the broader role.

The Conservation Reserve Porgram after the Contracts Expire: What Then? Richard T. Clark, (University of Nebraska), co-organizer and moderator; James B. Johnson (Montana State University), co-organizer and presenter; Michael R. Dicks (Oklahoma State University), Steven B. Kraft (Southern Illinois University), C. Robert Taylor (Auburn University), and Gary A. Margheim (SCS USDA)

CRP has removed nearly 34 million acres from production since 1986. The ten-year contracts will begin expiring in 1996, and the land will become eligible for cropping. Johnson, Dicks, Kraft, and Taylor provided regional estimates of the proportions of CRP that might return to crop production. Estimates ranged from a low of 10% in the southeast to 80% in the southern plains. Panelists expected a total of 19 million acres to return to crop production. Margheim, using a national rather than regional approach, estimated that from 14 to 16 million acres would remain in conservation use. Taylor, using AGSIM and related econometric simulation models projected the impacts of CRP lands returning to production on crop prices, acreages, and net farm income. Expected price reductions would range from 1% to 2% for livestock to 6% to 7% for hay. These reductions were below a baseline situation—the continuation of the 1985 Food Security Act provisions. U.S. net farm income was projected to decline about 10% if 19 million acres return to crop production. Discussion focused on policy options for maintaining selected lands in conservation cover. Options debated included targeting of certain land classes for compensated retention, payment of contract holders for differences in return to land between crop and livestock production, extending contracts to fifteen years and stiffening requirements for conservation compliance.

Black Farmers: Trends, Problems, and Prospects. Surendra P. Singh (Tennessee State University), organizer; Christina H. Gladwin (University of Florida), moderator; F. S. Bagi (North Carolina A&T University), Tesfa G. Gebremedhin (West Virginia University), Richard D. Robbins (North Carolina A&T University), Surendra P. Singh and Sammy Comer (Tennessee State University)

In spite of the attention given by the government and private sources, the crisis facing black farm operators continues to escalate. This symposium discussed and assessed from a variety of perspectives, conditions and problems of black farm operators. Gladwin introduced the topic by pointing out some relevant statistics and the importance of small farms for rural communities in general. Singh presented briefly the trends and characteristics of black farmers. He also pointed out the major problems facing black farmers. Their problems are grave, and they are broader than economic adjustment within the agricultural sector alone. Bagi discussed the relative efficiencies and resources used on black and white farms. He concluded from a study in Tennessee that there were no significant differences in technical inefficiencies on black and white farms. Gebremedhin discussed present policies and their implications for black-operated farms. He emphasized various appropriate public policy measures to help black farm operators. Robbins discussed and presented a case study on how land grant institutions can help small black farm operators by showing them how to manage their enterprises more efficiently. Audience participation was great, and their comments included reports on land loss, alternative enterprises, off-farm work, and programs to help black farm operators. It was suggested that the heterogenous nature of black farm operators, intrinsic value of land, and small size of black-owned parcels be recognized and considered in developing future programs and policies to assist black farm operators.

Rural Infrastructure Issues: Roles of Researchers and Extension Workers in the 1990s. John Halstead (University of New Hampshire), moderator; Mark S. Henry (Clemson University), Gerald A. Doeksen (Oklahoma State University), and Danny Klinefelter (Texas A&M)

Rural infrastructure has been identified by the Cooperative Extension Service and experiment station leadership as a priority issue. This resulted from the fact that rural infrastructure (*a*) is in poor condition, (*b*) is poorly funded (federal government is decreasing funding), and (*c*) influences economic growth and development. This symposium examined what extension and research professionals can do to provide assistance to local decision makers. Henry suggested research to measure the relationship between infrastructure and economic growth, on how to use the GIS system in infrastructure analysis and to continue budgeting research which includes funding alternatives. Issues of equity and efficiency need to be addressed. Doeksen identified extension areas as community leadership development, information dissemination, technical information for specific projects, and overall capital improvement planning. Klinefelter reviewed a document published by the Southern Rural Development Center which discusses case studies of innovative infrastructure financing and delivery systems. The publication presents case studies on transportation, business incubators, emergency medical services, fire, industrial sites, recreation, education, health, water and sewer, roads and bridges, social services, and solid waste. A copy can be obtained from the Southern Rural Development Center.

New Productivity Measurement Research. Roger K. Conway (ERS USDA), organizer; Frank Gollop (Boston College), moderator; Eldon Ball (ERS USDA), P. A. V. B. Swamy (Federal Research Board), Rolf Färe (Southern Illinois University), Jet Yee (ERS USDA), Erwin Diewert (University of British Columbia), Wallace Huffman (Iowa State University), and Dan Primont (Southern Illinois University)

Ball and Conway described the new ERA Törnqvist productivity indices created in response to AAEA task force recommendations. These indices are quality adjusted and will provide a detailed data base suitable for studies of producer behavior. Swamy indicated a method to separate scale from technology changes as well as forecast productivity changes using stochastic coefficients. Diewert cautioned that inflation effects were not accounted for and coefficient restrictions were needed to get theoretically valid estimates. Swamy agreed and indicated restricted estimates of his method could be obtained. Malmquist indices offer many virtues according to Färe, such as the ability to separate changes in performance from changes in the frontier of technology. Adjusting for capacity utilization, Yee found agricultural productivity growth declined around 18% between 1949–80. Self-employed labor was in surplus throughout, while capital was in shortage until 1980. Primont observed each method seeks to decompose the sources of growth. Huffman called for greater resources directed to data development with land grant universities assisting the process.

Potential Role of the Service Sector in Rural Economies. Stephen M. Smith, (Pennsylvania State University), organizer and moderator; Frank M. Goode (Pennsylvania State University), Cathy D. Kassab (Pennsylvania State University), Shirley L. Porterfield (ERS USDA), Glen C. Pulver (University of Wisconsin)

The purpose was to present and discuss issues and evidence related to the effects and role of the service sector in rural economic growth. Goode focused on the causal versus passive role of services in economic growth. Evidence for Northeast communities showed that manufacturing growth was more likely in communities with a complex versus a simple service structure. Porterfield discussed the nature of producer services growth in rural counties. National county-level data showed that producer services grew rapidly in nonmetro counties with highly educated labor that were regional centers adjacent to metro counties, and that such growth was more dependent on manufacturing growth than in metro counties. Kassab considered the effect of growing rural service employ-

ment on incomes. For the more remote rural areas, both low and high wage services led to an increase in middle income groups. In centrally located communities, however, service growth led to a more bipolarized income distribution. Pulver summed up by focusing on needed research, emphasizing classical versus nontraditional location factors for specific service sectors, particularly those amenable to policy manipulation, and wage and income distribution impacts. Audience discussion centered on measurement issues and suggested areas for future research.

A National Policy of "No Net Loss" of Wetlands: What do Agricultural Economists Have to Contribute? Jon Goldstein (U.S. Department of the Interior), moderator; Ralph E. Heimlich (USDA), Peter J. Parks (Duke University), John C. Bergstrom (University of Georgia), and Leonard Shabman (Virginia Polytechnic University)
Most wetlands lost recently were converted for agricultural production. President Bush proposed "No Net Loss" as a national goal, meaning that restoring wetlands must complement conserving wetlands to offset unavoidable losses. This symposium explored how "No Net Loss" might operate and the economist's role in developing this policy. Heimlich traced wetland policy evolution. He concluded that proposals to restore wetlands in the 1990 farm bill and the "No Net Loss" task force are a logical next step. Parks reviewed normative and positive approaches to estimate costs of acquiring wetland easements. Estimating landowners' participation in easement programs and participating acreage is more difficult than estimating wetland opportunity costs. Bergstrom stressed that economists urgently need to extend site-specific benefit studies to regional evaluation models (REMS) for more general policy development. Local wetland benefit studies are still needed to help assess programs for conserving and restoring wetlands. Shabman suggested that economists' experience in designing institutions that rely upon financial incentives rather than command and control regulation can benefit wetland programs to achieve no net loss. Wetland development fees based on development value rather than wetland value could help rationalize the permitting process.

Emerging Nonparametric Techniques for Applied Production Analysis. Tom Cox (University of Wisconsin), moderator; Jean-Paul Chavas (University of Wisconsin), Hongil Lim and C. Richard Shumway (Texas A&M University), Alfons Weersink (University of Guelph), Giancarlo Moschini (Iowa State University)
Nonparametric techniques facilitate economic analysis under less restrictive maintained hypotheses than commonly implied by traditional parametric approaches. In particular, these techniques do not require the ad hoc, a priori, parametric specification of choice functions (such as supply and demand, profit, cost, nor production functions). Several variations on this nonparametric theme have been applied to topics in agricultural economics. One major variation, popularized by Färe, extends Farrell's seminal work on technical efficiency measurement using linear programming to estimate nonparametric production frontiers. A second major variation derives from Varian's use of "revealed preference" analysis to generate sets of testable inequalities implied by alternative axioms of producer behavior. A third major theme concerns kernel estimation of nonparametric density functions to generate nonparametric and/or hybrid semiparametric specifications. The symposium summarized the current use of these emerging nonparametric techniques for applied production analysis with emphasis on the strengths and weaknesses of these emerging techniques relative to more traditional approaches for applied production analysis. Chavas provided an insightful, integrative overview/contrast of the Färe and Varian approaches. Lim and Shumway, Weersink, and Moschini then contrasted the strengths and weaknesses of the Varian, Färe, and kernel estimation approaches relative to traditional parametric alternatives, respectively.

Base Flexibility and Related Options for Reducing Price Distortions for Input Use. Clayton Ogg (U.S. EPA), moderator; David Zilberman (University of California), Stanley Johnson (Iowa State University), David Ervin with Ian McCormick and Kazim Konyar (ERS USDA)
Reducing price distortions and base flexibility are central to recent farm policy debates. Price distortions that encourage input use undermine farm program goals and add to environmental problems. This symposium examined how distortions occur, their extent or seriousness, and proposed remedies available within current farm program structures. Zilberman found that agricultural and resource policies have been inconsistent, although some progress has been made in addressing this problem. Farming activities have been conducted in environmentally sensitive areas, while agricultural production capacities in less-sensitive areas have been idle. Coordination of commodity and resource programs will require interagency management of agricultural resource policy, a unified research effort to address and assess efficiency, and equity and environmental consideration of alternative policies. Johnson used input demand and output supply functions to evaluate trade-offs for commodity program parameters, emphasizing impacts for distortions. Results show opportunities for more efficient design of programs and improved targeting of benefits. Ervin, McCormick, and Konyar find effects of planting flexibility very sensitive to design features: for example, which crops are permissible on bases and level of flexibility will determine resource use and environmental impacts.

China's Agricultural Trade in the 1980s and Prospects for the 1990s. Wen S. Chern (Ohio State University), moderator; Shi Ru (International Trade Research Institute, MOFERT, China), Francis C. Tuan (ERS USDA), Torng-Chuang Wu (Council of Agriculture, Taiwan), Joseph Chai (University of Hong Kong), Y. Y. Kueh (MacQuaire University, Australia), Niu Ruofeng (Research Institute of Agricultural Economics, MINAG, China), and Hsi-Huang Chen (National Taiwan University)
Chinese agricultural trade, both mainland and Taiwan, changed rapidly in the 1980s. In mainland China, institutional and other economic reforms have enhanced agricultural production and increased agricultural commodity exports in the 1980s. Taiwan's liberalization of agricultural trade rapidly altered its trade structure between Taiwan and the United States and between Taiwan and many other countries. Shi and Tuan summarized China's agricultural trade development and discussed prospects. Wu stated Taiwan's agricultural trade growth and future policies. Chai and Kueh analyzed major factors affecting China's agricultural trade. The symposium concluded with Niu and Chen's comments on the above presentation.

What, If Anything, Can the Fellows Contribute to the Profession? R. J. Hildreth (Farm Foundation), moderator; Wayne D. Rasmussen (ERS USDA, retired), Otto Doering (Purdue University), and Paul Barkley (Washington State University)
A supply exists of fellows who are willing to try and help improve the profession. However, it is unclear whether a demand exists for such services. This symposium explored the matching of supply and demand through activities to be sponsored by the AAEA Fellow's Activity Committee. Rasmussen presented a historical foundation for tomorrow's profession. Otto Doering, chairman of the Adaptive Planning Committee, discussed the supply and demand sides of the question and presented possible undertakings for the Committee from the perspective of the Adaptive Planning Committee's deliberations. Barkley also discussed the supply and demand issue as well as possible activities of the Fellow's Committee from the perspective of activities planned and conducted by the Professional Activities Committee. Discussion and interaction with the audience was a major aspect of the symposium. The outcome of the symposium is a major input to planning by the Fellow's Activities Committee.

Software Packages for Statistics and Econometrics: A Case Study—SHAZAM. Oral Capps, Jr., (Texas A&M University), moderator; Kenneth J. White (University of British Columbia), Donna Wang (University of British Columbia), Diana Whistler (University of British Columbia), Doug Pearce (University of British Columbia), Jeffrey Perloff (University of California, Berkeley), Quentin Grafton (University of British Columbia), and Meredith Scantlen (University of British Columbia)
Software packages for statistics and econometrics are growing in number. The list includes SAS, RATS, TSP, ESP, and SHAZAM. Without much investment in time, it is difficult for quantitative analysts to make decisions concerning which package(s) to use for research purposes. Also, it is generally not possible for researchers to interact with software developers. This symposium centered attention on SHAZAM. White provided a discussion of the development and description of this econometrics package. Others discussed possible upgrades of this package. Interaction took the form of suggestions to include upgrades or new procedures, to write special programs, and to improve existing routines. As well, symposium attendees were able to get "hands on" experience with the software package. This symposium was unique in that it permitted interactions between analysts and software developers.

Prioritizing Riparian Lands for Restoration, Including Wetlands and Stream Corridors. Peter Kuch, presiding (U.S. EPA), G. C. Van Kootan (University of British Columbia), Andrew Schmitz (University of California, Berkeley), Steven Lovejoy (Purdue University) and Clayton Ogg (U.S. EPA)
Priorities need to be established protecting wetlands and retiring croplands made eligible in the new U.S. farm bill proposals for "environmental reserve programs" (ERP). Van Kootan illustrates the key role that current farm support programs have had in depleting waterfowl habitat. This has occurred both because of the way benefits are determined and the fact that programs discourage animal husbandry. Schmitz notes however, that potholes impose added operating costs on the farmer in terms of machine operating time and hassle. He also points out that once land has been converted to grainland, it usually does not return to grassland regardless of relative prices. Lovejoy reports on work comparing the efficacy of various "structural type" approaches for reducing sedimentation damage. He finds targeted conversion of uplands produce the greatest reduction, but the targeting is very information intensive. Vegetative filter strips along watercourses proved to be almost as good and required a lot less information. Ogg notes that prioritizing farmers ERP bids to favor vegetative filter stips and wetland reserves represents an administrative challenge, as does coordination with state water quality plans. International cooperation to avoid price distorting policies will address the causes of wetland and other environmental losses, while furthering farmer objectives.

Conflicts in Food and Agricultural Policy. Kate Clancy (Syracuse University), organizer and pre-

senter; Carol Kramer (Resources for the Future), moderator and presenter; Jean Kinsey (University of Minnesota), and Katherine Reichelderfer (Resources for the Future)
Conflicts and complementarities among the various interests in agricultural and food policy are longstanding. However, new issues and proposed policy changes frequently highlight the conflicts without emphasizing the potential for complementarity. The areas covered in this symposium were selected critical conflicts among food safety, nutrition, food production and marketing, and environmental policies. Extensive audience discussion followed the presentations. Two main themes emerged. The first was the question of the jurisdictional level—state, federal, or international—at which regulatory standards should be set, and the appropriate role of public and private decision makers. A related concern was the appropriate combination of production, processing, and product standards and enforcement mechanisms. The case of organic certification nicely illustrates many of the issues. There was agreement that there is a need for better comprehension of complex issues involving different policy sets and their inherent conflicts, including the impact on production agriculture of changes in demand for nutrition, health and environmental amenities.

Economic Issues in Trade Disputes Over Agricultural Products. Erna van Duren (University of Guelph), organizer; Randy Wigle (Wilfrid Laurier University), moderator; Heather Meek (Agriculture Canada), Carol Goodloe (ERS USDA), James Rude (University of Guelph)
Canada applied more economic logic to settling countervailing duty disputes than the U.S. and is more consistent with the GATT Subsidies Code. However, both countries could improve the application of their countervailing duty law by basing the law on economic principle. Despite the fact that economic models are imperfect, can be based on different assumptions, and encompass a range of elasticities, they can focus on the correct issue, the impact of one country's subsidy on the welfare of another's producers, and what type and level of countervailing duty should be imposed to remove the injury. Economic studies of the hogs and port dispute (U.S. vs Canada) have led to remarkably similar types of results, despite the diversity of modelling approaches and specifications used. Canada and the U.S. apply their antidumping laws in a manner that, if applied with some ingenuity, makes it impossible to lose this type of case on a horticultural product.

The Food-Processing Sector: The Role of Economic Information to Facilitate Adjustment and Growth. Ray Bollman (Statistics Canada), organizer; Rebecca Lent (Université Laval), moderator; Howard Migie (Agriculture Canada), Tim Hazeldine (University of British Columbia), and Randy Westgren (Macdonald College of McGill University)
The Canadian federal government has initiated the first extensive agricultural policy review in two decades. A major player in this review is the food-processing industry. Economists can play a vital role in providing appropriate information to the private sector. Trade issues such as the import ban on margarine, the U.S. countervail on Canadian hog products, and cross-border shopping illustrate the consequences of different degrees of support and protection. Coloring restrictions on margarine in Ontario and Quebec, regulation of grain and oilseed freight rates, and producer domination of supply management institutions indicate that much of current regulation is based on a producer focus rather than on a broader industry focus. This emphasis may be modified through policy review. Research in the area of competitiveness is essential to understanding how to encourage more collaboration between firms without stifling rivalry. Traditional economic analysis is important and useful for answering specific policy questions, however more analysis of institutions and rent-seeking behavior is needed to consider these issues in a comprehensive way.

Preparing to Assess the Long-term Impact of Immigration Reform on Agriculture: Can We Build on the Early Indicators of Farmer and Worker Adjustment? Howard R. Rosenberg (University of California, Berkeley), organizer and moderator; Leo C. Polopolus (University of Florida), Robert G. Mason (Oregon State University), Jeffrey M. Perloff and Susan M. Gabbard (University of California), H. L. Goodwin (Texas A&M University), Shannon Hamm (Commission on Agricultural Workers)
Although Congress passed the Immigration Reform and Control Act of 1986 (IRCA) explicitly to control illegal immigration, various other effects of the law have been desired, feared, predicted, and perceived as emerging. Individual responses so far to IRCA's complex set of inducements and penalties only begin to form its long-term impact on agriculture. Polopolus described recent efforts to develop benchmark data about seasonal farm work force, wages, management practices, and labor market structure in Florida and analyzed simultaneous concerns about future labor surpluses and shortages. Mason observed that minimum wage raises and product market competition make highly productive illegal aliens increasingly preferable to local legal residents in Oregon harvests. Perloff reviewed national survey data showing very low rates of worker departure from agriculture in fiscal 1989, notably except for those employed by farm labor contractors. Goodwin reported employer adjustments in Texas ranging from provision of new fringe benefits and more use of FLCs to mechanization and cropping pattern changes, the lat-

ter related also to irrigation constraints. Hamm outlined research planned by the Commission on Agricultural Workers to meet its statutory charge. Interacting with other legal, natural resource, and market forces, IRCA calls attention to farm labor issues that will continue to present rich opportunities for research contributing to policy as well as theory. Complexity and sensitivity of studies in this field necessitate public support for collection of relevant time-series data.

Selected Papers

The Managerial Economics of Agribusiness Firms (Bryan W. Schurle, Kansas State University, presiding)

"Comparative Performances of Food-Processing Cooperatives and Investor-Owned Firms." Claudia Parliament (University of Minnesota) and Zvi Lerman (Hebrew University)
Financial performance of cooperatives and investor-owned firms in two food industries is compared over time. Contrary to expectations, cooperatives do not exhibit lower profitability, overinvestment in assets, or excessive borrowing. The difference in objectives between cooperatives and investor-owned firms is not reflected in their financial performance.

"Industry and Size Effects in Agricultural Cooperatives." Zvi Lerman (Hebrew University) and Claudia Parliament (University of Minnesota)
The analysis of financial data from 1970–87 reveals significant size and industry effects among forty-three agricultural cooperatives. Large regional cooperativies are more efficient in utilizing assets to generate sales, while small regional cooperatives have higher profit. Dairy cooperatives are the strongest performers, and food marketing cooperatives are weakest.

"Are Milk Assembly Costs Linear in Volume Only? Evidence from the Greater Ohio Milkshed Suggests That They Are Decidedly Nonlinear." Edward W. Gallagher (Federal Milk Market Administrator's Office, New York City), Cameron S. Thraen and Gary D. Schnitkey (Ohio State University)
A nontraditional multi-output cost function for milk haulers is estimated. Outputs are defined as (*a*) assembly miles, (*b*) transport miles, and (*c*) volume of milk hauled. Data from forty firms provide evidence that the cost function is not linear in any of the outputs.

"An Evaluation of Input Purchasing Behavior at Local Farm Supply Cooperatives." Marcus L. Hartley and Jim Cornelius (Oregon State University)
This study explores a model of purchasing behavior at farm supply cooperatives. Using a methodology of seemingly unrelated regressions, purchases of different farm inputs were estimated based on a set of highly correlated, often subjective, independent variables. Generally, these attitudinal variables were of limited significance in explaining patronage of cooperatives.

"Analysis of Compensation in Agribusiness: The Case of the Retail Fertilizer Industry." Bradley P. Martens and William J. Taylor (Virginia Polytechnic Institute and State University)
This analysis examines the determinants of compensation from both employee and firm perspectives. The findings indicated that experience, education, firm size, and form of ownership are the key determinants of compensation.

Selected Issues in Agricultural Management (Gregory M. Perry, Oregon State University, presiding)

"Dynamically Optimal Biannual Range Culling Decisions versus Culling When Open in the Southwest." Russell Tronstad and Russell Gum (University of Arizona)
Optimal range culling decisions are solved by considering the age of the cow, pregnancy state of the cow, and replacement-calf-slaughter price levels. Results indicate that annual profits can be increased by about $37.00 per year from following an optimal culling strategy instead of culling whenever the cow is open.

"Weather Forecast Information and Farm and Ranch Decision Making: Results of a Survey." Kevin P. McNew (North Carolina State University) and Harry P. Mapp (Oklahoma State University)
Surveys of farmers and ranchers identified weather information used in production, marketing, and management decisions across a diverse agricultural region. Timing of planting, harvesting, and pesticide applications were based on temperature, precipitation, relative humidity, and wind movement. Short-term forecasts were more important for timing decisions on diversified operations.

"Managing Timberlands for Profitability." John P. Dwyer, Ronald L. Plain, and William B. Kurtz (University of Missouri)
This research evaluates long-term effects of thinning and pruning on net present value of oak timber. Analyses indicate no significant differences in grade or value of lumber result from pruning. However, thinning was found to have a significant effect on the quantity, grade, and value of timber produced.

"A Cash Flow Approach to Land Affordability." Gregory D. Hanson (Pennsylvania State University) and John F. Jinkins (USDA ERS)
A land price affordability model is proposed as a leading indicator of land price changes. Patterned after a housing affordability index, the model comple-

ments econometric models of land markets. Results show increases in ability to cash flow land purchases since the mid-1980s. Land is slightly less affordable in 1990.

"An Economic Comparison of Subsurface Micro-irrigation with Center Pivot Sprinkler Irrigation for Row Crop Production." Darrell Bosch (Virginia Polytechnic Institute and State University), Norris L. Powell and F. Scott Wright (Tidewater Agricultural Experiment Station)
An economic comparison is made of center pivot sprinkler irrigation and subsurface micro-irrigation for a corn and soybean rotation. For smaller fields, micro-irrigation has lower per-acre investment costs and higher net returns. As field size increases, center pivot systems have lower per-acre investment costs and higher net returns.

The Economics of Nontraditional and Sustainable Agricultural Enterprises (Larry Van Tassell, University of Tennessee, presiding)

"The Economics of Meat Goat Enterprise for Small-Scale Producers." Tesfa G. Gebremedhin (West Virginia University)
A comparison of net present values, payback periods, and financial feasibility analysis were the methods used to determine the most profitable operation of small-scale meat goat production. A cash surplus, attributed to land, family labor, and management for three alternative investment systems, occurred at the end of the third year.

"Profitability of Alternative Farming Systems in Ohio." M. S. Diallo, D. L. Forster, F. J. Hitzhusen and M. T. Batte (Ohio State University)
Profitability measures (net farm income and return on assets) are related to several factors including low input farming practices. Results indicate that farm size and financial leverage are related to profitability. Low input practices, such as diversification, reduced fertilizer and chemical use, and legume based rotations, have negligible impacts.

"Does Sustainable Farming Pay: A Case Study." Kathleen M. Painter (Washington State University)
A well-publicized western wheat farm has produced competitive yields without commercial fertilizers and minimal pesticides over the past eight decades. Under crop prices and program provisions for 1986–89, however, the farm's green manure rotation earned net returns averaging 23% lower than a typical conventional rotation for this area.

"The Role of Crop Insurance in Reducing Pesticide Usage." Eli Feinerman (Hebrew University of Jerusalem), Joseph A. Herriges and Derald Holtkamp (Iowa State University)
This paper investigates the potential for crop insurance to serve as a tool for reducing pesticide usage by providing a substitute for the risk management benefits of pesticides. A representative farm simulation model is employed to consider the interaction of pesticide restrictions, crop insurance, and the federal commodity program.

"A Financial Simulation Analysis of Hybrid Striped Bass Production Stages from Hatchery to Market." F. F. Wirth, C. M. Gempesaw, II, J. R. Bacon, and G. F. Vaughn (University of Delaware)
An increasing number of farmers are diversifying and seeking alternative crops and farming systems. This study evaluates hybrid striped bass aquaculture as another source of farm income. Dynamic simulation and stochastic dominance are used to analyze the economics of four phases in hybrid striped bass production.

Conceptual Issues In Agricultural Management (Cole R. Gustafson, North Dakota State University, presiding)

"Efficiency Measures Using the Ray-Homothetic Function: A Multiperiod Analysis." David L. Neff, Philip Garcia, and Robert H. Hornbaker (University of Illinois)
Recent investigations provide mixed assessments of farm efficiency. This analysis examines a homogenous sample of farms over a six-year period and efficiency measures are found to increase with temporal aggregation. Stratification of the farms by size indicates that the ray-homothetic function attributes high-scale inefficiencies to larger farms.

"Multiple Objective and Nearly Optimal Solutions in Greenhouse Management." Cleve E. Willis and Michael S. Willis (University of Massachusetts)
A linear programming model of greenhouse decisions based on expected profit maximization is modified to generate noninferior solutions based on family labor savings and expected profit considerations. These solutions are contrasted with nearly optimal solutions generated by the HSJ procedures.

"The Simultaneous Optimization of Product Quality and Production Quantity." S. Andrew Starbird and Paul M. Thompson (Santa Clara University)
A general class of profit maximization problems which optimally allocate resources between product quality and production quantity is formulated and analyzed. Expected profit is expressed using a stochastic qual-

ity variable. Profit-maximizing conditions are derived for quality variables with a normal, exponential, and Weibull distribution. Rework and give-away costs are considered.

"A Conceptual Framework for the Management of Farm Businesses." Robert A. Milligan and Guy K. Hutt (Cornell University)
A comprehensive integrating conceptual framework for the management of farm businesses is developed. The framework, based on the management literature, emphasizes the management of people, including oneself, and the functions of the manager—planning, organizing, staffing, directing, and controlling. The framework is currently being used in research and extension programs.

"A Test of the Applicability of Strategic Management to Farm Management." K. Harling (Wilfrid Laurier University) and W. Paterson (University of Kentucky)
Strategic management has proven a useful conceptual approach for nonfarm business managers. In this paper, its applicability to farm management is tested using discriminant analysis. Successful farmers are found to think more strategically than less successful ones, suggesting that it can be a useful way of thinking about farm management.

Managing the Agricultural Business Under Uncertainty (Darrell Bosch, Virginia Polytechnic Institute and State University, presiding)

"Analyzing Risk-Income Performance with Adaptive versus Nonadaptive Enterprise Mix Decisions." Larry J. Held and Mark E. Schutt (University of Wyoming)
Risk-income benefits of revising a firm's enterprise mix in response to updated information is examined from the standpoint of historical income variability and frequency and amount of target loss. The impact of improved information on a firm's risk status appears to depend heavily upon the type of risk expression.

"Double-Cropping Soybeans into Traditional Crop Rotations Under Government Commodity Program Restrictions." Jayson K. Harper (Pennsylvania State University), Jeffery R. Williams and Robert O. Burton, Jr. (Kansas State University), Kenneth W. Kelley (Southeast Kansas Branch Experiment Station)
Six enterprise combinations, four with double-crop soybeans, were evaluated using stochastic dominance analysis assuming government program participation. Wheat and double-crop soybeans followed by full-season soybeans was the preferred rotation for all risk preference intervals analyzed. Sensitivity analysis showed that when constraints limit double cropping, combinations with less than maximum double-crop acres are preferred to those without doublecropping.

"Use of a Crop Simulation Model to Provide Long-term Data for Economic Analysis: The Case of Early Maturing Soybeans." Robert O. Burton, Jr., Guido van der Hoeven, and Allen M. Featherstone (Kansas State University), George V. Granade (Georgia Experiment Station)
A target MOTAD model is used to investigate incorporating early maturing soybeans into a crop farm in southeastern Kansas. A weather (WGEN) and crop simulation model (SOYGRO) are used to generate a long-term series of soybean yields. Results indicate that early maturing soybeans offer a risk-reducing diversification strategy.

"A Dynamic Analysis of Irrigation Technology Adoption in the Central High Plains." Raylon C. Earls and Daniel J. Bernado (Oklahoma State University)
A dynamic model is presented for determining the optimal temporal pattern of irrigation investment and water allocation for irrigators in the Central High Plains. The model is applied to a representative irrigated farm. Optimal investment strategies are shown to be sensitive to initial pump lift, energy price, and crop price expectations.

"Multiperiod Rangeland Investment Analysis with Safety-First Constraints and Uncertain Data." David K. Lambert and Thomas R. Harris (University of Nevada, Reno)
Impacts of crested wheatgrass seeding investments on ranch equity and income indicators are examined. Expected ending new worth is maximized subject to stochastic forage production and prices using multiperiod nonlenear programming with safety-first income constraints. Seedings are found to be beneficial by stabilizing forage supplies and permitting herd expansion.

Farm Management: Surveys, Perceptions, and Decision Making (Paul N. Wilson, University of Arizona, presiding)

"Friend or Foe? Farmer Perceptions of Biotechnology." J. E. Hobbs and W. A. Kerr (University of Calgary), K. K. Klein (University of Lethbridge, Alberta, Canada)
This paper is the result of a survey investigating the attitudes of western Canadian farmers towards two biotechnological products, Enfix-L and PB-50. Farmers were asked to rate both the importance and the performance of twenty-one attributes of the products. Soil depletion was found to be an important

concern to many farmers. Personal and environmental risks were less of a concern. Overall, it was found that the nonbiotechnical aspects of a product would prevail in purchasing decisions.

"Obtaining Management Profiles of Ontario Swine Producers Through Cluster Analysis." Alejandro Rosenberg and Calum G. Turvey (University of Guelph)
This paper develops managerial profiles of Ontario Swine Producers for extension use, using mail survey data and cluster analysis. Results indicate that there are four major discriminant variables which can be used to identify different classes of farmers. These management profiles can be used for targeted extension efforts.

"Preference for, and Accomplishment of, Farm Tasks by Farm Wives in Dona Ana County, New Mexico." Wilmer M. Harper and Rossana Alvarez de Ayala (New Mexico State University)
Wives are major participants in agricultural operations and management. If their tasks are unrecognized or undocumented, their labor contribution may be inadequately documented, leaving this resource unacknowledged and/or misallocated. Paired comparison is used to develop a preference hierarchy of tasks for farm wives in Dona Ana County, New Mexico.

"Computer Adoption and Characteristics of Computer Usage on Farms." Gregory A. Baker (Santa Clara University)
A survey of computer usage on New Mexico farms was conducted. Results indicated that adopters of computer technology tended to be well-educated operators of large farms with a favorable attitude toward change. Age, education, attitude toward technological change, and farm size did not influence the success of the system.

"Information Usage among Ohio Fruit Producers: A Socioeconomic Analysis." Eugene Jones, Marvin T. Batte, Gary D. Schnitkey (Ohio State University)
Producers of perishable and other farm commodities face considerable risk and uncertainty. Producers attempt to mitigate these factors by utilizing accurate and reliable information. However, socioeconomic factors influence the accomplishment of these objectives. This research analyzes the impact of socioeconomic factors on the "adequacy" of information usage for marketing decisions.

Lasers, Livestock, Perennials, and Investment (Daniel Lass, University of Massachusetts, presiding)

"Capital versus Management-Intensive Technology Adoption." Lydia Zepeda (University of Wisconsin)
Factors explaining capital versus a management-intensive technology adoption are examined with a multinomial logit model of technological choices on California dairies. Results show differences in adoption probabilities but not in the marginal effects of explanatory variables. Thus, the explanatory variables' level appears to determine the probability of technology adoption.

"Strategic Investments in Agriculture: The Case of Laser Leveling in Arizona." David P. Anderson (Texas A&M University) and Paul N. Wilson (University of Arizona)
Decisions concerning strategic investments create risks associated with time and switching costs. In the case of cotton growers in Arizona, the decision to adopt laser-leveled fields was positively related to farm size and negatively correlated with age and soil intake rates.

"Estimating Asymmetric Supply Response Functions: An Application of Burton's Model to the Ontario Hog Sector." Heather Meek and Larry Martin (University of Guelph)
Asymmetric supply response is hypothesized to be an important explanatory factor in an increased hog production trend in Ontario from 1975 to 1988. A nonlinear hog supply specification is estimated, and the results indicate that asymmetric supply response in hog production exists.

"Planting Decisions for Perennial Crops: A Dynamic Unobserved Components Approach." N. G. Kalaitzandonakes and J. S. Shonkwiler (University of Florida)
In perennial crop supply analysis, separate estimation of the qualitatively different new planting and replanting investment relationships is desirable. Commonly, data paucity restricts estimation to a single reduced-form equation. This study develops a dynamic unobserved components method where separate estimation of the structural equations is possible without specific data on new plantings and replantings.

"Short-Run Output Response in the Western Canadian Cattle Industry." Theodore M. Horbulyk (University of Calgary)
The results of recent empirical work are interpreted with respect to the short-run production flexibility of cow-calf producers in western Canada. The principal findings are that many of the short-run supply and factor demand responses of firms are elastic with respect to within-season price variability.

Technical Change and Productivity Growth (Michelle Marra, University of Maine, presiding)

"Endogenous Regional Agricultural Production Technologies." Chris Fawson (Utah State University) and C. Richard Shumway (Texas A&M University)
This research examines and compares estimates of technical bias for each of ten multistate farm production regions comprising the contiguous forty-eight states of the United States. The applied methodology allows for price-dependent aggregate technical choice and stochastic variation of the production technology in computing measures of technical bias.

"Factor-Augmenting Technical Change as a Stochastic Process." J. Stephen Clark, W. Hartley Furtan, and Julia S. Taylor (University of Saskatchewan)
Technical change is modeled as a general stochastic process. The pure time trend model of measuring technical change is rejected for a translog system using aggregate Canadian data. We find that technical change is more appropriately measured as a random walk with drift.

"Can Productivity Growth Sustain Real Net Incomes in Agriculture?" Gary E. Bond (International Finance Corporation) and Stanley R. Thompson (Ohio State University)
An analytical framework decomposing real farm income movements into productivity, terms of trade and other components in presented. Analysis of data from thirteen countries shows productivity growth in all but one has been insignificant.

"Technical Change and the Derived Demand for Cotton in the U.S. Textile Industry." Shangnan Shui and John Beghin (North Carolina State University)
Using time-series data we estimate a linear logit model of cost shares of fiber use in U.S. textile production, which incorporates the impact of technical change and partial adjustment on the derived demand for cotton, wool, and manmade fibers. Technical change has decreased cotton use in U.S. textile mills.

"The Political Economy of Technical Change." John W. McClelland and George Frisvold (RTD ERS USDA)
This paper discusses issues that determine the pace and direction of technical change in U.S. agriculture. Impacts of changes in environmental legislation, patent policy, R&D funding, and farm policy introduce a CGE analysis. Technology parameters in the model are restricted to 1960 levels and effects of a stagnant technology on sector prices analyzed.

Assumptions and Elasticities (Utpal Vasavada, Université Laval, presiding)

"Measurement Error Tests of Separability in State-Level Agricultural Technology." Hongil Lim and C. Richard Shumway (Texas A&M University)
Stochastic tests of separability in agricultural production technology were conducted for eleven states. The empirical findings do not rule out a reasonable amount of data aggregation, both among outputs and inputs. The nature and extent of the justified aggregation varies among states.

"Dynamic Factor Demands in U.S. and Canadian Agriculture." Susan M. Capalbo (Montana State University), Michael D. Denny (University of Toronto), and Jane Friesen (Simon Fraser University)
We develop and estimate a set of data-based dynamic factor demand models for U.S. and Canadian agriculture. Data-based models attempt to let the data describe the dynamic process underlying the observed time-series data. The results suggest little support for the equilibrium factor demand model in either country.

"How Misleading Can Allen Elasticities of Substitution Be?" Timothy G. Taylor and Gautam Gupta (University of Florida)
The Allen elasticity of substitution has recently been shown to be an incorrect measure of substitutability when there are more than two inputs. This paper presents an empirical comparison of the Morishima and Allen Elasticities based on a translog cost function estimated using data for aggregate southeastern U.S. agriculture.

"Fixed Effects and Stochastic Frontier Estimates of Firm-Level Technical Efficiency." Boris E. Bravo-Ureta, Ricardo E. Quiroga, and Laszlo Rieger (University of Connecticut)
Parameter estimates from OLS, fixed effects and stochastic production frontier models are compared using panel data for a sample of Vermont dairy farms. The results confirm that OLS production function models without firm effects lead to biased estimates. The estimates from the production frontier model are also deemed to be biased.

"Measures of Scope and Scale Economics Using a Dynamic Framework." J. Fernandez-Cornejo, C. M. Gempesaw, II, and J. G. Elterich (University of Delaware), S. E. Stefanou (Pennsylvania State University)
Measures of multiproduct economies of scale and scope developed from static dual models are extended to a dynamic cost of adjustment framework using a dual cost function. These measures are em-

pirically estimated for German dairy producers in the presence of a production quota.

Chemicals, Health, and Sustainable Production (Ted Horbulyk, University of Calgary, presiding)

"The Economics of Storage Technology." Erik Lichtenberg (University of Maryland) and David Zilberman (University of California, Berkeley)
We present a framework for analyzing decisions about storage technology (pesticides, irradiation, temperature/humidity control). Policies that reduce the effectiveness or raise the cost of spoilage reducing inputs affect both total output and the temporal distribution of consumption. Future consumption and market welfare will decline, but overall consumer (producer) income may increase if future demand is elastic (inelastic).

"Health Costs of Long-Term Pesticide Exposure in the Philippines—A Medical and Economic Analysis." Prabhu L. Pingali and Cynthia Marquez (International Rice Research Institute)
Medical examination of a sample of Philippine farmers found a significant proportion suffering chronic health effects attributable to pesticide use. Farmer health costs are positively associated with total pesticide use, the hazard category of pesticides used and unsafe handling procedures. Relatively lower labor productivity can be expected of affected farmers.

"Toward Efficient Use of Swine Manure: In a Sustainable Agricultural Production System." Vern Pierce, Jim Kliebenstein, and Mike Duffy (Iowa State University)
This study includes development of typical Iowa crop/livestock farm production systems using an economic engineering analysis. Information evaluated for these case study farms include labor constraints, manure application strategies, crop nutrient need support, and projected farm income levels. The evaluation is done in a linear programming framework.

"Dynamic Optimization of Feed Quality and Quantity in Fish Culture." Oscar Cacho and Upton Hatch (Auburn University)
A dynamic programming model is presented that determines the optimal trajectory of feeding rate and dietary protein for catfish culture. Deterministic and stochastic versions of the model are compared. The stochastic solution yielded higher optimal protein, lower optimal feeding rate, and a 4.2% increase in profit over the deterministic case.

"Economic Determinants of Chemical Residues on Agricultural Crops: Tobacco and Maleic Hydrazide." Bruce A. Babcock (Iowa State University) and William E. Foster (North Carolina State University)
Maleic hydrazide (MH) residues on North Carolina tobacco respond to economic incentives. Regression estimates indicate a 10% increase in price implies a 7% decrease in residues; a 10% increase in wages implies a 3.5% increase. A 95% assurance rate that residues are below 80 ppm requires a doubled MH price, decreasing annual producer welfare by $2.7 million.

Sources of Production Inefficiency (Carl Nelson, University of Illinois, presiding)

"Risk-Corrected Efficiency Measures." Charles B. Moss, Nicholas G. Kalaitzandonakes, and Timothy G. Taylor (University of Florida)
Farrell's seminal paper spawned economic efficiency measurement as an important topic in agricultural economics research. Similarly, risk has long been recognized as an important dimension in decision making at the firm level. However, little integration has occurred between the two sets of literature. This study suggests one approach for integration.

"Nonparametic Efficiency Measurement: Using Complementary Information from Radial and Nonradial Measures." Steven C. Deller (University of Maine) and Carl H. Nelson (University of Illinois)
We show that, when calculating measures of technical efficiency, comparison of radial and nonradial efficiency measures can provide important information that is not available from either measure alone. This information is important when the efficient reference technology contains isoquant segments that are parallel to coordinate axes.

"Share Tenancy and Allocative Inefficiency." Hyunok Lee and Agapi Somwaru (ERS USDA)
A nonparametric frontier technology was formed by the observations of eighty-two rice farms in California to model optimal input use under various share cropping contracts. The results suggest profit loss from price (allocative) inefficiency resulting from share-renting. Price inefficiency also varies with the contract rule.

"The Technical Efficiency of Corn Farms in the Corn Belt: A Methodological Note." Hisham S. El-Osta, Robert A. Pelly, and Gerald W. Whittaker (ERS USDA)
Extreme observations may generate biased parameter estimates when corrected ordinary least squares (COLS) is utilized in technical efficiency studies. While most studies employ ad hoc procedures, this study suggests the use of "minimization of absolute deviation" as an alternative to COLS.

"The Relationship between Technical Efficiency and Farm Characteristics in the Stavropol Region, USSR." Karl D. Skold (Iowa State University)
Estimates of technical efficiency in crop production are generated using the stochastic frontier approach. Individual farm-level technical efficiency estimates are generated for grain, corn, sunflower, and vegetable production. These efficiency estimates are then related to farm organization structures, labor payment methods, and direct characteristics.

Nontraditional Inputs and Efficiency (William Foster, North Carolina State University, presiding)

"Labor Contracting and a Theory of Contract Choice in California Agriculture." Ann M. Vandeman, Elisabeth Sadoulet, and Alain de Janvry (University of California, Berkeley)
We present a model of labor contract choice where seasonality, sensitivity to labor quality and work intensity, and the relative efficiency of labor contractors in recruitment and extracting work determine the choice of employment contract. We estimate the probability of contracting and wages as functions of worker and job characteristics.

"Economic Measures of the Effect of Intellectual Property Rights on Plant Breeding." William E. Foster and Richard Perrin (North Carolina State University)
The paper presents a model of economic incentives for plant breeding research and examines the effects of the Plant Variety Research Act on the pattern of breeding activity across twenty-four crops and on the pattern of breeding activity in soybeans through time.

"Computer Appliciations by Ohio Commercial Farmers." Jean J. Botomogno (Dschang University Center); Marvin T. Batte, Gary D. Schnitkey, and Eugene Jones (Ohio State University)
The evolution of microcomputer technologies has been paralleled by the evolution of software suitable for farm applications. This research identifies factors that influence the number and type of applications for which farm computers are used. Multinomial logit analyses were utilized to determine factors associated with farmers' choices of computer applications.

"Efficience technique dans le secteur laitier québécois." Nabil Amara and Robert F. J. Romain (Université Laval)
A partir d'un modèle probabiliste et paramérique d'une fonction de production frontière dans la productin laitière au Québec, deux approaches furent confrontées pour construire des indices d'efficience technique. Le niveau d'efficience s'est avéré (plus de 80%) et sa distribution assez concentrée. Une conclusion majeure est l'indépendance entre l'efficience technique et la taille de l'entreprise. De plus, des variables socio-économiques (gestion, scolarité, . . .) qui influencent l'efficacité technique ont également été identifiées.

"Decomposition Measures of Technical Efficiency for Ontario Dairy Farms." Alfons Weersink, Calum G. Turvey, and Abdullahi Godah (University of Guelph)
Technical efficiency measures are decomposed for Ontario dairy farms using nonparametric methods. Higher efficiency levels were associated with larger herd sizes. Variation in optimal scale between herd sizes, however, implies a range of farm sizes will continue to exist provided the appropriate technology for the scale of operation is chosen.

Issues Affecting Financial Intermediaries (Alan D. Barkema, Federal Reserve Bank of Kansas City, presiding)

"An Empirical Analysis of Duration Based Financial Hedging Strategies." William Thompson and David Leatham (Texas A&M University)
This paper compares a duration based hedging strategy with a combination of a duration and spread-hedging strategy that includes hedging changes in the yield curve. The duration and spread hedge reduced lender's interest rate risk associated with fixed-rate loans by 89% compared to 68% for the duration based hedges.

"An Evaluation of Alternative Hedging Strategies for Federal Farm Credit Bonds." J. C. O'Neill (Peavy Company), J. T. Akridge and William D. Dobson (Purdue University)
Strategies used by the Federal Farm Credit Bank's Funding Corporation and two alternatives for hedging anticipated liabilities were evaluated in this study. Current hedging procedures of the Funding Corporation (barbell strategy) and the price sensitivity approach performed equally well and better than a no-hedge strategy.

"Risk Behavior at Agricultural Banks." Glenn Pederson and Champak Pokharel (University of Minnesota)
A firm-level theoretical framework is developed to analyze portfolio responses of small agricultural banks in the context of bank funds constraints and imperfect loan market conditions. The estimated model suggests bankers respond to default risk and interest rate risk. Portfolio adjustments for major loan categories and securities are investigated.

"Farm Credit 'Junk' Bonds?" Douglas G. Duncan (ERS USDA) and Michael A. Singer (Texas A&M University)
The level and structure of risk premiums on Farm Credit System bonds are shown to have undergone major shifts during 1985. It is suggested that default risk was the primary cause of the shift, but more evidence is needed on the role of liquidity risk.

"Determinants of Agricultural Bank Participation in Farmer Mac: A Multinomial Logit Analysis." Clifford Rossi and Steven Koenig (ERS USDA)
Commercial banks are a primary lender group that will participate in Farmer Mac, but only 32% of agriculturally defined banks have elected to participate. A multinomial logit model estimates the factors that influenced agricultural bank participation. Results suggest that location, degree of lending specialization, loan quality, and bank size affected participation. Results suggest that initial origination volume from banks could be limited.

Farm Finance Issues (Glenn Pederson, University of Minnesota, presiding)

"Economic Analyses of Rangeland Leasing Practices and Rates." Larry Janssen, Martin Beutler, and John Cole (South Dakota State University)
Major characteristics of 444 rangeland leasing arrangement used by South Dakota ranchers were examined. Econometric modeling results indicate lease rates per acre from 1986–88 are explained by tract productivity, tract size, regional location, selected leasing practices, and by type of lease (private, state, tribal trust, or federal).

"Farm Accounting Rates of Return: Stability of Performance." Paul N. Ellinger and David A. Lins (University of Illinois)
High farm profitability is generally associated with higher business- and financial-management skills. This analysis evaluates the relative performance over time of a well-defined group of farms. Characteristics of farms that are superior producers along with farms that exhibit large and small amounts of rank variation are observed.

"Systematic and Unsystematic Risk Costs for Southeastern Kansas Farm Enterprises." Koffi N. Amegbeto and Allen Featherstone (Kansas State University)
Six measures of farm returns are used to estimate the most "appropriate" market index for southeast Kansas farms. Systematic and unsystematic risks and risk costs were estimated for farm planning. Results suggest that regional indices are more appropriate for use as the market index than state indices.

"An Application of the Single Index Model to Regional and Farm-Level Risk Analysis." Calum G. Turvey (University of Guelph)
This paper uses equally and proportionally weighted reference portfolios for determining regional and farm-level risk with the single index model. Using Ontario county-level data consideration in analyzing regional and farm-level systematic risks are presented. It is concluded that the SIM can be a useful method for managing risks in agriculture.

"Farm Consumption and Liquidity Constraints." Michael R. Langemeier (Kansas State University) and George F. Patrick (Purdue University)
This study develops a model to determine whether liquidity constraints prevent farm families from behaving according to the life cycle–permanent income hypothesis. Results, using a sample of Illinois farms, indicate that the consumption levels of an insignificant proportion of farm families are liquidity constrained. These results support the life cycle–permanent income hypothesis.

Taxes and Financial Contracts (Calum G. Turvey, University of Guelph, presiding)

"Do Farmers Pay Federal Income Tax?" Ron Durst and Clifford Rossi (ERS USDA)
This paper examines the proposition that the federal income tax provides a net subsidy to the farm sector. The net effect on federal income tax revenues from exempting farm income and disallowing farm losses for various sizes and types of farms is determined. The analysis finds that the income tax acutally results in a net surplus to the U.S. Treasury.

"Economic Depreciation and Tax Policy: The Case of Combine Harvesters." John Goroski, Vincent H. Smith, Joseph A. Atwood, and Myles J. Watts (Montana State University)
An econometric model of depreciation is constructed for combine harvesters to test the hypothesis that the rate of depreciation is constant over the life of the asset. This hypothesis is rejected. Depreciation is shown also to depend on tax policy and demand shift variables such as gross farm income.

"Agricultural Resource Adjustment and Capital Gains Taxation." Michael LeBlanc and James Hrubovcak (RTD ERS USDA), Ron Durst (ARED ERS USDA), and Roy Boyd (Ohio State University)
This paper examines the effects and implications on agriculture, forestry, and resource conservation of the president's proposal to reduce the tax on capital gains. A general equilibrium approach is adopted to capture the competition for resources.

"Debt Service Reserve Fund (DSRF) as a Response to Repayment Risk." Madhab Raj Khoju (University of Illinois)
Debt service reserve fund (DSRF) plan as a response to repayment risk seems appealing to both the parties in a loan contract. However, its size and other design specifications should also be acceptable to both parties. A theoretical model for determining lender and borrower optimal size of DSRF is developed and its application potential demonstrated.

"Limited Liability, Moral Hazard, and the Theory of the Farm Firm." Robert Innes (University of California, Davis)
This paper analyzes the optimal input, output and contractual choices of a risk-neutral producer who borrows from "outside" investors, makes an unobservable effort choice, and is subject to limited liability on his investment contract. The optimal financial contract is found to resemble a combination of a standard debt instrument and a commodity bond.

International Dimensions of Agricultural Finance (Barry K. Goodwin, Kansas State University, presiding)

"On the Relation between Adjusted Basis and Hedge Results." Francesco S. Braga (University of Guelph)
The results of a hedge placed on futures priced in a foreign currency are not uniquely related to adjusted basis changes unless the proper currency hedge is also in place. Empirical evidence for the corn and soybean markets in Chatham, Ontario, is provided for the period from January 1981 to April 1989.

"Group Credit in Costa Rica: An Analysis of Information Transfer." Mark D. Wenner (ERS USDA)
Group lending with joint liability is a promising innovation in financial intermediation involving smallholders. Signaling theory is used to examine the effect of improved information regarding borrower creditworthiness on loan repayment rates. Costa Rican data is used for analysis.

"Experimental Measurement of Discount Rates in Rural India." John L. Pender (Stanford University)
Discount rates of individuals in south India were measured using experimental games with significant rewards. Increasing the time frame or magnitude of rewards reduced discount rates consistent with previous studies using hypothetical questions. The discounted utility model is inconsistent with the results of the games.

"Farm Household Access to Credit Markets Under the Household Responsibility System in China." Loraine A. West (Stanford University)
Rural credit markets in China are examined and a logit model is used to identify farm households rationed out of the formal credit sector. Results indicate the primary rationing criterion is loan use and this is largely caused by the institutional structure of credit cooperatives and homogeneity of farmers.

"Credit Rationing in Rural Financial Markets: A Portugese Study Case." Nelson A. Aguilera and Douglas H. Graham (Ohio State University)
This paper demonstrates that, to analyze credit discrimination, one should have a well-defined demand and supply model. This model should be estimated using data on both loans granted and loans rejected. The criteria by which credit applications were rejected or accepted should also be explicitly incorporated into the analysis.

***Ex Post* Analysis of the 1980s Financial Crisis (Bruce L. Ahrendsen, University of Arkansas, presiding)**

"Community Development and Commercial Bank Performance: A Mutually Dependent Relationship." Shaun Beauclair and Cole Gustafson (North Dakota State University)
To test the circular relationship between bank lending practices and community development in North Dakota countries, a two-stage simultaneous regression using pooled cross-sectional, time-saving data from 1972–86 was constructed. Increased credit at retail, wholesale, and farm levels heightens economic activity and leads to greater loan demand and bank profitability.

"Analysis of Restructured Loan Nonperformance." Glenn Pederson and Ananth Rao (University of Minnesota)
Post-restructure performance of Federal Land Bank loans is analyzed using logit regression. Financial variables (debt structure index, gross cash farm income) are found to be inversely related to the odds that a restructured loan would not perform. Restructure variables (interest rate, collateral ratio) are positively related to loan nonperformance.

"Nature and Success of Voluntary Financial Workouts: A Case Assessment of Wyoming Bankers and Borrowers." Alan Schroeder and Larry J. Held (University of Wyoming)
The voluntary efforts of agricultural lenders to develop workout plans with troubled borrowers are examined. Survey results of Wyoming bankers suggest voluntary workouts are used both extensively and successfully—being initiated in over two of three de-

fault cases with successful results in nearly 70% of their workout cases.

"Examination of Chapter Twelve Farm Reorganization Bankruptcy Filings and Approved Reorganization Plans." Burton Pflueger and Larry Janssen (South Dakota State University)
Major financial characteristics of Chapter Twelve farm debtors and their creditors are examined in South Dakota, a state where reorganization bankruptcy is widely used. Debt reduction and other characteristics of 101 confirmed reorganization plans are presented. FmHA and commercial banks had the least amount of debt recovery.

"Estimates of Bankruptcy under Chapter Twelve." Robert N. Collender (North Carolina State University/ERS) and Theodore A. Feitshans (North Carolina State University)
Using White's model of indirect bankruptcy costs we find that total bankruptcy costs under Chapter Twelve may be as high as 106% of asset value at time of filing for 106 farms in North Carolina. This compares to White's estimates of 60% for a cross-section of firms filing under Chapter Eleven.

Theoretical Issues in Risk Analysis (Michael E. Wetzstein, University of Georgia, presiding)

"Risk versus Uncertainty and the Value of Waiting to Invest." Richard S. Gray (University of California-Berkeley)
If information arrives over time, there is some value in waiting to make an investment involving a sunk cost. Recent work, which specifies the nature of the stochastic process for prices, has shown the standard investment rule—to accept projects whenever net present value is postive—is generally quite wrong.

"A Simple Duality Model of Production Incorporating Risk Aversion and Price Uncertainty." Barry T. Coyle (University of Manitoba)
Proceeding within the framework of a linear mean-variance utility function, this paper develops a duality model of production that incorporates risk aversion and price uncertainty. In contrast to risk models based on an expected utility function, this model provides a practical alternative to standard duality models for econometric research.

"Quadratic Risk Programming—Expected Utility Maximization Consistency and Elliptical Symmetry." Carl H. Nelson (University of Illinois)
Results of Meyer are extended to multivariate portfolio choice problems. If a set of random variables is elliptically symmetric and is linearly combined, then expected utility is solely a function of the mean and variance of returns. Risk-averse decision makers will choose from the mean–standard deviation efficiency frontier.

"Relaxing the Expected Utility Hypothesis and Entry/Exit Decisions of the Risk-Averse Firm." Israel Finkelshtain and Julie Ann Hewitt (University of California)
A risk aversion theory is formulated directly from a preference relation, rather than with a utility function representation. An example concerning insurance demand provides intuitive support. This theory is applied to analyze firms' entry/exit decisions, the long-run equilibrium of an industry and comparisons between firms with different risk attitudes.

"Comparative Statics for Rank-Dependent Expected Utility Theory." John Quiggin (University of Maryland)
A number of generalizations of the expected utility (EU) model have been proposed. Rank-dependent expected utility (RDEU) theory is a generalization of EU theory based on the concept of probability weighting. A major class of comparative static results can be extended to the RDEU model but not to the case of general smooth preferences.

Risk Management in Marketing and Policy (Michael Bowker, Nova Scotia Agriculture College, presiding)

"Risk Analysis in the Ontario White Bean Sector." Mike von Massow, Alfons Weersink, Scott Rozelle, and Calum G. Turvey (University of Guelph)
Utilizing variance decomposition procedures, changes in the average and variance of Ontario white bean production are found to be largely the result of changes in acreage. Risk elements were incorporated into an acreage response model. Results indicate acreage is affected more by the expected values of prices and yields rather than its associated risk parameters.

"L'impact des programmes et assurances agricoles sur la production de maïs au Québec." Evelyne Martel and Robert Romain (Université Laval)
L'impact de la réduction de la variabilité des rendements et des prix sur la production de maïs au Québec a été estimé. Vu la caractéristique du programme d'assurance-stabilisation des revenus qui garantie le coût de production d'une ferme-type, une augmentation de la variabilité des prix fera augmenter les ensemencements.

"Risk Management in the Marketing of Sweet Potatoes: An Application of Target MOTAD." Larry L. Bauer (Clemson University)
The yield of sweet potatoes increases after the crop is initially ready for harvest and can be sold at har-

vest or cured and stored for later sale. Target MOTAD is used to analyze the decisions of when to harvest and when to market.

"Production, Hedging, and Speculative Decisions with Options and Futures Markets." Harvey Lapan and Giancarlo Moschini (Iowa State University), Steven Hanson (Michigan State University)
This paper analyzes production and hedging with both futures and options, given price and basis risk using the expected utility model. When markets are perceived unbiased, optimal hedging involves using only futures (options are redundant). Options are used together with futures as speculative tools when markets are perceived biased.

"The Calibration of Expected Soybean Price Distributions: An Option-Based Approach." Bruce J. Sherrick (University of Illinois), D. Lynn Forster and Scott H. Irwin (Ohio State University)
No-arbitrage option pricing models are used to recover complete probabilistic descriptions of expected soybean futures prices. The usefulness of the approach is examined via calibration tests. Results indicate that the estimated distributions are fairly reliable and that a three-parameter Singh-Maddala distribution is useful in characterizing expected prices.

Risk Analysis of Crop Insurance, Diversification, and Pest Management (Mark Cochran, University of Arkansas, presiding)

"The Impact of Risk on Pest Management Strategies." Uri Regev (Ben-Gurion University)
The paper analyzes the effects of pest-related uncertainties on pest control tactics and strategies. In general, increasing uncertainty of various pest aspects will not necessarily lead to increased pest control application. Pesticides, are often conceived by farmers as risk reducing but are risk increasing in the long run.

"Returns to Limited Crop Diversification." Steven C. Blank (University of California, Davis)
A new single-index model application enabling users to more easily assess risk/return tradeoffs between crop portfolios is suggested. A decision criterion is presented, based on a new crop portfolio performance measure. The procedure helps reduce data sensitivity problems often faced when using quadratic programming or standard SIM techniques.

"A Comparison of Subjective and Historical Yield Distributions with Implications for Multiple Peril Crop Insurance." Jean C. Buzby (University of Kentucky), Phil L. Kenkel (Oklahoma State University), Jerry R. Skees (University of Kentucky), James W. Pease (Virginia Polytechnic Institute and State University), and Fred J. Benson (University of Kentucky)
This study examines the relationship between subjective yield distributions elicited from Kentucky farmers in 1987 and 1989 and their historical yield distributions. The results indicate a close correspondence between the first two moments of the distributions. The evidence suggests that farmers underestimate their downside risk.

"A Comparison of Crop Yield Coverage Plans for Multiple Peril Crop Insurance." Gerald D. Toland, Jr. (Southwest State University), Brian H. Schmiesing (South Dakota State University), and J. Roy Black (Michigan State University)
Producers' purchase decisions for multiple peril crop insurance (MPCI) were analyzed under the AREA and Actual Production History (APH) Coverage Plans. Global certainty equivalents were determined to predict MPCI purchases in a simulation using subjective crop yield probability distributions. The frequency of predicted MPCI purchases increased under the APH plan.

"Area-Yield Crop Insurance Reconsidered." Mario J. Miranda (Ohio State University)
Crop insurance that bases both premiums and indemnities on the aggregate yield of a surrounding area provides more effective yield-loss coverage than individually tailored insurance and avoids most of the adverse selection and moral hazard problems that have historically undermined the actuarial performance of the Federal Crop Insurance Program.

Incorporating Risk into Economic Models (Harry Hall, University of Kentucky, presiding)

"Economies of Scale and Output Flexibility in Northeastern U.S. Dairy." Adesoji O. Adelaja and Madalene C. Bruun (Rutgers University)
In northeastern U.S. dairy, capital intensity, risk, and specialization are shown to increase with size, while output flexibility or responsiveness is shown to decrease with size. The greater flexibility of smaller farms is shown to make them as viable as larger farms despite economies of scale.

"Measuring Scale and Technical Change from Observable Data Under Uncertainty." Paul R. Flacco (East Carolina University) and Douglas M. Larson (University of California, Davis)
Returns to scale and technological change can be measured without econometric estimation for industries with output price uncertainty using panel data. Since expected utility maximization implies cost minimization, with panel data it is possible to approximate marginal cost using observed prices and

quantities, from which scale and productivity measures follow.

"A Regional Analysis of U.S. Corn Yield Variability." John W. Wade, Michael S. Kaylen, and Deon Frank (University of Missouri)
Regional corn yield models which incorporate stochastic trends, prices, and weather variables are developed. Empirical 1989 U.S. corn yield distributions are generated with weather and estimated residuals as the sources of randomness. Hypothesis tests suggest yield variability has been increasing, with weather changes being a major source of this increase.

"A Simple, Efficient, and Theoretically Correct Approach to Simulation Analysis." W. G. Boggess, O. A. Ramirez, and C. B. Moss (University of Florida)
This study uses the multivariate hyperbolic sine probability density function as a basis to develop a simple, efficient, and theoretically correct approach for generating correlated, non-normal random variables.

"Modeling Cyclical Cattle Prices in a Monte Carlo Setting." Larry W. VanTassell (University of Tennessee), J. Richard Conner and James R. Richardson (Texas A&M University)
A methodology for simulating harmonic regressions is presented that allows for the stochastic simulation of the harmonic regressions when various orders of autocorrelation are present. Statistical properties of the historical correlations are respectably maintained in an empirical example using ten livestock classes which exhibit first- and twelfth-order autocorrelation.

Issues in Interregional and International Marketing (Ellen Goddard, University of Guelph, presiding)

"Spatial Equilibrium in Fluid Milk Markets." Howard McDowell and Ann Fleming (ERS USDA)
Fluid milk markets are compared in an interregional trade framework as currently regulated with the single price-basing region, regulated multiple price-basing regions, and under competitive market conditions. Simulated prices and dairy surpluses are highest under current regulations, followed successively by multiple-region price basing, and competitive conditions.

"Repeat Purchase and Switching Probabilities in the International Wheat Trade." William W. Wilson and Kin N. Lau (North Dakota State University)
Models of purchasing behavior are of particular importance in understanding intercountry competition in specific import markets. In this paper, a model was developed which incorporates the impacts of both stationary and nonstationary phenomena on purchasing behavior. The results are illustrated for two important wheat importing countries which have distinctly different characteristics, Japan and the USSR.

"Application of Intervention Analysis to a Trade Restriction: The Case of Canadian Potash." Harry L. Vroomen (ERS USDA)
Intervention analysis is used to analyze the impacts of the 1987 U.S. antidumping case against Canadian potash producers. The case resulted in significantly higher potash prices, leading to increased U.S. farm costs of a half billion dollars through June 1989 and increased revenues for both U.S. and Canadian potash producers.

"The Impact of Liberalizing Trade on the World Rice Market." Gail L. Cramer, Eric J. Wailes, and Stanley S. Philips (University of Arkansas)
A spatial equilibrium model of world rice trade was utilized to estimate the impact of world trade liberalization. Rice trade was separated into high-quality indica, low-quality indica, and japonica. Models of free trade, constrained free trade, and industrialized market economy liberalization were developed, assessed, and compared.

"Attitudes Toward Beef in Hokkaido, Japan." P. L. Klein, K. K. Klein, and S. Yoshida (University of Lethbridge, Alberta, Canada)
Consumers in Hokkaido, Japan, were surveyed about their attitudes toward consumption of beef. It was found that Hokkaido residents eat very little beef, particularly imported beef. Consumption seems to be sensitive to income and price changes; this has important implications since Japan has recently reduced import restrictions on beef.

Producer Response to Marketing Issues (T. Randall Fortenbery, North Carolina State University, presiding)

"Short-Run Aggregate Catfish Producer Supply Response to Production and Price Risk." William Branch and Daniel S. Tilley (Oklahoma State University)
Short-run aggregate supply response to production and price risk is estimated using ordinary least squares. A statistically significant, positive response to input and output price risk is indicated. Results suggest processors and feed manufacturers may want to consider alternative pricing strategies designed to reduce risk in the system.

"Risk Management for Livestock Producers: Hedging and Contract Production." John D.

Lawrence (University of Minnesota) and Michael S. Kaylen (University of Missouri)
A chance-constrained stochastic dynamic programming model is developed to analyze risk management for hog finishing operations. Optimal placement, ownership, and hedging decisions are found under production and price uncertainty and are compared via simulation.

"Area Responsiveness of Canola on the Canadian Prairies." T. Richards and K. K. Klein (University of Lethbridge, Alberta, Canada)
The objective of this study is to determine if the elasticity of area planted to canola has changed now that the crop has attained a more "mature" status. The area in western Canada planted to canola was modeled using several specifications. The results suggest the crop has a much lower output elasticity than what was previously estimated, where previous estimates were based on data recorded before 1978.

"On Nonlinear Dynamics: The Case of the Pork Cycle." Matthew T. Holt and Jean-Paul Chavas (University of Wisconsin)
New methods for analyzing nonlinear dynamic processes are used to evaluate the hog-corn price ratio. The results present evidence of nonlinear dynamics in the pork cycle. Moreover, while GARCH processes account for some non-linearities, the pork cycle is apparently characterized by more complex dynamic forms.

"Nonparametric Analysis of Cost Minimization and Changes in Cigarette Characteristics." Ruey-er Chang (North Carolina State University/AT&T) and Daniel A. Sumner (North Carolina State University/USDA)
Nonparametric analysis indicates the presence of violations of cost minimization in the combination of different tobacco types in cigarette manufacturing. However, regression of the degree of violation of cost minimization on change in product characteristics indicates the significant impact of exogenous shifts in cigarette attributes on cost shifts.

Issues in Advertising and Consumer Demand (Gary W. Williams, Texas A&M University, presiding)

"Lag Structures in Commodity Advertising Research." Jonq-Ying Lee and Mark G. Brown (Florida Department of Citrus)
This paper examines basic assumptions about the lag structure of advertising. Evidence suggests for frequently consumed commodities, the lag structure is probably a monotonic decreasing function. Confusion may exist over advertising variables used and the shape of lag structure. Cumulative structures need to be differentiated from decay structures.

"Product Labeling, Advertising, and Demand for Grapefruit Juice and Grapefruit-Juice Cocktail." Mark G. Brown, Jonq-Ying Lee, and Robert M. Behr (Florida Department of Citrus)
Demand relationships for two closely related products—grapefruit juice and grapefruit-juice cocktail—were estimated to analyze the contention that consumer confusion exists between the two products. Results suggest confusion may exist, with grapefruit-juice advertising not only increasing the demand for grapefruit juice but also for grapefruit-juice cocktail.

"Factors Influencing Bids for Vacuum-Packaged Retail Beef: An Experimental Economics Approach." George W. Borden, Dale J. Menkhaus, Glen D. Whipple, and Ray A. Field (University of Wyoming); Elizabeth Hoffman (University of Arizona)
Tobit analysis was used to identify factors influencing the value consumers place on beef steaks in a vacuum skin package relative to steaks in an overwrapped styrofoam tray. Experimental economics was used to obtain value information. Results suggest that information regarding the vacuum skin package enhances the value of beef.

"Consumer's Preferences Regarding Steaks: A Market-Oriented Approach." Roger Paguaga Barreto, Francesco Braga, Larry Martin, Victor Roth, and Ron Usborne (University of Guelph)
The southwestern Ontario beef steak market can be divided into five segments on the basis of consumer's product characteristics preferences. The beef industry should consider changing its current commodity focus to a more market responsive approach in order to satisfy and exploit the opportunities offered by these market segments.

"Factors Influencing Consumer Rankings of Alternative Retail Beef Packaging." Pierre M. L. Pelzer, Dale J. Menkhaus, Glen D. Whipple, and Ray A. Field (University of Wyoming); Elizabeth Hoffman (University of Arizona)
Ordered probit models were used to identify factors which influence consumer rankings of vacuum skin packaged steaks and roasts. Information pertaining to the color of the beef in, and the benefits of, the vacuum skin package was among the most important factors for enhancing the preference for this package type.

Information in Price Determination (Raymond Leuthold, University of Illinois, presiding)

"Price Transmission Across Marketing Levels in a Hedonic Framework." Douglas D. Parker and David Zilberman (University of California, Berkeley)

This paper analyzes the behavior of prices for a perishable product as functions of time and product quality characteristics. A conceptual model analyzing the behavior of the marketing margin is developed. The results identify potential gains from improving quality and developing price signals which compensate for characteristics other than weight.

"Effect of Contract Disclosure on Price: Railroad Grain Contracting in the Plains." Stephen Fuller, Fred Ruppel, and David Bessler (Texas A&M University)

Staggers Rail Act of 1980 granted railroads freedom to establish rates and enter into confidential contracts with grain shippers. Recent legislation (1986) required contract terms to be disclosed. This study shows rail rates in the plains region commenced an upward trend after implementation of the disclosure policy. Results suggest disclosure increased reliance on posted tariffs which subsequently facilitated rate coordination among the oligopolistic railroad industry.

"L'impact de la vente par encan électonique centralisé: quelques résultats préliminaires au Québec." Zhigang Chen, Carol Gilbert, and Rebecca Lent (University of Laval)

A series of preliminary tests as well as an analysis by vector autoregression (VAR) confirm certain hypotheses concerning the impact of the electronic auction market on the primary hog market in Quebec. Hog prices have become more sensitive to changes in corn and pork prices, indicating an improvement in information conditions.

"Are Pre-Release Estimates of USDA Hogs and Pigs Reports Rational?" Phil L. Colling and Scott H. Irwin (Ohio State University)

For expectations to be rational, they must incorporate all available, relevant information. This study investigates the rationality of pre-release estimates of USDA *Hogs and Pigs* reports. The estimates are rational in that they are unbiased predictors, their forecast errors are not autocorrelated, and they incorporate all available, relevant information.

"The Rationality and Value of USDA Crop Forecasts." Fen-Chin Yu and Peter Orazem (Iowa State University)

Forecasts of barley, corn, oats, soybeans, and spring wheat planted acreage and harvest size are investigated. Several forecasts are found to be inefficient and/or biased. Nevertheless, these forecasts can substantially improve market supply information. Early forecasts are much more valuable than later forecasts.

Current Issues in Price Determination (Ed Estes, North Carolina State University, presiding)

"Factors Affecting Spring Season Fresh Peach Prices." Charles Hall and Stephen Fuller (Texas A&M University)

This research measures factors affecting weekly spring peach price. Results show own-shipments, peach size, origin, and competing fresh fruits have an important influence. Potential producers must give attention to early varieties, whereas later-maturing varieties may be profitable as a result of the observed premium associated with larger-sized fruit.

"Testing for Supply Asymmetry in the Market for Organic Lettuce." L. Lohr (Michigan State University) and Timothy Park (University of Nebraska)

Organic grower certification may require farmers to adopt a bundle of new technologies or inputs. Divestment and subsequent reinvestment in the certification process incur costs which may be a source of irreversibility in the supply function. This paper tests for supply asymmetry in the market for organic lettuce in California.

"Market Integration, Efficiency of Arbitrage, and Imperfect Competition: Methodology and Application to U.S. Celery." Richard J. Sexton, Catherine L. Kling, and Hoy F. Carman (University of California, Davis)

This paper develops and applies a methodology to test for efficiency in interregional commodity arbitrage. The methodology is empirically manifest as a switching regression model with three regimes: efficient arbitrage, relative shortage, and relative glut. Results from application of the model to U.S. celery marketing indicate significant departures from efficient arbitrage for both California and Florida celery.

"Price Determination and Acreage Adjustment Before and After the Implementation of a Marketing Order." Richard L. Kilmer and Timothy G. Taylor (University of Florida)

Price determination and planted acreage adjustments are evaluated before and after the installment of a marketing order in the Florida celery industry. The industry deviated from marginal cost pricing. However, current acreage planted was influenced by different factors before the marketing order than after.

"The Effect of Non-Phenotypic Data in Price Determination of Thoroughbred Yearlings." Malcolm Commer, Jr. (University of Maryland)

The equine sector of American agriculture is a virtually unresearched area. This paper investigates price determination factors in the thoroughbred market. Through regression analysis, four continuous independent variables and six sets of indicator independent variables were found to be statistically significant at the .05 level or greater.

Use and Efficiency of Futures Markets (Elunid Jones, Virginia Polytechnic Institute and State University, presiding)

"The Price Adjustment Process and Efficiency of Grain Futures Markets Implied by Return Series of Various Time Intervals." Shi-Miin Liu and Sarahelen Thompson (University of Illinois)
This study investigates the price adjustment process and efficiency of corn and oats futures markets using data from the 1986 contracts traded on the CBOT. Amihud-Mendelson's (1987) model, Box-Jenkins' (1970) techniques, and Black's (1986) criteria are employed. The competitive performance of speculators in grain futures markets is also examined.

"Nonstationarity of Soybean Futures Price Distributions: Option-Based Evidence." Bruce J. Sherrick (University of Illinois), Scott H. Irwin and D. Lynn Forster (Ohio State University)
No-arbitrage option pricing models are used to estimate *ex ante* soybean futures price distributions. Volatility measures of these distributions are modeled in an endogenous-switchpoint regression as functions of price level and time-to-maturity. Results indicate volatility measures are not stationary and exhibit regime-dependent influences of time-to-maturity and price level.

"How Efficient Is the Rough Rice Futures Market?" Linwood A. Hoffman (CED ERS USDA, Crops Branch)
Efficiency of the rough rice futures market is analyzed relative to the Arkansas cash market. Market activity is examined and various efficiency tests are performed. Inefficiencies were found in beginning or low volume contracts, but some market efficiency criteria improved with time and greater contract volume.

"Factors Influencing Producer Use of Futures and Options in Commodity Marketing." Larry D. Makus, Biing-Hwan Lin, John Carlson, and Rose Krebill-Prather (University of Idaho)
A probit model is used to quantify factors influencing the probability that producers used futures or options for commodity marketing. Results suggest previous use of forward contracts, location, size, having a college degree, and membership in a marketing club have the greatest impact on the probability of using futures and options.

"Hedging Effectiveness of the Winnipeg Oats Futures Market." Gary Warkentine, Milton S. Boyd, and Merle D. Faminow (University of Manitoba)
The Winnipeg feed oats futures contract was found to be an effective hedge for Canadian feed oats, as well as for food grade oats previously handled by the Canadian Wheat Board. The Winnipeg market was also found to be a more effective hedge for Canadian oats than the Chicago market.

Information and Technology Effects on Consumer Demand (Hal Harris, Clemson University, presiding)

"Milk Component Pricing via a Retail-Level Hedonic Analysis." John E. Lenz (Cornell University) and Ron C. Mittelhammer (Washington State University)
Household food consumption survey data was used in a hedonic retail-level analysis of milk component values. Protein, fat, and calcium components of raw milk were perceived by consumers to have significant value with the protein component having 28% more value than fat, on average, per point.

"Analysis of a Conjoint Study of Aquaculturally Produced Hybrid Striped Bass." Catherine Halbrendt, John D. Pesek, and J. Richard Bacon (University of Delaware)
Conjoint analysis was used to examine buyer preferences toward aquaculturally produced hybrid striped bass. The repeated measures approach was used to correct for correlation concerns associated with the aggregate approach. Results showed that buyers prefer a two- to three-pound fish that has been filleted, is available year round, and is competitively priced.

"Biotechnology and the Consumer: The Case of Bovine Somatotropin." Anya M. McGuirk, Warren P. Preston, and Gerald M. Jones (Virginia Polytechnic Institute and State University)
A mailed questionnaire is used to assess consumer concerns and potential consumption response attributable to the introduction of bovine somatotropin (BST). Responses from 605 households in Virginia are described and analyzed. Potential impacts on consumer demand for fluid milk are assessed.

"A Cross-Sectional Evaluation of Generic Advertising: The Case of Catfish." Henry Kinnucan and Meena Venkateswaran (Auburn University)
A conceptual framework for evaluating advertising effects using cross-section data is developed and applied to catfish. The eight-equation, partially recursive econometric model linking advertising awareness to beliefs, attitudes, and purchase frequency indicates generic advertising had a significant effect both on attitude and consumption of catfish.

"*Ex Ante* Evaluation of the Economic Impact of Agricultural Biotechnology in the Multiproduct U.K. Pigmeat Market." Catharine Lemieux (Indiana State University), C. Martin Palmer (U.K.

Meat and Livestock Commission), and Michael Wohlgenant (North Carolina State University)
Introduction and adoption of the growth stimulator, Porcine Somatotropin (PST), will have a significant impact on the U.K. pigmeat industry. Results indicate that, for a five-year adjustment period, producers' surplus will increase between 44 million and 101.3 million pounds; consumers' surplus will increase between 29.6 million and 65.9 million pounds.

Empirical Demand Models (James Seale, University of Florida, presiding)

"Aggregate U.S. Demand for Cheese and Animal Proteins: Analysis of Time-Series Data with Demographic Factors." Federico Perali, Thomas L. Cox, and Brian Gould (University of Wisconsin)
The Lewbel modifying function technique is applied to a demand system containing the translog indirect utility and almost ideal demand system as special cases. Scaling and translating versions of these demographically modified systems are then estimated, tested for, and compared using annual, per capita disappearance data.

"The Demand for Wine in Ontario." Lorrie MacKinnon and Bruno Larue (University of Guelph)
Two demand systems are estimated to capture the relationships between imported and domestic wines of different colors and between wines from different countries. Policy simulations were conducted to evaluate different schemes that Ontario could use in order to comply with a recent GATT ruling.

"Advertising, Information, and Product Quality: The Case of Butter." Hui-Shung Chang and Henry Kinnucan (Auburn University)
The hypothesis that health concerns affect consumers' quality perceptions about butter was tested using a cholesterol information index. The empirical results show that concerns about cholesterol decreases and DBC advertising increases the demand for butter; the negative effect is larger, in absolute sense, than the positive effect of advertising.

"Demand Trends for Beef Cuts—By Quality, Convenience, and Season." Donald E. Farris and David W. Holloway (Texas A&M University)
Total demand for beef has declined during the 1980s, but demand for the higher-valued cuts have increased relative to the average. Price ratios of retail and wholesale cuts to the carcass composite price were used to develop trends in demand for individual cuts. Increased demand for higher quality is clear; demand for convenience (steak or ground beef versus roasts) was indicated. Seasonality of demand varies among cuts.

"Simultaneity and Structural Change in Fed Beef Demand." James Eales and Inshik Lee (University of Illinois)
Simulations illustrate potential dangers of looking for structural change in demand when the true culprit is a supply shock. Applications to fed beef suggests, if demand is static, parameter shifts are significant and quantities and prices are endogenous, while, if dynamic, no significant shifts exist and prices are predetermined.

Measurement Issues in Demand Analysis (Barry Coyle, McDonald College, presiding)

"Effects of Measurement Error in Disappearance Data on Estimated Demand Elasticities for Meats." Gary W. Brester (Kansas State & North Carolina State University) and Michael K. Wohlgenant (North Carolina State University)
The traditional approach of using USDA disappearance data as a proxy for per capita consumption in estimating retail demand elasticities for meats results in biased elasticity estimates. A new procedure for obtaining unbiased estimates is developed that does not impose the assumption of fixed proportions technology in the processing sector.

"Demographic and Income Distributional Factors and Aggregation in Demand Analysis." Deborah Peterson and Timothy D. Mount (Cornell University)
Demographic and income distributional factors are incorporated into household demand systems, and theoretically consistent aggregate demand equations are derived. Food consumption data from 1980 and 1986 are used to evaluate how changes in average income, skewness of income, tax schedules, and demographic characteristics affect consumption of eight food commodities.

"A Note on Testing Separability in Nonparametric Demand Analysis." Thomas L. Cox and Jean-Paul Chavas (University of Wisconsin)
This paper seeks to clarify the empirical options for testing separability in nonparametric demand analysis. It is noted that the Afriat-Varian characterization of weak separability can be obtained only under the restrictive assumption of a concave utility function. An alternative nonparametric separability test is discussed under weaker assumptions.

"Effect of Length of Time on Measured Demand Elasticities: The Problem Revisited." Oral Capps, Jr., and Rodolfo M. Nayga, Jr. (Texas A&M University)
This study centers attention on the effect of varying lengths of time (weekly, biweekly, monthly observations) on measured demand elasticities for disag-

gregate fresh beef products. Parameter estimates and elasticities based on monthly data differ from those based on biweekly or weekly data. Generally, inventory adjustment dominates with the latter time intervals. On the other hand, for four of the six disaggregate fresh beef products analyzed, habit formation is the dominating effect with monthly data.

"Construction of True Cost of Food Indexes from Estimated Engel Curves." William Noel Blisard and James R. Blaylock (ERS USDA)
This paper applies a technique to derive true cost-of-living indexes from the estimation of a simple system of Piglog Engel curves. This technique allows a maximum amount of commodity disaggregation, and the indexes show the impact of inflation on households with different expenditure levels and demographic characteristics.

Demand Methodology (Jean-Paul Chavas, University of Wisconsin, presiding)

"Modeling Consumer Expenditures Under Rationing in People's Republic of China." Wen S. Chern and Zhi Wang (Ohio State University)
An almost ideal demand system incorporating rationing is estimated for eight consumer expenditure groups using data of 1981–87. The study compares different specifications of rationing scheme and estimation methods. The results show that the rationing in housing, grains, and fuels created excess demand for nonstaple food and consumer durables in China.

"The Slutsky Matrix, Homogeneity, and Invariance in Intertemporal Consumer Theory." Michael R. Caputo (University of California, Davis)
An *m*-member intertemporal household production model with labor supply and durable and nondurable goods is studied. The dynamic law of demand applies to cumulative discounted demand functions, rather than their instantaneous counterparts. Hence observations of upward sloping Hicksian demand functions, which refute static theory, are consistent with dynamic theory.

"Preference Change Bias in Meat Demand: An Indirectly Separable, Semiparametric Model." Giancarlo Moschini (Iowa State University)
The hypothesis that preference changes may partly explain U.S. meat consumption is tested with an indirectly separable model in semiparametric form using the kernel estimator. The results support the notion that changes in consumer preferences may explain an increased consumption of white meat and a decreased consumption of red meat.

"Symmetry and Scale Effects in a Logistic Demand System." Tim Considine (Pennsylvania State University)
This paper presents a method to impose symmetry on the linear logit model of cost shares. The underlying cost function is approximated by using the share predictions as numerical approximations of the price integrals. The concavity conditions are relatively stable functions of the cost shares.

"Incorporating Demographic Information in Demand Analysis." Basile Goungetas, Helen H. Jensen, and Stanley R. Johnson (Iowa State University)
This paper develops a method for incorporating commodity-specific demographic information into the linear approximate almost ideal demand system (LA/AIDS). As it turns out, the resulting demand system is a LA/AIDS model with the demographic variables specified as intercept shifters. The model was estimated using household expenditure data from Indonesia.

Estimates of Conjectural Variations and Implications for Analyzing Industry Conduct and Performance (Warren P. Preston, Virginia Polytechnic Institute and State University, presiding)

"Marketing Margins, Market Power, and Price Uncertainty." John R. Schroeter (Iowa State University) and Azzeddine M. Azzam (University of Nebraska)
We examine marketing margins in the case in which food-processing firms exercise product and input market power and face output price uncertainty. An empirical application reveals that farm/wholesale pork margins contain a significant oligopoly price distortion and are positively related to the level of price risk.

"Implications of Increased Regional Concentration and Oligopsonistic Coordination in the Beef-Packing Industry." Azzeddine M. Azzam (University of Nebraska) and John R. Schroeter (Iowa State University)
Previous empirical studies of packer market power in cattle procurement either follow the ad hoc "structural approach" of the Bain tradition or conduct the analysis at the national level. This paper combines an explicit behavioral model of beef packing firms with an attempt to respect the regional scope of cattle markets.

"Dominant Firm Market Power in the Coconut Oil Export Market." David E. Bushena and Jeffrey M. Perloff (University of California, Berkeley)
Legal and institutional changes that increased concentration in the Philippine coconut oil refining and exporting industries enabled the Philippines to exercise dominant firm market power, raising the world price 150% above the competitive level. Reductions

in coconut oil demand because of health concerns will decrease Philippine export revenues.

"Performance in Canadian Food Manufacturing: An Industrial Organization Perspective." Tim Hazledine and Maingi Maundu (University of British Columbia)
The paper examines interindustry differences in profitability and in pricing between 4-digit SIC Canadian food and beverage processing industries. Two issues focused on are the impact of seller concentration results on market power and cost efficiency and the extent to which Canadian tariff protection creates rents which are dissipated in higher costs.

"Policy Analysis in an Imperfectly Competitive Market: A Conjectural Variations Model for the Food-Manufacturing Industry." Leo Maier (Cornell University)
The effects of government intervention are analyzed in a conjectural variations model of U.S. food manufacturing. The policy elasticities of the perfectly competitive model are valid predictors of policy effects irrespective of the type of oligopoly. Changes in the degree of competition may alter the magnitude of the policy elasticities.

Market Organization and Competitive Strategies in the Food Industries (Stanley Fletcher, University of Georgia, presiding)

"The Effect of Quality Changes and Limited Marketing Seasons on the Demand for Fresh Blueberries." Antonia L. Hoelper and Michele C. Marra (University of Maine)
This study examines the notion that fresh fruit prices follow a trend separate from that due to supply changes over the marketing season. Quality changes and a limited marketing season are hypothesized to contribute to changes in demand. The empirical results support the hypotheses in the Boston fresh blueberry market.

"A Dynamic Control Approach to Discerning the Potential for a Supply-Management Marketing Order for Southeastern Sweet Onions." W. T. Huang (National Ping-Tung Agricultural College) and J. E. Epperson (University of Georgia)
Dynamic optimal control was used to ascertain the potential effectiveness of a supply-control marketing order for southeastern sweet onions. A dramatic increase in producers' surplus relative to the free market case was evident from imposition of the order. However, the reduction in social welfare was noticeable.

"Vertical Coordination: A Transaction Cost Approach." Stuart D. Frank and Dennis R. Henderson (Ohio State University)
Vertical coordination has been shown to be superior to vertical integration as an element of industrial structure. In this paper, the effects of transaction costs on vertical coordination are investigated. The results confirm the theoretical expectation that transaction costs are the primary motivation for vertical coordination.

"An Oligopoly Model of a Vertical Market System." Kostas Karadininis and Murray Fulton (University of Saskatchewan)
Many agricultural markets are vertical systems with oligopolistic firms operating alongside smaller, more competitive, price-taking firms. Despite the prevalence of this structure, little theoretical modeling has been undertaken. The purpose of this paper is to develop a model that incorporates these aspects. The model is also used to examine countervailing power.

"Motives for the International Licensing of Branded Food and Related Products." Ian M. Sheldon and Dennis R. Henderson (Ohio State University)
Given initial empirical observations of international licensing of food and beer brands, this paper presents a simple game-theoretic model of the motives for licensing. The model suggests that imperfect competition in overseas markets and imperfect information about incumbent firms' payoffs are important determinants of a branded product licensing equilibrium.

Reexamining Conventional Wisdom on Common Property Resources and Water Demand (Robert Patrick, Colorado School of Mines, presiding)

"Migration as the Cause of Common Property." Greg Hertzler (University of Western Australia)
Migration, one of three fundamental ways a resource stock can change, makes a resource common property. This study models migration and the degree of common property along the continuum from exclusive access through limited access to open access. Most migratory resources will have limited access between the two extremes.

"On the Efficiency of Private Property: Reexamining the Empirical Evidence from the Oyster Grounds of the Chesapeake Bay." George D. Santopietro (Radford University) and Leonard A. Shabman (Virginia Polytechnic Institute and State University)
Agnello and Donnelley's analysis of the oyster industry has become the standard reference for evidence of the tragedy of the commons. In this paper, we explain why reestimation of their model with more recent data yields different results and explore why the economic profession has been so willing to accept Agnello and Donnelley's results.

"Beyond the Commons: Maryland's Oyster Industry." Ivar Strand, Douglas Lipton, and Amy Buss (University of Maryland)

Many economists argue that leasing common oyster grounds can prevent resource depletion. We argue that privatization must consider seed, not just submerged bottom. The history of Maryland's industry shows that the broodstock and shellstock are necessary elements in producing seed and hence must be considered in any privatization scheme.

"Information and the 'Optimal Control' of an African Rangeland Resource." Brent M. Swallow (University of Wisconsin) and Ray F. Brokken (International Livestock Centre for Africa)

A simple dynamic model of rangeland utilization is specified for the case of Lesotho. Lack of information regarding ecological relationships, investment strategies, exchange mechanisms, and resource management hamper the model's usefulness for determining the existence of open access or the potential impacts of alternative policy instruments.

"Municipal Water Demand: Evidence of Consumer Irrationality?" James Booker (Colorado State University)

Estimation of municipal water demand functions is complicated by nonuniform rate structures. Misspecification bias in using an income difference variable may be important in anomalous results reported in recent studies. Demand estimates using an alternative specification offer one interpretation of these results.

Soil Erosion and Water Quality: Can Economists Un-Muddy the Waters? (Richard Farnsworth, University of Illinois, presiding)

"Erosion Restrictions for Water Quality Improvement: Impacts of the Agricultural Sector." Marc O. Ribaudo (ERS USDA)

A soil-productivity-based erosion rate limit on cropland, imposed to improve surface water quality, would generate large erosion reductions at relatively low cost to producers and consumers. However, such a restriction would generally not result in regions characterized by high concentrations of sediment reaching a water quality goal.

"An Economic Assessment of 1990 Farm Bill Water Quality Options." C. Tim Osborn, Marc O. Ribaudo, and Ken Algozin (ERS USDA)

With greater attention being given to impact of agriculture on both surface and ground water quality, the 1990 farm bill debate is sure to include consideration of water quality programs. In this paper, the authors investigate the economic impacts of two land retirement programs similar in concept to the Conservation Reserve Program of the Food Security Act of 1985. Results indicated that expansion of the CRP to address surface and ground water quality issues is possible and would generate positive economic benefits for water users.

"Low Input, Sustainable Agriculture: Economic and Environmental Implications of Increased Alfalfa Production in the Eastern Corn Belt." John C. Foltz, Marshall A. Martin, and Jess Lowenberg-DeBoer (Purdue University)

Inclusion of alfalfa in crop rotations on Eastern Corn Belt farms with high and low productivity soils was analyzed with a mathematical programming model. Net incomes were larger with the government program but inclusion of alfalfa in the rotation reduced nitrogen fertilizer and herbicide use, potentially reducing environmental degradation.

"Erosion and Sediment Reduction Benefits of Conservation Compliance in an Agricultural Watershed." Tony Prato and Shunxiang Wu (University of Missouri)

Erosion and sediment reduction benefits are determined for resource management systems that maximize annual net returns in a northern Idaho watershed subject to achieving the erosion control standards established by conservation compliance. Net benefits are positive relative to conventional tillage but negative relative to reduced tillage.

"Off-site Sediment Damage Effects of the Conservation Reserve Program." Robert R. Alexander, Burton C. English, and Kurtis Hale (University of Tennessee)

One purpose of the Conservation Reserve Program is to reduce sediment and improve water quality. An interregional sedimentation model, the Micro-Oriented Sediment Simulator II, is used to evaluate the impact of the Conservation Reserve Program on sedimentation and on the offsite costs of sediment damage.

Evaluating Alternative Timber Management Objectives and Demand (Ilan Vertinsky, Director, University of British Columbia, presiding)

"The Roles of Finished Product Inventory and Price Expectations in the Softwood Lumber Industry." Jan K. Lewandrowski (RTD ERS USDA)

This paper presents a regional model of the U.S. softwood lumber sector. The firm's production, inventory, and sales behavior follow from a single optimization problem. Producers act based on inventories and rational price expectations. The demand for lumber is derived from the demands for new and remodeled houses.

"Timber Supply from Nonindustrial Private Forests: Reconsidering the Conventional Wisdom." Bill Provencher (University of California, Davis)
This paper challenges a bit of conventional wisdom by arguing that private forest owners who derive satisfaction from a variety of forest outputs may nevertheless manage their forests simply to maximize timber profits. A reexamination of regression analyses reported in the literature supports this argument. Policy implications are discussed.

"Solving the Aggregation Problem with Area-Frame Samples: The Analysis of New Land Use Policies." Ian Hardie (University of Maryland) and Peter Parks (Duke University)
The aggregation problem implicit in the production of regional land use response to new government policies may be solved using a random variable profit maximization model and area-frame sample data. Such a model is illustrated by predicting landowner and land use response to cost subsidization policies for pineland reforestation.

"The Economics of Plantation Forestry for Electrical Power Generation in Eastern Ontario." Brian P. Cozzarin, Wayne C. Pfeiffer, Glenn C. Fox, Andrew Gordon, and Willem van Vuuren (University of Guelph)
The question of whether intensively managed hybrid poplar and willow trees grown on a plantation can compete economically with coal and oil in generating electrical power was addressed. Break-even prices and the impact of key variables on them were determined for three management systems (*a*) short-rotation hybrid poplar, (*b*) minirotation hybrid poplar, and (*c*) minirotation hybrid willow.

Improving Efficiency in Irrigated Agricultural Water Use (Richard Gardner, State of Idaho, presiding)

"A Multicrop Production Model of Lands Served by the Bureau of Reclamation." Michael R. Moore (ERS USDA) and Donald Negri (Williamette University)
To analyze the issue of water conservation on cropland served by the Bureau of Reclamation, we develop a multicrop production model with water and land as fixed, allocatable inputs. Crop supply and land allocation equations are estimated for six regions. Elasticities with respect to the water constraint generally are inelastic.

"Production Functions of Western Irrigated Crops." Noel R. Gollehon and Michael R. Moore (RTD ERS USDA), Donald H. Negri (Willamette University)
For two functional forms, this paper reports econometric estimates of production functions for thirteen major irrigated crops using a common dataset and a consistent specification of the variables across crops. Estimates of the output elasticity of irrigation water are uniformly highly inelastic for each crop.

"Economic Feasibility of Contingent Water Markets for Columbia Basin Project Irrigated Agriculture." Philip Halverson and Norman K. Whittlesey (Washington State University)
A contingent water market is proposed for Columbia Basin Project irrigators as a means of supplementing Pacific Northwest firm energy supplies. Linear programming and stochastic simulation are used to estimate the increase in value of the region's firm power and the long-run impacts to irrigators' net farm income.

"Price Effects of Irrigation Technology Transitions in the Pacific Northwest." Glenn Schaible and C. S. Kim (ERS USDA), Norm Whittlesey (Washington State University)
Parks' modified multinomial logit (MML) model is applied to determine price effects on irrigation technology transitions in the Pacific Northwest. Parks' MML model accounts for the (standard) logit approximation error and for specification error. The results indicate elastic but relatively small price effects. Locational factors also affect technological transitions.

"Drought Insurance for Municipalities: Water Lease Options." Tariq S. Khokhar, Kim D. Dillivan, James J. Jacobs, and Larry J. Held (University of Wyoming)
Municipalities facing water shortages should consider the temporary transfer of water from irrigation to urban use. This paper analyzes the exercise cost of water lease options for Casper, Wyoming. The estimated cost of water lease options indicate a substantial savings to Casper when compared to the recommended alternative.

Economic Issues in Fishery Management and Demand (Daniel Huppert, University of Washington, presiding)

"Input Controls in a Fishery: Success or Failure?" Diane P. Dupont (University of Guelph)
This paper examines the effectiveness of input controls in a fishery in preventing rent dissipation. The paper uses duality techniques to define an elasticity that can measure input substitution possibilities in firms facing input controls. Data from the British Columbia salmon fishery show that controls have not worked.

"Seasonal Patterns and Regional Preferences for Salmon in Japan." Cathy Roheim Wessells (University of Rhode Island) and James E. Wilen (University of California, Davis)

Japanese demand for salmon plays a central role in the U.S. salmon fishery. In an effort to better understand the factors that influence the import demand, a system of retail demand equations was used to analyze intertemporal and regional patterns of consumption of salmon and other fish in Japan.

"Intraseason Regulation and Economic Efficiency in Recreational Fisheries: An Application to Pacific Salmon." Stephen K. Swallow (University of Rhode Island)
This paper focuses on efficient regulation of the within-season harvest process for recreational fisheries. Efficient allocation within a season can improve economic benefits, even though political or biological objectives determine the season's quota. The paper includes simulation results for setting creel limits in a hypothetical Pacific salmon fishery.

"An Hypothesis on the Role of Capital Markets in the Development of Brazil's Shrimp Aquaculture Industry." James R. Wilson and Roberto De Soussa Medina (Université du Québec à Rimouski)
Forty-nine Brazilian shrimp aquaculture firms were analyzed to determine the capital intensity of their operations, and the relation this had to financial health. This data plus the history of Brazilian shrimp aquaculture support the hypothesis that capital markets played a role in shaping aquaculture technology toward factors intensive in land/environmental goods.

"The Returns from Wetland Reclamation versus Preservation." W. van Vuuren and P. Roy (University of Guelph)
Private and social returns from wetland reclamation and from preservation are calculated. For both wetland reclamation and preservation the difference between social and private returns are large. From the viewpoint of society preservation is the best option, while from the owner's point of view reclamation gives the highest returns.

Benefit-Cost Analysis and Revealed Preference Approaches for Evaluating the Interface of Wildlife and Environmental Quality with Marketed Natural Resources (John Loomis, University of California-Davis, presiding)

"Hedonic Estimation of Implicit Price and Demand for a Louisiana Deer Hunting Lease Attribute." Mark L. Messonnier and E. Jane Luzar (Louisiana State University)
A hedonic framework is used to estimate the implicit price of a selected Louisiana deer hunting lease attribute, acreage available per member of a deer hunting club. A survey of 473 hunting clubs provides primary data for estimation of the hedonic price model specified in flexible Box-Cox functional form. The willingness-to-pay function for increased acreage per hunting club member is also empirically estimated, providing information on hunter willingness-to-pay to avoid congestion.

"Effects of Exhaustible Resource Exploitation on Renewable Resource Production: An Economic Analysis of Oil Development and Caribou." Uma Ganapathy and Stephen K. Swallow (University of Rhode Island)
Trade-offs between exhaustible resource development and losses in renewable resource benefits are examined by analyzing impacts of oil development on benefits from subsistence hunting of caribou in ANWR, Alaska. Losses in caribou benefits are evaluated by linking the environment's carrying capacity for caribou to the acreage allocated to oil development.

"Conjoint Analysis of Demand for Waterfowl Hunting." John Mackenzie and Benaifer R. Eduljee (University of Delaware)
This paper compares the conjoint measure approach with conventional contingent valuation methods. It develops a conjoint analysis of demand for waterfowl hunting as a composite of various trip attributes which are arguments in the utility function or the dual expenditure function. Marginal valuations of attributes, including travel time, are derived.

"Valuing Unpriced Quality Improvements from Observed Data: Southwestern Fishing." Frank A. Ward and Ibrahim Isytar (New Mexico State University)
A marginal benefits function defined over environmental characteristics is specified to be consistent with a flexible form utility index. The ordinary demand system from the utility index is estimated from observed data. Results from southwestern reservoirs reveal recreational water values ranging from $130 to $6,500 per acre foot.

"A Hedonic Analysis of Herbicides: Does Safety Matter?" E. Douglas Beach and Gerald A. Carlson (North Carolina State University)
Farmers may value water and user safety characteristics of herbicides as they select among producers to obtain weed control. Prices per application in the corn and soybean herbicide markets are explained by safety, market, and weed control characteristics. Leaching and user toxicity are statistically significant, but elasticities are small relative to some productivity characteristics.

Making Natural Resource Models More Realistic: Incorporating Risk, Uncertainty, and More Re-

alistic Assumptions (Murray Fulton, University of Saskatchewan, presiding)

"Resource Policy Analysis: Quality Control with Uncertainty." Donna J. Lee (University of Hawaii)
Random events often confound legislative efforts to achieve resource quality goals. Lack of sufficient information and risk-averse behavior can cause legislators to overinvest in control. This paper describes a new methodology for evaluating resource policy when the outcome is uncertain. Empirical results for water quality in a western river basin are presented.

"A Chance-Constrained Programming Analysis of Soil Conservation: An Examination of the Normality Assumption." Minkang Zhu and Daniel B. Taylor (Virginia Polytechnic Institute and State University), Randall A. Kramer (Duke University)
The rainfall erosion index, and thus soil loss, follows a lognormal rather than a normal distribution. The impacts of formulating a chance constraint on soil loss using a normal distribution, linearizing that constraint, and employing a lognormal distribution are assessed. Maintaining the normality assumption can bias the results.

"The Buffer Value of Groundwater with Stochastic Surface Water Supplies: The Case of a Confined Aquifer." Yacov Tsur and Ted Graham-Tomasi (University of Minnesota)
When utilized with a stochastic source of surface water for irrigation, groundwater may serve to mitigate fluctuations in the supply of water. The corresponding benefit is the buffer value of groundwater. We show that the buffer value is positive. Numerical studies reveal that its magnitude can be significant.

"An Economic Evaluation of Alternative Crop Management Systems Under Risk and Uncertainty in Prairie Agriculture." Randolph Seecharan, Shankar Narayanan, and V. O. Biederbeck (Agriculture Canada)
The study evaluates a selection of existing and alternative crop management systems in terms of their impact on sustainability of the soil resource base and on the economics of annual net returns, imposing risks, and uncertainty resulting from variability in rainfall, yields, and output prices in the Brown soil zone in Saskatchewan.

"Using Referenda for Natural Resource Investment Decision Making: Examining the Self-Interest Voting Model." Leonard Shabman and Kurt Stephenson (Virginia Polytechnic Institute and State University)
The self-interest model of voting behavior is used to analyze a single issue referendum for the approval and financing of a flood control investment in Roanoke, Virginia. Results indicate that some assumptions underlying the model are invalid. The implications of the model on natural resource decision making are discussed.

Policy Mechanisms for Environmental Control (John C. Bergstrom, University of Georgia, presiding)

"Water Markets and Water Quality." Marca Weinberg, James E. Wilen, and Catherine L. Kling (University of California, Davis); Zach Willey (Environmental Defense Fund)
A nonlinear programming model is developed to simulate grower response to water market scenarios. Significant reductions in drainage are predicted as a result of water conservation and improvements in irrigation efficiency, indicating the potential role of water markets as a policy tool for addressing the environmental problems of irrigated agriculture.

"The Effects of Consumer Demand on Regulation of Food Safety." Timothy H. Brown (University of California, Berkeley)
In a model where production inputs contaminate a homogenous food product, the demand response of informed consumers is compared to efficient regulation. Information changes the market failure from a health hazard among consumers to a common pool externality among competitive producers. Full information alone is not sufficient for efficiency.

"Incentives for Nonpoint Pollution Control." James S. Shortle (Pennsylvania State University)
Emissions-based instruments are inappropriate for nonpoint pollution. Two input-based incentive structures for nonpoint pollution control are presented. One is incentive compatible and obtains the efficient outcome. The second economizes on information but with a corresponding loss of efficiency.

"Marketable Pollution Permits with Incomplete Enforcement." Andrew G. Keeler (University of California, Berkeley)
This paper explores the effect of incomplete enforcement on pollution quantities and the number of complying firms in a pollution control system relying on marketable permits. Results indicate the possibility that pollution could be higher than under a comparable uniform standard and fewer firms might comply with their legal limits.

"Principles for Obtaining Optimal Emission Levels When Abatement Costs Are Private Information." Eirik Romstad (Norwegian Agricultural Economics Research Institute) and Olvar Bergland (Oregon State University)

A method of finding optimal emission levels when the regulatory agency does not know the individual firm's pollution abatement costs and firms are reluctant to reveal these costs is developed. The optimal emission level is where the emission permit market price equals the inferred price from the emission damage function.

Conceptual Issues in Value Measurement (John R. Stoll, Texas A&M University, presiding)

"Recreation Site Definition and Benefit Measurement." Raymond B. Palmquist and V. Kerry Smith (North Carolina State University)
The value of recreation site quality has become an important policy issue, yet the definition of a site is often unclear. This depends on aggregation issues within an individual's utility function. Empirical results show that relatively small changes in aggregation result in significant differences in value estimates for environmental improvements.

"Valuing Complex Policies with Contingent Valuation: Functional Forms and Estimation Procedures." John P. Hoehn (Michigan State University)
A valid contingent valuation design accounts for the substitutions that households make across policy components. Flexible functional forms are specified that allow one to estimate valid Bradford bid curves and to test for substitution effects. Estimates conform to theory. Results indicate that regional environmental conditions are strict substitutes in valuation.

"Testing the Fallacy of Independent Valuation and Summation in Multipart Policies: An Empirical Test of Whether Too Many Proposals Pass the Benefit Cost Test." John B. Loomis (University of California, Davis), John Hoehn (Michigan State University), and Michael Hanemann (University of California, Berkeley)
Statistical tests demonstrate the error of independent valuation and summation of related programs. Benefits of reducing farm drainage contamination and increasing wetlands in California would be overestimated by a factor of two if independent benefit estimates were simply summed. A more correct holistic valuation approach is demonstrated whereby respondents value packages of individual programs.

"Evaluating Use Benefits Under Uncertainty: Is There a 'Correct' Measure." Charles E. Meier and Alan Randall (Ohio State University)
This paper discusses the many "correct" measures of uncertain use benefits. The measures include expected surplus, option price, the willingness-to-pay focus, and the expected value of fair bet payments. Each measure's appropriateness depends upon both state-conditional pricing and insurance, whose roles are shown to be quite distinct.

"Uncertainty and Voluntary Contributions to Collective Risk Reduction Programs." Jason F. Shogren (Iowa State University)
Uncertainty has been shown to increase voluntary contributions to traditional public goods. This paper explores whether this result holds for collective risk reduction. Given risk is defined by probability and severity, and policy promoting voluntary provision of collective risk reduction will confront complexities which may render the effort ineffective.

Value Measurement and Confidence (Olvar Bergland, Oregon State University, presiding)

"Estimating External Costs of Municipal Landfill Siting through Contingent Valuation Analysis: A Case Study." Roland K. Roberts, Peggy V. Douglas, and William M. Park (University of Tennessee)
Contingent valuation was used to estimate external costs of siting a landfill in the Carter community of East Knox County, Tennessee. Estimates of annual external costs were $227 per household. Income, education, and perception of health risks were most important in determining a household's willingness to pay to avoid a landfill.

"Comparing Benefit Estimates from Discrete Choice Models for Contingent Valuation Surveys." Timothy Park (University of Nebraska) and John Loomis (University of California, Davis)
Mean willingness-to-pay estimates from a closed-ended contingent valuation survey are compared using the utility difference model suggested by Hanemann and a censored logistic regression model proposed by Cameron. Methods for deriving confidence intervals for benefit estimates from the two approaches are developed.

"Improvement in Estimation Efficiency and Precision of Benefit Estimates from Use of Double Bounded Dichotomous Choice Contingent Valuation." Michael Hanemann (University of California, Berkeley), John Loomis (University of California, Davis), and Barbara Kanninen (University of California, Berkeley)
The precision of willingness-to-pay estimates can be improved by asking each respondent two linked dichotomous choice questions rather than one. The two responses are used to estimate a double-bounded logit equation. An empirical analysis shows the confidence interval on the benefit estimates is substantially tightened using the doubled bounded logit approach.

"Valuing Environmental Quality Changes Using Averting Expenditures: An Application to Groundwater Contamination." Charles W. Abdalla and Brian A. Roach (Pennsylvania State University)
The averting expenditures method for valuing environmental quality changes offers a means for generating theoretically sound benefit estimates, yet it has received little empirical application. This paper reviews the theoretical basis for averting expenditures and presents the results of an application to groundwater contamination.

"Measuring Willingness to Pay for Nonmarket Goods." Douglas M. Larson (University of California, Davis)
The change in expenditure with changes in nonmarket goods like environmental quality can be obtained from empirical demand systems whether or not preferences are weakly complementary. The separability structure usually assumed in empirical work can be exploited instead. This makes possible measurement of use and nonuse values of environmental resources.

Environmental Issue and Water Resources (Teofilio Ozuna, Jr., Texas A&M University, presiding)

"An Integrated Model of Surface and Ground Water Quality." Richard J. Brazee and Stephen R. Crutchfield (ERS USDA)
The off site of agricultural chemicals and soil erosion on surface and ground waters are incorporated in an integrated model of agricultural production. The interdependencies of ground and surface water quality are highlighted. The effectiveness of chemical use and soil erosion restrictions in protecting water quality are compared and contrasted.

"Overview and Analysis of Recent State Initiatives in Pesticide Regulation for the Control of Groundwater Contamination." Sherry Wise and Stanley Johnson (Iowa State University)
Various states have been active in regulating pesticides to control groundwater contamination. An overview of recent state initiatives in pesticide regulation is presented. Trends show increased use of regulations that reduce pesticide user's property rights. Tobit analysis shows the influence of various political, economic, and physical factors on the legislation.

"Relating Qualitative and Quantitative Evaluations of Collective Risks: The Case of Drinking Water Contamination." Donald J. Epp and Brian Roach (Pennsylvania State University)
A matrix of numerical risk statements and qualitative ratings was presented to respondents producing numerical equivalents for qualitative ratings of water contamination risk. There was general correspondence between risk magnitude and related seriousness, but large variance in qualitative ratings of numerical risks renders some of the variables derived statistically insignificant.

"An Empirical Study of the Welfare Effects of Climate Change on World Agriculture." John Reilly, James Tobey, and Sally Kane (ERS USDA)
Previous studies of the economic effects of climate change on agriculture in individual countries have been largely limited to domestic yield effects. Using a model of world agricultural trade, we evaluate the changes in economic surplus when climate change directly alters domestic agricultural yields, and indirectly alters world trade.

"The Effect of Commodity Programs on Fertilizer and Pesticide Use in Agriculture." Glenn A. Helmers and Azzeddine Azzam (University of Nebraska)
A one output-seven input equilibrium model of U.S. agriculture was developed to study commodity program alternatives. The present program (land retirement and target prices) was compared to decoupling or free markets, an output quota, and modifications of the existing program. The results demonstrate that commodity programs have a very strong impact on the use of fertilizer and pesticides in agriculture.

Quantitative Methods and Public Policy I (Richard Howitt, University of California, Davis, presiding)

"Alternative Empirical Measures of the Supply Effect of the Corn Price Support Program." Frank M. Howland (Wabash College)
A methodology for measuring the supply effect of price support programs on individual farms is developed and empirically implemented on a sample of 104 Illinois farms, observed over the period 1976–85. The supply effect measures require less restrictive assumptions than analyses based on aggregate time-series data.

"Modeling the U.S. Grains Programs: A Microeconomic Approach." Marinos E. Tsigas, Thomas W. Hertel, and Paul V. Preckel (Purdue University)
A framework is presented for analyzing the impact of U.S. grains programs. The model's advantages are its endogenous treatment of the participation decision and the recognition of producer heterogeneity. The estimated model predicts that the 1986 freeze on program payment yields for wheat increased returns to land.

"An Application of Neutral Networks in Predicting Planted Acreage of Corn and Wheat in the United States." J. William Uhrig (Purdue University) and Clayton Jay Botkin (The WEFA Group, Inc.)
Corn and wheat planted acreages are analyzed using a trained neutral network consisting of highly parallel, interconnected processing elements. Network training was accomplished by presented examples to the network corresponding to actual input-output data sets.

"Gibrats' Law and Farm Growth in Canada." Murray E. Fulton and J. Stephen Clark (University of Saskatchewan)
This paper develops a model where firms' growth rates can be autocorrelated without violating Gibrats' Law. The test of Gibrats' Law is shown to be a unit root test. Using data for the prairie region of Canada, we find that Gibrats' Law is not rejected.

"An Econometric Model of Government Intervention in the Dairy Sector." Donald J. Liu (Iowa State University); Harry M. Kaiser, Timothy D. Mount, and Olan D. Forker (Cornell University)
In the dairy market, two regimes are possible: a competitive regime occurs when the market price exceeds the support price, and a government regime occurs otherwise. This paper presents and tests an econometric framework for estimating a two-regime structural system for the dairy industry.

Quantitative Methods and Public Policy II (Thomas Spreen, University of Florida, presiding)

"Modeling Policy Design and Imperfect Competition: The General Stackelberg Case." Anoush Farhangi and Paul V. Preckel (Purdue University)
Models of optimal policy design and imperfect competition are formulated as bilevel programming problems. The general bilevel programming problem is then reformulated as a single nonlinear complementarity problem. The reformulation is illustrated for two examples of market equilibrium problems with imperfect competition employing Stackelberg leader-follower behavior.

"The Impact of Regional Trade Liberalization on National Food Security: The Case of Senegal." Ousmane Badiane (International Food Policy Research Institute)
Regional trade liberalization has been proposed as a means of improving food security in Sahelian West-Africa. A general-equilibrium model is used to stimulate its impact on level and stability of food consumption in Senegal. It concludes that liberalizing food trade stabilizes food consumption but does not raise its level.

"Implicit Additivity as a Strategy for Restricting the Parameter Space in CGE Models." Thomas W. Hertel (Purdue University), Everett B. Peterson (Virginia Polytechnic Institute and State University), Yves Surry (Agriculture Canada), and Paul V. Preckel (Purdue University)
The purpose of this paper is to illustrate the value of the constant difference elasticity (CDE) functional form in applied general equilibrium analysis. It is a natural generalization of the commonly used CES form which permits the researcher to calibrate a model to complete vectors of own-price and income elasticities.

"The Welfare Significance and Non-Significance of General Equilibrium Demand and Supply Curves." Walter N. Thurman (North Carolina State University)
In certain circumstances, surplus measures behind general equilibrium supply and demand curves measure welfare changes from several markets. However, when there is feedback through both demand and supply channels, only the welfare triangle constructed from the curves has welfare significance; the surplus areas behind the curves do not.

"The Obsolescence of Social Cost-Benefit Analysis? Libertarian Pull and Socialist Drift." G. C. Van Kooten (University of British Columbia)
This paper argues that social cost-benefit analysis is buffeted by theories of political philosophy and social justice that threaten its usefulness and acceptance. One such theory is responsible for "socialist drift" in project evaluation procedures; the other denies government a role in the economy, thereby seeing no need for project evaluation.

Econometric Methods (Richard Boisvert, Cornell University, presiding)

"Bootstrap Confidence Intervals for Flexibilities Derived from Linear Equations." Teofilio Ozuna, Jr., and Andrew Tan (Texas A&M University)
Efron's Bootstrap is proposed as an alternative method for constructing confidence intervals for flexibilities. An empirical illustration is presented and it points out potential pitfalls when using Fieller's confidence interval method. The bootstrap is quite easy to implement and can be extended to more sophisticated and complete demand/supply equations.

"Confidence Intervals for Elasticities and Flexibilities." Jeffrey H. Dorfman (University of Georgia), Catherine L. Kling and Richard J. Sexton (University of California, Davis)
This paper examines methods for constructing confidence intervals around elasticity and flexibility point estimates, including three bootstrap-based approaches, a Taylor's series approximation, and ap-

proaches proposed by Fieller and Scheffe. Results show that all methods except Scheffe's worked reasonably well, but the Fieller and Taylor's series methods outperformed the bootstrapped-generated intervals.

"Symmetry and Small Samples: Impacts of Theory and Data on Estimation." Abiodun Ojemakinde (Albany State College) and Mark D. Lange (Louisiana State College)
Applications of duality have contributed greatly to our understanding of the agricultural production sector. However, most studies suffer from problems of finite samples and restricted estimation with unknown covariances. The resulting standard errors from the estimation are understated. Bootstrapping standard errors is analyzed as an additional estimation improvement.

"Measurement Error and Proxies: An Empirical Assessment." John G. Lee and Hector O. Zapata (Louisiana State University), Kent Lanclos (Purdue University)
Aggregate economic time series and proxy variables are likely to be troubled by systematic measurement error; however, the effect of such errors on estimated model results is infrequently considered. A diagnostic procedure is introduced and applied to a trade model. Results from the application indicate that the error in variable problems is relevant.

"Cointegration and Causation: Some Monte Carlo Results." Hector O. Zapata (Louisiana State University)
Performance of the Direct Granger test is examined under integrated and cointegrated models in a Monte Carlo framework. The nature of the long-run equilibrium relationship affects test performance and sensitivity to sample size. Granger causality testing without cointegration analysis may result in mixed, and unexpected, outcomes.

Topics in Quantitative Methods (Garth Holloway, Purdue University, presiding)

"Forecasting in the Presence of Structural Change: An Analysis of Cattle Prices with a Gradual Switching VAR System." Barry K. Goodwin (Kansas State University)
A multivariate gradual switching VAR system is used to model structural change in the cattle industry. The model is used to generate forecasts which are superior to those obtained from standard VAR and univariate models. Impulse responses indicate that cattle prices have become much quicker to adjust to new information.

"A Reappraisal of the Box-Cox Methodology." Octavio A. Ramirez and J. S. Shonkwiler (University of Florida)
This study establishes that the function currently used as a basis for implementing the Box-Cox methodology is not a valid probability density function. Simulation evidence documents that the original Box-Cox approach can result in considerable bias.

"A New Estimation Approach Using Alternately Actual and Synthesized Observations: Application to a Quarterly Cow Inventory Model." Bruce L. Dixon and John W. Goodwin (University of Arkansas), Danny R. Pippin (Tennessee Co-op Extens. Service)
An efficient method for estimating regression parameters when observations on the dependent variable are alternately actual observations and synthesized observations is developed. A quarterly cow inventory model is estimated using this technique. Increases in real, short-term interest rates are shown to have had a major impact on cow inventories.

"Analyzing Complex Dynamic Bioeconomic Systems Using a Simulation Optimization Technique." Richard F. Kazmierczak, Jr., and George W. Norton (Virginia Polytechnic Institute and State University)
A hybrid approach to optimizing high dimension, complex dynamic systems is introduced. The method employs discrete computer simulation and maximum principle conditions to optimize nonanalytic deterministic or stochastic systems. Application is demonstrated with a policy problem in the area of pesticide regulation and the management of pest resistance.

"Stochastic Optimal Control for Agricultural and Resource Economists." Bruce A. Larson (ERS USDA)
This paper analyzes the optimum control of stochastic processes. An investment model is used to introduce stochastic differential equations, interpret Ito's lemma, and derive Bellman's equation. An economic model of soil conservation where erosion is a stochastic process is then used to derive and interpret the stochastic maximum principle.

Food Aid: Motives and Impacts (Carl C. Mabbs-Zeno, ERS USDA, presiding)

"Food Aid and Food Security: A Cautionary Note." Derek Byerlee and Daphne Taylor (CIMMYT)
A simple model is presented to examine the effects of instability in global food aid supplies on foreign exchange expenditures and food availability in recipient countries. When global food prices rise, food aid

recipients are doubly affected through (*a*) decreased availability of food aid and (*b*) higher costs of additional commercial imports needed to make up the shortfall.

"Urbanization and Food Imports in Sub-Saharan Africa." James Tabi, Wayne H. Howard, and Truman Phillips (University of Guelph)
Granger causality was used to determine the relationship between total food imports/food aid and urbanization. Urbanization Granger caused total food imports in thirteen of the twenty-four countries, while food imports caused urbanization in three countries. Food aid, however, caused urbanization in sixteen of the twenty-four countries.

"A Note on the Income Effects of P.L. 480 Food Aid." Richard Ball (University of California, Berkeley)
Previous studies have claimed that PL 480 imports might have little effect on food prices, because food aid receipts increase real income, and hence shift out the demand curve. This paper shows that, by reducing producers' incomes, food aid imports may actually decrease aggregate income, and therefore depress food prices.

"Is there an Alternative to Famine Relief?: An Example from the Sahel." Meredith J. Soule (University of California, Berkeley) and Gerald C. Nelson (University of Illinois)
Aid agencies spend large sums to provide famine relief and are typically unwilling to provide project support for long periods. Yet, in at least one case in the Sahel, it would be cheaper to provide a long-term subsidy for an existing irrigation project than to provide periodic famine relief.

"Donors, Institution Building, and a Sense of Strategy: Relieving the Constraint." John J. Waelti (University of Minnesota)
Donor efforts to assist third world educational institutions fail to address the fundamental constraint, a shortage of faculty resources with which to conduct basic teaching and research. Donors could address that constraint through augmented staffing, using funds to top off indigenous positions staffed by expatriates.

Technology Adoption and Applied Research Impact on Agricultural Productivity (Christina H. Gladwin, University of Florida, presiding)

"The Technology Adoption Process in Subsistence Agriculture: The Case of Cassava in Southwestern Nigeria." Rudolph A. Polson and Dunsten S. C. Spencer (International Institute of Tropical Agriculture)
A dichotomous choice model is used to analyze factors affecting the adoption of improved cassava (Manihot esculenta, Crantz) variety (TMS 30572) by subsistence multicrop producers in the humid rainforest ecology of southwestern Nigeria. Implications of the empirical results for agricultural extension policies in this agroecology are discussed.

"Biological Diversity and Technology Adoption in Andean Potato Agriculture." Stephen B. Brush, J. Edward Taylor, and Mauricio R. Bellon (University of California, Davis)
Biological diversity in cradle areas of crop origins is an important source of genetic resources for world agriculture. Econometric findings from Peru indicate that adoption of high-yielding potato varieties results in reductions, but not complete loss of, biological diversity on farms. Farmer planting decisions may complement off-site conservation methods.

"Identifying the Relationship between Agronomic Research and Changes in Producers' Surplus." Greg Traxler (CIMMYT)
A framework for evaluating agricultural research is presented and tested using a case study from the Yaqui Valley, Mexico. The model's ability to capture the impact of both applied and adaptive research efforts makes it a potentially useful tool for assisting research administrators to allocate resources.

"Why Do Peasants Appear Sluggish in Spite of a Hectic Life?" Alain de Janvry (University of California, Berkeley), Marcel Fafchamps (Stanford University), and Elisabeth Sadoulet (University of California, Berkeley)
Using a peasant household model, this paper shows that market failures can be responsible for the low price elasticity of cash crop production; for internal instability in peasants' work effort and food consumption; and for the role of consumer goods availability, taxes, and technological change in inducing cash crop production.

"An Economic Analysis of Technological Adoption in Swaziland." Ganesh P. Rauniyar and Frank M. Goode (Pennsylvania State University)
This study investigates the socioeconomic determinants of adopting technological packages in Swaziland. Factor, cluster, discriminant, and logit analyses were used. The results indicate that three technological packages and four farmer classes exist. Access to funds to purchase inputs and information regarding improved cultivation methods were the most important explanatory variables.

Food Policies: Projects, Reforms and Analyses (Roberta Van Haeften, OICD USDA, presiding)

"Incorporating Nutrition into Agricultural Development Projects." Pat Graham (University of Northern Colorado)
Although opportunity exists in agricultural projects to incorporate nutrition objectives, nutrition is frequently overlooked in applied economic development. Neglect is caused by the complexity of malnutrition and a lack of methodology. By amending the planning process, nutrition can be made an explicit objective in conjunction with other development goals.

"Food and Agricultural Policy Reform: The Case of Venezuela." Barry Krissoff (ERS USDA) and Paul Trapido (Inter-American Development Bank)
The Venezuelan government has taken the first steps towards agricultural policy reform. Based on simulation experiments, we find that the removal of support, mainly in grains, leads to greater dependence on imports of corn, sorghum, and rice, but lower feed grain prices spur production and exports of meats.

"The Costs of Indonesian Sugar Policy: A Policy Analysis Matrix Approach." Gerald C. Nelson and Martin Panggabean (University of Illinois)
Indonesian sugar policy is a complex web of contradictory policies, including mandatory production requirements, price supports, and input subsidies. The policy analysis matrix is used to measure the efficiency of sugar production in irrigated and dryland areas and to identify the distribution of resource transfers.

"The Poultry Industry as an Endogenous Factor in Mexican Agricultural Policy: A Neoclassical Approach." Lovell S. Jarvis (University of California, Davis) and C. Federico Perali (University of Wisconsin)
Rising demand for chicken in Mexico is alleged to have increased sorghum production and imports, thereby contributing to lower corn production and higher corn imports and prices. Because corn is consumed by the poor, a "food versus feed" controversy has emerged in Mexico. We model and empirically analyze this issue.

"A Goal Programming Evaluation of the Fisheries Development Plan for Sri Lanka's Coastal Fishing Fleet, 1988–1991." Palitha Muthukude (Govenment of Sri Lanka), James L. Novak and Curtis Jolly (Auburn University)
The ad hoc nature of selecting targets and resource allocations has been cited as the major reason for consistent underachievement of Sri Lanka's fisheries development plans. To overcome these shortcomings, this study used goal programming to optimize the achievement of fisheries development goals for the planning period 1988–91.

Agricultural Technology: An Assessment of Economic and Financial Constraints and Risk Management (Donald R. McDowell, North Carolina A&T State University, presiding)

"The Impacts of Capital and Land Constraints on the Economics of New Livestock Technology in Western Kenya." Fanny B. Nyaribo (Winrock Foundation) and Douglas L. Young (Washington State University)
Land constraints prevented the smallest modeled farms in a western Kenya region from benefitting from new forages, milk marketing improvements, credit, or goat management assistance. Expanded credit, however, permitted modeled medium and large farms to vigorously exploit these innovations; credit also expanded income more than did goat management improvements.

"A Modern View of Joseph's Policy: Food Stocks as Financial Assets." Peter Berck and Irma Adelman (University of California, Berkeley)
Buffer stocks are financial assets and should compete with other financial assets for scarce investment funds. We use the consumption-based capital asset pricing model to evaluate the desirability of holding stocks in an LDC versus the United States. Results are presented for eighteen LDCs.

"The Structure and Importance of Informal Financial Groups in Cameroon." Gertrud Schrieder and Carlos E. Cuevas (Ohio State University)
Based on a 1988 survey, this paper shows that informal groups in Cameroon are capable of responding to widely different demands for financial services. The striking importance of these informal groups in Cameroon highlights the need to consider the likely effect on these groups of financial policy measures.

"Farmer Risk Management Strategies: The Case of the West African Semi-Arid Tropics." Patricia Kristjanson (Abt Associates, Inc.) and Peter J. Malton (WARDA)
This paper sets out a conceptual framework to identify and analyze risk management practices employed by farmers in the West African semiarid tropics. Primary farm-level data from Burkina Faso are used to illustrate the approach. Implications for the design of new production technologies and policy formulation are discussed.

"Analyzing the Effects of New Technologies on Risk Using On-Farm Trials in Dryland Agriculture." E. Loehman, D. Ngambeki, Z. Yu, and R. Deuson (Purdue University)
In formulating objective functions for farm models in a risk context, historical data have been weighted equally to represent weather and cross-sectional risk,

thus relying on long time series rarely available in developing countries. A method is proposed to measure risk associated with new technologies introduced in Cameroon in 1984–87.

International Trade, Debt and Economic Development (Magid Dager, University of Arkansas, presiding)

"Will the Latin American Countries Ever Pay Their Debts?" John Baffes and Robert G. Chambers (University of Maryland)
The 1980s have been characterized by major borrowing levels of the Latin American countries. A common question asked by the creditors is whether those countries will be able to pay their debts back. This paper gives an answer to this question by utilizing the theory of cointegration. The results show that the countries examined have violated their borrowing limits.

"Cereals Protection and Agricultural Development Strategy in the Sahel." Christopher L. Delagado (IFPRI)
The stagnation of Sahelian agriculture under seemingly unchangeable exchange rates has led to calls for supporting growth and food security through protection of cereals. It is argued that this will harm both objectives by ignoring the true comparative advantage of the region in livestock and other exports to the coast.

"Analyse du commerce extérieur agricole de l'Afrique de l'Ouest théories économiques et évidences empiriques." Sylvain Lariviere and Frédéric Martin (Université Laval)
Les théories économiques des avantages comparés et de la dépendance fournissent des éléments d'explication de la structure du commerce extérieur agricole de l'Afrique de l'Ouest. Cependeant, leur caractère parfois simpliste et réducteur explique les écarts existants entre les prévisions de ces théories et l'évidence empirique.

"Trade Determinants as Sources of Economic Growth: An Empirical Inquiry." Thomas L. Vollrath and Paul V. Johnston (ERS USDA)
Trade specialization patterns generally correspond to the stages of development explanation of growth. Commercial policy distortions and factor intensity reversals explain why trade does not always fit the skilled labor continuum. Calculated income elasticities with respect to openness imply that economies become less dependent on international markets as they grow.

"Developing Countries' Performance in High-Value Product Trade." Mary E. Burfisher and Margaret Missiaen (ATAD ERS USDA), Allen Blackman (University of Texas, Austin)
This analysis of the high value agricultural exports of thirty-five LDCs to the OECD during 1970–87 concludes that LDCs can benefit from a shift to high value, but not necessarily processed, agricultural exports. Favorable supply factors have become more important in determining successful export performance.

Modeling the Diverse Factors Influencing Agricultural Development (Donald W. Larson, Ohio State University, presiding)

"Control in a Dynamic Local Economy: Modeling the Behavior of the Chinese Village Leader." Scott Rozelle and Richard N. Boisvert (Cornell University)
Village leaders in the Chinese reform economy are assumed to maximize a multiple-attribute utility function; their behavior is modeled in a dynamic control framework. Structural and control equations for five industrial and agricultural variables are estimated. Results confirm hypotheses that village leaders are preoccupied with rural industrialization but must maintain high agricultural productivity.

"A Temporary General Equilibrium Framework for the Analysis of Macroeconomic Influences on Agriculture in Sudan." Rashid Hassan (CIMMYT), A. Hallam (Iowa State University), and B. D'Silva (USDA)
Unfavorable macroeconomic conditions have been blamed for the failure of devaluations and liberalization to correct the bias against agricultural exports in Sudan. A general equilibrium model, with an endogenous money creation mechanism, is constructed to analyze macroeconomic linkages to agriculture. Stronger economic performance is achieved when exchange rate adjustments are supported with monetary control and less indirect taxation.

"Agrarian Structure and Internal Migration in Ecuador." Ricardo E. Quiroga and Boris E. Bravo-Ureta (University of Connecticut), Jorge Brea (Central Michigan University)
A logistic regression model is formulated to study internal migration in Ecuador. The results indicate that the individual's decision to migrate is significantly affected by agrarian structure variables such as land reform, population pressure, and land inequality. Also, expected income differentials and personal attribute variables significantly determine labor mobility.

"Optimal Service Area Under Stochastic Inflow Conditions: Medium-Scale Irrigation in Thailand." Sam H. Johnson, III (University of Illinois)

Chance-constrained programming is used to determine optimal service area for a reservoir in Thailand. Present design includes wet and dry season service areas of 3,371 hectares. The optimal design is an area of 2,192 hectares for the wet season with extensive canals and 1,179 hectares using intensive canals for dry season crops.

"Examining the Optimal Use of Cereal Grain and Straw in the Mafraq Farming Region of Jordan with a Mixed Integer Programming Model." David W. Hughes, Walter Penaranda, and Walter R. Butcher (Washington State University); Abdulla Jaradat (Jordan University of Science & Technology)

Grazing in lieu of harvest is an important decision for dryland crop and livestock farming in the Middle East. The harvest versus graze decision and the use of cereal grains and straws is examined with a mixed-integer programming model. The harvest decision is relatively insensitive to changes in key variables such as levels of alternative feed sources.

Modeling Agricultural Product Trade (Catherine Halbrendt, University of Delaware, presiding)

"Oligopsony in Wheat Trade." Utpal Vasavada (Université Laval)

The hypothesis that importers possess market power in the international wheat market is evaluated with data on market shares. A two-stage budgeting algorithm is proposed to account for departures from perfect competition. This methodology generalizes the celebrated Armington model. Techniques to estimate import demand functions and test hypotheses are discussed.

"Price Dynamics in International Wheat Markets." Ted C. Schroeder and Barry K. Goodwin (Kansas State University)

Vector autoregressions are used to evaluate dynamic relationships among prices in six important international wheat markets. The effects of freight rates and exchange rates are also considered. The results indicate that Canada is the dominant market, supporting views which assume an oligopolistic price leadership role for Canada.

"Determinants of the World Wheat Trade: An Application of the Gravity Model." Won W. Koo (North Dakota State University) and David Karemera (Wayne State University)

A gravity model is applied to the world wheat market to analyze trade flows of wheat. The study reveals that production capacities, national income, import and export unit value indexes, and trade policies (long-term agreement and credit sales) play an important role in determining trade flows of wheat in the 1980s.

"An Investigation of International Trade in a Processed Agricultural Product: The U.S. Import Demand for Wheat Gluten." Francois Ortalo-Magne (Purpan Graduate School of Agriculture) and Barry K. Goodwin (Kansas State University)

This paper discusses the international market for wheat gluten, an important protein supplement in processed grain products. An econometric analysis of the U.S. import demand for wheat gluten is undertaken. The price of flour, income, and domestic protein supplies are found to be important determinants of wheat gluten imports.

"Import Demand for U.S. Fresh Apples in Three Pacific and One European Markets." Amy L. Sparks (ERS USDA), James L. Seale, Jr. (University of Florida), and Boyd M. Buxton (ERS USDA)

U.S. apple producers in recent years have increased production, while domestic consumption levels have remained stable. Accordingly, exports of apples will become increasingly important. The system-wide approach to import allocation provides insights into U.S. competitiveness in four of its major export apple markets.

Tariffication and Other GATT Issues (Barry Goodwin, Kansas State University, presiding)

"Tariffication with Imperfect Competition: The Case of the Canadian Chicken Market." Giancarlo Moschini and Karl D. Meilke (University of Guelph)

In order to improve market access following the Uruguay Round of trade negotiations the United States has proposed that all nontariff barriers be converted to these tariff equivalents and then lowered over a transition period. This paper explores the implications of "tariffication" for the Canadian broiler chicken market, an interesting case study because tariffs and quotas are not equivalent policies in markets characterized by imperfect competition.

"An Economic Analysis of the Impact of Removing U.S. Import Quotas on Dairy Products." Steven A. Neff (ERS USDA)

Many GATT members object to the 1955 waiver granted exclusively to the United States. Under its authority, the U.S. maintains import quotas on dairy products. The paper uses multicommodity comparative statics simulations to evaluate three alternative policies, finding an equivalent tariff more feasible than deficiency payments or a free market.

"Calculating Protection Coefficients: Is it Always Appropriate to Use World Reference Prices?" Derek Byerlee and Michael L. Morris (CIMMYT)

Protection coefficients are usually calculated using world reference prices. Under certain conditions, world

reference prices do not represent a good approximation of the prices that would prevail in the absence of market distortions. Data from Pakistan illustrates how failure to consider these conditions can result in misleading policy recommendations.

"Is the PEG a Viable Option? A Look at Long-Run Issues." Bruno Larue and James Oxley (University of Guelph)
The Producer Entitlement Guarantee has been offered as a viable scheme which will provide support for agricultural producers and not be trade distorting. This paper addresses the assignment and long-run adjustment issues in allocating PEG levels internationally and offers an alternative manner of monitoring for trade distorting PEG levels.

"Tariffication: Issues, Concepts, and the European Community." Walter H. Gardiner and Mary Lisa Madell (ERS USDA)
"Tariffication," essentially the replacing of quantitative restrictions with equivalent tariffs, was originally included in the 1988 U.S. proposal to the negotiating group on agriculture in the current round (Uruguay) of multilateral trade talks. This paper presents the concept, the issues and an application to the EC wheat market.

Macroeconomic Linkages and Price Formation (Patricia Lindsey, Oregon State University, presiding)

"An Alternative Analysis of Smuggling." James Oxley and Bruno Larue (University of Guelph)
Analysis of the welfare effects of smuggling have been based on the traditional trade theoretic model. It is shown that this method may be inappropriate. An alternative framework is developed using a welfare function approach.

"World Price Variability versus Protectionism: A Causality Analysis." Isabelle Miramon and Bruno Larue (University of Guelph)
This paper analyzes the causal relationship between world price variability and protectionism in the agricultural sector, by testing for Granger causality for eleven commodities. Two definitions of price variability are used, and protectionism is measured by the level of PSEs for each commodity over the period 1979–88.

"Deviation of Relative Agricultural Prices from the Short- and the Long-Run Equilibria." Mark Denbaly (NEH ARED ERS USDA)
Important policy implications of relative agricultural price movements have resulted in much analyses regarding the deviations of relative prices from their equilibrium levels in the 1980s. Using two alternative definitions of equilibrium, two models which account for the cause of deviations are developed and statistical procedures for estimations are proposed.

"Macroeconomic Policy and the Real Exchange Rate in Jordan: Implications for Vegetable Exports." Curtis E. Youngblood (Sigma One Corporation) and Grant M. Scobie (SER/Sigma One Corporation)
The effects of real exchange rate changes on vegetable exports from Jordan are estimated. We model the linkage between monetary, exchange rate, and fiscal policies on the real exchange rate. We estimate the extent of real exchange rate appreciation under fixed exchange rates in the presence of high domestic inflation. This creates disincentives to vegetable exports.

"Relative Uncertainty of Price and Output in Farm and Nonfarm Sectors." Doo Bong Han and Dennis W. Jansen (Texas A&M University)
Uncertainty about inflation, nonfarm output growth, and farm output growth are analyzed using the multivariate GARCH-M model. The results indicate that only uncertainty about nonfarm output has real effects. However, farm output growth is not affected by uncertainty about nonfarm output growth.

Analysis of Bilateral and Multilateral Trade Agreements (Harold Von Witzke, University of Minnesota, presiding)

"The Effects of the Canadian–United States Free Trade Agreement on Bilateral Trade Flows of Agricultural and Industrial Products." Ihn H. Uhm (Canadian International Trade Tribunal) and Won W. Koo (North Dakota State University)
A bilateral trade model is developed to evaluate impacts of the Canadian–United States Free Trade Agreement on trade flows of agricultural and industrial products between the two countries. This study found that the FTA would increase trade flows between the two trading partners, primarily through reductions of their import prices and increases in income levels. Exchange rate movements, however, would be a key parameter in determining the bilateral trade flows during the post-FTA era.

"US–EC Proposals for Long-Term Agricultural Reform in the Uruguay Round of GATT Negotiations: Will Minor Modifications in Agricultural Support Rates Lead to the Final Agreement? Glenn C. W. Ames (University of Georgia)
A world net trade model was used to evaluate the implications of partial price support reduction in the United States and European Community. Results were compared with complete multilateral trade liberalization and U.S. and EC proposals for long-term ag-

ricultural reform in the Uruguay Round of GATT. Wheat trade declined more than other commodities under both scenarios.

"U.S. and Canada FTA and Its Agricultural Economic Ramifications." C. Thomas Worley (Washington State University) and Dean Baldwin (Ohio State University)
The U.S.–Canada Free Trade Agreement (FTA) should increase economic welfare and specialization in agriculture for both nations. Producers and regions that are most (least) competitive may benefit (lose). Resources are reallocated among industries and regions. A quadratic program quantifies these issues for the short term and long run for both nations.

"U.S. Sugar Policy: A Welfare Analysis of Policy Options Under Pending Caribbean Basin Expansion Act Legislation." William A. Messina, Jr., and James L. Seale, Jr. (University of Florida)
A welfare analysis of two U.S. sugar import quota policy options was conducted. Results indicate that relaxing U.S. quotas to Caribbean Basin sugar-exporting countries would generate net domestic gains and gains to these countries, potentially in excess of those provided by the entire Caribbean Basin Initiative.

"1990 Farm Bill and Developing Countries." Liana C. Cuffman Neff (ERS USDA)
The 1990 Farm Bill will affect world markets and thereby will affect developing countries (LDCs). Projections of how world food markets might change in 1991/92 in three policy options show that with increased openness of U.S. agricultural markets, aggregate world prices increase and LDC agricultural trade balance improves.

LDC Debt and Market Structure Issues (Gerald C. Nelson, University of Illinois, presiding)

"The Competitive Structure of U.S. Agricultural Exports." Daniel H. Pick (ATAD ERS USDA) and Timothy A. Park (University of Nebraska)
The competitive structure of agricultural exports from the United States is examined using a model of export behavior based on pricing decisions across destination markets. The hypothesis of price discrimination is rejected for cotton, corn, soybeans, and soybean meal. Strong evidence against competitive market structure is obtained for wheat.

"Random Weather Shocks and Biased Estimates of Excess Demand." B. Stephen Labson (University of California, Berkeley)
In an excess demand system where random weather shocks enter multiplicatively, rather than additively, estimates of the underlying parameters will be inefficient under the "small country" assumption and biased in the "large country" case. A Monte Carlo simulation demonstrates that the magnitude of the bias is potentially very large.

"Empirical Investigation into the Effect of Financial Stress on Trade Flows for Selected Caribbean and Latin American Countries." Maria Veronica Gottret, James L. Seale, Jr., Charles B. Moss, and Carlton G. Davis (University of Florida)
The debt incurred by developing countries in the 1970s followed by increased real interest rates in the 1980s led to financial difficulties in these countries in the mid- and late 1980s. This study investigates the effect of financial stress on trade flows for several Caribbean and South American countries.

"LDC Debt and Policy Linkages in the Determination of World Commodity Prices." Gordon C. Rausser and Coleman D. Bazelon (University of California, Berkeley)
The effects of industrial country commodity policies and macroeconomic policies and the LDC external debt on world commodity prices are investigated. A theoretical framework is developed to provide the foundation for an empirical model that is estimated, assessed, and then simulated to isolate the effect of debt relief on commodity prices.

"Ghana: A Case Study in Macroeconomic Adjustment." William A. Amponsah and Leroy J. Hushak (Ohio State University)
Ghana's macroeconomic misalignment in the 1970s and 1980s necessitated structural adjustment. Using a multisectoral partial equilibrium model, we identify price incentives in the major export sectors, real exchange rate realignment, increased foreign capital inflows, higher interest rates, lower inflation, and domestic savings as major areas for government policy consideration.

Trade Liberalization Impacts (E. Kwon Choi, Iowa State University, presiding)

"Liberalizing Agricultural Policies in China: Effects on World Markets." Praveen M. Dixit and Shwu-Eng Webb (ERS USDA)
A world net trade model is used to study the distortionary consequences of agricultural protection in the People's Republic of China. Results suggest that Chinese policies have depressed world agricultural prices considerably, especially for rice and pork. The study also shows that policy reform in China would benefit producers immensely.

"The Impacts of Liberalizing Japanese Pork Markets." Thomas I. Wahl, Dermot J. Hayes, and Stanley R. Johnson (Iowa State University)

The paper examines the probable impact on Japanese pork consumption and imports of Japanese acceptance of the U.S. tarrification proposal.

"Trade Agreements and U.S. Citrus Exports to Japan." Pattana A. Jierwiriyapant, Jonq-Ying Lee, and James L. Seale, Jr. (University of Florida)
The Rotterdam model was used to study the Japanese import demand for U.S. citrus. Results indicate that U.S. fresh grapefruit exports to Japan would have to compete against imports of bananas and pineapples for the Japanese import dollars, and that U.S. citrus juice exports would have to compete against the juices from Brazil and Israel.

"Agricultural Policy Adjustments in the Korean Rice Economy." Hiroshi Yamauchi (University of Hawaii, Honolulu) and Yong Dae Kwon (Chungnam University, Korea)
A political preference function is used to endogenize government actions in a simultaneous equation model that is tested for Korean rice policy. The effects of macroeconomic changes on rice pricing decisions through estimated political weights are validated to open the way for better understanding of policy adjustments in East Asia.

"Rates of Protection in the Japanese Beef Market." Hiroshi Mori (Senshu University, Japan), William D. Gorman (New Mexico State University), and Biing-Hwan Lin (University of Idaho)
Rates of protection are estimated around 80% by comparing wholesale and CIF prices of imported "chilled carcasses" and ordinary imported beef. When LIPC's net profit figures are used, the rate of protection is found to be even smaller. Our estimates are substantially lower than most other studies.

Domestic and International Agribusiness Policy (S. Andrew Starbird, Santa Clara University, presiding)

"Agricultural Protectionism in a Strategic Trade Policy Context: An Application to the U.S. Cheese Market." Steve McCorriston (University of Exeter, Devon, England) and Ian M. Sheldon (Ohio State University)
Using a general conjectural variations model, this paper shows that even though import tariffs may be justified where markets are imperfectly competitive, such a policy may be inferior to alternative forms of trade intervention. These results are evaluated in the context of the U.S. cheese-processing sector.

"An Examination of the Likely Impact of the Withdrawal of Bovine Growth Promotants on the U.S. Beef Industry." Eric Grundmeier and Dermot Hayes (Iowa State University)
The paper examines the probable impacts on prices, quantities, and profits in the U.S. beef industry in the event of a voluntary ban on hormone use by beef producers.

"Off Farm Employment in Agribusiness: A Policy Perspective For Child Care and Family Support Programs." Forrest Stegelin (University of Kentucky) and Dolores Stegelin (University of Cincinnati)
A research-based policy position documents the expanding and critical role of corporate agribusiness in the provision of family-support and child care options for off-farm employed individuals and their families, especially as family-life issues top federal and states levels' legislative agendas.

"Opportunities and Pitfalls of International Futures Markets Trading by Developing Countries: The Case of Zaire Coffee Exports." Jack E. Houston and Mavuangi Khonde (University of Georgia)
Profitable direct and cross-hedging opportunities exist for Zaire coffee hedgers, and some periods may offer significantly superior opportunities. External events and internal policy changes contributed to instability of Zaire hedge ratios. The importance of internal economic and financial changes must also be considered to supplement international coffee market information.

"Multiproduct Costs, Shadow and Scale Elasticities: New Evidence for Fluid Milk Processing in the United States." Desmond F. Nolan (Pepsico), Cameron S. Thraen and David E. Hahn (Ohio State University)
The cost structure of the fluid milk-processing industry continues to change rapidly. Little is currently known about the internal cost/output structure of this important value-added food industry. This study provides new estimates of factor substitution and demand elasticities along with measures of cost and production scale elasticities.

Evaluation of Commodity Programs (Harry S. Baumes, Jr., ERS USDA, presiding)

"The Market Effects of Alternate Wool Policies." Glen D. Whipple, Dale J. Menkhaus, and John P. Hewlett (University of Wyoming)
The results of an analysis of the impacts of two policy alternatives to the wool act: An additional import tariff and restrictive import quotas are reported. They show that either approach could eliminate government expenditures while increasing producers' revenue. However, both place the burden for support on domestic wool consumers.

"The Impact of Product Demand and Government Intervention on Milk Prices." Kenneth W. Bailey, Abner Womack, and D. Scott Brown (University of Missouri)
This paper develops a framework to assess the impact of government intervention on the U.S. dairy industry. The model consists of markets for raw milk and three dairy products. The empirical results suggest that government removals have different effects on milk prices depending on which product is removed.

"Analysis of the Past and Future Impacts of the Wheat, Feed Grains, and Conservation Reserve Provisions of the Food Security Act of 1985 on U.S. Agriculture." John N. Ferris (Michigan State University)
AGMOD, an econometric model of U.S. agriculture, projected that the crop provisions of the Food Security Act of 1985 if continued at 1990 levels would contribute $7.5 billion in real (1982–84 $) discounted net cash income annually during 1986–2000, $3 billion of which is attributed to the Conservation Reserve.

"Production Rights with Limited Transferability: A Case Study of the U.S. Tobacco and Peanut Programs." Randal R. Rucker and Walter N. Thurman (North Carolina State University), Daniel A. Sumner (USDA and North Carolina State University)
Sale of tobacco and of peanuts into the domestic edible market requires quota. Recently, quota has been transferable only within counties. Such restrictions can cause deadweight costs. Our modeling and analysis of North Carolina data indicates that for peanuts these costs are zero and for tobacco they are relatively small.

"Spatial Distribution of the U.S. Dairy Industry: Long-Term Impacts of Policy Change." Jork Sellschop and Robert J. Kalter (Cornell University)
Use of a QP spatial equilibrium sector model showed that increased price supports shift dairy production westward. Reduced supports shift production northeast. Removal of fluid differentials without changing supports increases midwestern and Pacific but reduces northeastern and southeastern shares. Eliminating both policies boosts Lake States' share, reducing Northeast's and Southwest's.

International Policy Reform Considerations (Douglas Young, Washington State University, presiding)

"Lessons from New Zealand for Agricultural Policy Reform." William D. Dobson (Purdue University)
New Zealand's Labor government adopted sweeping agricultural policy and other economic reforms beginning in mid-1984. Farmers and agribusinesses generally adjusted effectively to the reforms. This paper discusses why and how the reforms were implemented and lessons others might extract from New Zealand's experience.

"Food Insecurity and the Role of Food Aid." Stacey Rosen and Shahla Shapouri (ERS USDA)
Food security can be defined as the ability of food deficit countries to meet target consumption levels. This paper evaluates the size and causes of food insecurity in thirty-five developing countries, assesses subsequent food aid response, and evaluates possibilities for increasing the role of food aid to improve food security.

"Dynamic Games in International Agricultural Policy." Shelley L. Thompson (University of Saskatchewan)
The formulation of agricultural policy in the U.S. and the EC is treated as a noncooperative dynamic game between governments and producers. The outcome of such policy is contrasted to cooperative policy. The results are discussed in the context of multilateral trade negotiations.

"A Model of Farm Behavior for the Current Chinese Grain Production Economy." Shihua Pan and Stanley R. Johnson (Iowa State University)
In the mixed system of China, marginal decisions of farms are affected by state prices only if market price is uncertain. If market price is known, marginal decision rules in market economics are directly applicable. Results under uncertainty show the importance of not simply ignoring free market price variability.

"The Impact of a Change in the Western Canadian Grain Transportation Policy." D. M. Dunlop and M. L. Lerohl (University of Alberta)
Current grain transportation policy subsidizes shipping export grain. This paper reports a simulation in which farmers pay full grain transport costs. Simulated over the 1983–87 period, the results suggest: (*a*) less grain production, mostly reduced barley output; (*b*) overall positive net welfare changes; and (*c*) reductions in shipping costs.

The Political Economy of Agricultural Policy (David Bullock, University of Illinois, presiding)

"Commodity Policy and Underinvestment in Agricultural Research." Harry de Gorter (Cornell University), David Nielson and Gordon C. Rausser (University of California, Berkeley)
Interactions between subsidies and the results of research efforts can lead to underinvestment in re-

search. Under conditions common to agriculture, subsidies can be used to compensate farmers for losses incurred from technical change. In such cases, underinvestment in research may be even more severe in the absence of subsidies.

"Accounting for Farm Programs." Julian M. Alston and Colin A. Carter (University of California, Davis), James A. Chalfant (University of California, Berkeley), and Steve Schonberger (University of California, Davis)
This paper synthesizes and extends the literature on political economy models of farm commodity programs. We examine thirteen agricultural products in a range of developed and developing countries. Our empirical results show that choices of policy instruments and levels of protection are jointly endogenous, depending on market and commodity characteristics.

"Budget Pressure and Farm Programs." Neilson C. Conklin (University of Arizona)
Institutional changes in the budget process have increased pressure on farm price support programs. The political-economic model in this paper suggests that budget pressure may bias policy toward supply controls.

"Optimal Evaluation of Research Portfolios." James F. Oehmke (Michigan State University)
This paper examines the optimal allocation of a given budget between research projects and the evaluation of these projects. Optimal evaluation expenditures increase as the budget increases and as the efficiency of evaluation increases relative to that of research. Results are interpreted in today's fiscal climate.

"An Evaluation of the Jamaican Agro 21 Export Diversification Program: A Policy Analysis Matrix Application." Carlyle A. J. Farrell (University of Manitoba)
The Monke-Pearson Policy Analysis Matrix is used to evaluate the economic impact of an export diversification program in Jamaica. Government policies failed to provide adequate protection to the program's winter vegetable sector; and resulting losses were J $100m. Gains from removal of inefficient policies are, however, too low to compensate for financial losses.

Alternative Production Practices in Agriculture (Roger Conway, ERS USDA, presiding)

"Agrichemical Restriction: Effects of Policy on Income and Its Distribution." C. Matt Rendleman (ERS USDA)
This study uses a ten-sector CGE model to measure the impact of a restriction in farm chemical use. Whether farmers benefit or not depends on whether a tax, a use restriction, or a production restriction is employed. In all cases, gross farm income rises but net income may fall.

"Commodity Programs and the Internalization of Erosion Costs: Do They Affect Crop Rotation Decisions?" Gregory L. Poe and Richard M. Klemme (University of Wisconsin), Shawn J. McComb (W.E.F.A. Group)
Using stochastic dominance, this paper investigates the impact of commodity programs and internationalization of erosion costs on crop rotation decisions. Commodity programs are found to shift decisions toward more erosive rotations. Internalization of erosion costs affect rotation decisions under historical market conditions but not under conditions of commodity program participation.

"Farm Program Impacts on Incentives for Green Manure Rotations." Douglas L. Young and Kathleen M. Painter (Washington State University)
Annual acreage reductions and deficiency payments generated mixed impacts on the relative profitability of a low-input versus conventional wheat rotation. Long-run incentives to maintain wheat base, however, introduced a consistent bias against the low-input green manure rotation. Current base flexibility proposals could reduce the "base barrier" to low-input rotations.

"Welfare Implications of Regulatory Policies Concerning Pesticide Residues in Food." Walter Ferguson (ERS USDA)
This paper illustrates the short-term implications for growers and consumers of the Environmental Protection Agency's new registration standard for lowering the risk from pesticide residues in food. National estimates are provided of the economic impacts of a fungicide ban on growers and consumers of nine vegetables and melon crops.

"Farm Policy Options for Agri-Chemical Reduction: A National/Regional Analysis." Kazim Konyar and Ian McCormick (ERS USDA)
Two scenarios that are designed to reduce nitrogen use are compared. The scenario that allows farm program participants to plant alternative crops on their base acreage results in lower government expenditures, lower farm income loss, and higher environmental benefits compared to the scenario that imposes a uniform tax on nitrogen use.

U.S. Trade Policy (Thomas Tice, AUS Consultants, presiding)

"U.S. Agricultural Policy and Environmental Quality: An Illustrative General Equilibrium

Model." James Tobey (ERS USDA) and Kenneth A. Reinert (U.S. International Trade Commission)
A simple general equilibrium model of international trade is developed to explore the resource use, income distribution, and environmental quality interactions of commodity and environmental policy toward agriculture. To analyze the environmental quality effects of policy changes, an environmental damage function is explicitly specified.

"An Agency Model of Expert Intervention: The Case of U.S. Wheat." David W. Skully (ERS USDA)
Public export agency intervention decisions are modeled in a principal-agent framework as balancing agency utility against budgetary costs. The CCC is shown to practice subsidy discrimination through its wheat export programs. The observed incidence of discrimination is consistent with the agency model. Implications for empirical demand estimation and wheat market modeling are discussed.

"Export Enhancement, Exporting Firms, and Efficiency of International Commodity Markets." Nicole S. Ballenger (Resources for the Future)
The large grain-export firms lobby against a U.S. export subsidy program that has paid nearly $3 billion in bonuses. This paper discusses the program characteristics that limit arbitrage opportunities and hinder traders' assessment and management of risk. These firm-level effects have implications for the international marketing system.

"Marketing Loan Programs and the Competitiveness of U.S. Cotton Exports." Carol E. Bray and Charles Bausell (U.S. General Accounting Office)
The U.S. cotton marketing loan did not keep U.S. cotton competitive on world markets in 1987 and 1988. Price relationships on the domestic market demonstrate that the U.S. loan rate continued to influence domestic floor prices, even under the marketing loan, through producer price expectations.

"U.S. Farmer Preferences for Agricultural Trade Policies: A Probit Analysis." Dennis A. Shields and Marshall A. Martin (Purdue University)
A probit model is used to estimate the influence of U.S. farmer characteristics on trade policy preferences. Four policies are considered: trade barrier reductions, farm subsidy reductions, world-wide production controls, and continuation of the Export Enhancement Program. Education, farm organization membership, and gross sales strongly influence farmer trade policy preferences.

Risk and Agricultural Labor (Joyce Allen, Joint Center for Public Studies, presiding)

"The Impact of Wage Differentials on Choosing to Work in Agriculture: Implications for the Immigration Control and Reform Act." Jeffrey M. Perloff (University of California, Berkeley)
A sample selection model of industry choice and wage determination was estimated for relatively uneducated rural males. A 1% increase in the relative wage in agriculture raises the probability of working in agriculture by 3.37% at the sample mean and by 1.3% averaged over the sample.

"The Impact of Nonfarm Labor Markets on Off-farm Income." H. Frederick Gale, Jr. (ERS USDA)
A regression model shows that higher nonfarm wage rates and lower unemployment are associated with greater off-farm income per farm. Effects are strongest in eastern regions and weakest in western areas. Off-farm labor supply appears quite responsive to nonfarm wages.

"The Saskatchewan All-Risk Crop Insurance Program: An Examination of Regional Insurance Value." W. P. Weisensel, W. H. Furtan, and A. Schmitz (University of Saskatchewan)
Saskatchewan Crop Insurance is an important stabilization program. However, critics maintain that it is not as useful to producers who farm in higher yielding regions. The purpose of this paper is to test the validity of these criticisms by comparing the regional value of insurance for various areas. The results support these criticisms.

"Explaining Participation in Federal Crop Insurance." Barry J. Barnett, Jerry R. Skees, and James D. Hourigan (University of Kentucky)
This study models participation in crop insurance for counties in thirteen wheat-producing states. The results indicate low price elasticity of demand for crop insurance. This suggests that a reduction in the loss ratio for crop insurance would be possible with an increase in rates.

"Effects of Disaster Assistance on Multiple Peril Crop Insurance Purchases by Iowa Crop Farmers." Mark A. Edelman (Iowa State University), Brian H. Schmiesing (South Dakota State University), and Khosrow Khojasteh (Iowa State University)
Logit regression was used to explain 1989 Multiple Peril Crop Insurance (MPCI) purchase decisions by Iowa Crop Farmers. The primary explanatory factor was whether MPCI had been purchased in 1988. Disaster payments and expectations that government would pass future disaster legislation were also found to reduce MPCI purchases.

Agriculture, Policy and Stabilization (Zuhair Hassan, Agriculture Canada, presiding)

"Estimating Price Distortions Caused by Canadian Wheat Board Initial Payment Policy." J. Stephen Clark and Catherine Fleming (University of Saskatchewan)
Limited dependent variable regression techniques are used to measure price distortions caused by initial payments as price floors. The results indicate that the degree of uncertainty producers have regarding the price floor is the critical issue in the level of price distortions.

"Impact of Changes in U.S. Grain Standards on Discounts for Insects in Stored Grain." Ronald Fleming, Bryan Schurle, Steven Duncan, and Carl Reed (Kansas State University)
The Federal Grain Inspection Service changed U.S. grain standards in 1988. Insect discounts given at the country elevator and at the terminal elevator level were analyzed for the impacts of the new standards. Insect discounts influence grain quality by affecting insect control decisions by farmers and elevator managers.

"Announcement and Implementation Effects of Agricultural Policies: An Example of Trade Liberalization." George C. Davis (North Carolina State University)
This paper demonstrates the policy announcement and implementation effects of direct intervention in agricultural markets. The importance of assuming inventories either depend only on predetermined variables or are constant in policy analysis is shown.

"Measuring Agriculture's Total Contribution to the Economy: A Sequential Extraction Approach." Carol A. Ferguson, John M. Halloran, and Stuart T. Nakamoto (University of Hawaii-Manoa)
Measurement of agriculture's economic contribution must consider possible replacement of farm production by imports and induced loss of forward-linked sectors. Sequential extraction, an input-output technique, is applied to the food system to assess total economic activity attributable to agriculture. The approach is demonstrated using Hawaii state data.

"Efficiency of Price Stabilization Under Rational Expectations." Robert Matheson and J. Stephen Clark (University of Saskatchewan)
The "price efficiency" of price stabilization programs is a function of the speed of convergence and path of prices. By examining the roots of a system of prices this efficiency level can be compared under alternative stabilization schemes. This recognizes the policy invariance of parameters under the rational expectations hypothesis.

Consumer and Household Economics (Jeff Alwang, Virginia Polytechnic Institute and State University, presiding)

"Product Quality and Value for Processed Foods." Orlen Grunewald (Kansas State University) and David J. Faulds (University of Tennessee)
This study investigates quality and value comparisons between national and private label brands of processed food products. Regression analyses indicate a weak relationship between price and quality for such products. Private label and national brands offer similar product quality, while private labels offer better values for consumers.

"The Effect of Functional Form on the Estimated Marginal Propensities to Spend Out of Food Stamps and Money Income." J. William Levedahl (ERS USDA)
With linear in the coefficients specifications, the marginal propensity to spend (MPS) on food out of food stamps is four–six times the MPS out of income. Using a generalization of Roy's identity and flexible indirect utility functions, alternatives were estimated.

"Income Sources of the Rural Poor: The Case of the Zona da Mata, Minas Gerais, Brazil." Stephen A. Vosti and Julie Witcover (International Food Policy Research Institute)
Microlevel data from Brazil show that higher household income is neither necessary nor sufficient for improved nutritional status. Income sources and output mix, which affect household access to food and intermediate health inputs, are linked to nutritional status. Female-headed households stand out, parlaying low income into high caloric intake; off-farm agricultural labor income was tied to lowered caloric intake.

"The Demand for Fresh Fruit: Nonparametric and Parametric Analysis." Gabriele Dono, Gary D. Thompson, and Nielson C. Conklin (University of Arizona)
During the last two decades, per capita consumption of fresh fruit has increased markedly. Although conventional wisdom suggests that this increase may be caused by heightened consumer concerns about health and diet, nonparametric tests can detect no change in average consumer preferences. Elasticity estimates indicate that grapes and strawberries have increasingly substituted for citrus fruit, particularly grapefruit.

"The Supply of Off-Farm Labor: A Random Coefficients Approach." Daniel A. Lass (University of Massachusetts) and Conrado M. Gempesaw, II (University of Delaware)

Off-farm labor supply functions are estimated by random coefficients techniques. Results are compared to standard selectivity results and variation in parameters considered. The random coefficients model appears to work well as an alternative to selectivity models and provides useful information on variation in individual responses to exogenous factors.

Regional Economic Analysis (Kevin McNamara, Purdue University, presiding)

"Economic Impacts of the Conservation Reserve Program in Virginia: A Break-even Analysis Using the IMPLAN Input-Output Model." Paul B. Siegel and Thomas G. Johnson (Virginia Polytechnic Institute and State University)
This paper assesses economic impacts of expanded enrollment in the Conservation Reserve Program in Virginia. It calculates break-even economic levels from the perspective of farmers and the regional economy and refines the appropriate interpretation of total gross output, employment, and income impacts in applications of input-output analysis to set-aside programs.

"Regional Impacts of the Conservation Reserve Program in the Southeast with Conversion to Trees: An Application of Input-Output Analysis." David E. Broomhall and Thomas G. Johnson (Virginia Polytechnic Institute and State University)
Using input-output analysis, this research shows that local economic impacts of the Conservation Reserve Program may be substantial in areas where land conversion is primarily to trees. Economic output and employment are estimated to decline in the early stages but later increase substantially during the tree harvest.

"Rural Economic Development in Multiregional Environment." David S. Kraybill (University of Georgia)
A multiregional computable general equilibrium model is used to analyze alternative rural economic development policies. Labor and capital subsidies are examined to determine their effectiveness in the presence of regionally exogenous shocks originating at the national and international levels.

"Estimating Regional Exports and Imports in U.S. Rural Development Models: Toward an Understanding of Spread and Backwash Effects." Binayak Bhadra (Tribhuwan University, Kathmandu, Nepal) and Bruce Weber (Oregon State University)
Testing rural-urban spread and backwash mechanisms require substate estimates of gross exports and imports. "Regional-purchase-coefficient"-based methods for estimating county-level gross trade flows are evaluated. Some obstacles to validation are identified. Multiregional rural-urban models are needed to better understand rural-urban interdependencies and development dynamics.

"Input-Output and Alternative Regional Models for Welfare Analysis." Roger Mann (Hydrosphere, Inc.) and Robert A. Young (Colorado State University)
Input-output is often used for analysis of regional welfare although the method must be augmented with additional information to obtain welfare implications. An interindustry linear programming model and a model using price responsive factor demands are used to evaluate a proposed irrigation development in southwestern Colorado.

Rural Development: Retail, Value-Added, and Diversification Opportunities (Larry Sanders, Oklahoma State University, presiding)

"The Measurement of a Community's Retail Market." James C. McConnon, Jr., and Steven C. Deller (University of Maine), Kenneth E. Stone (Iowa State University)
This paper provides a direct comparison of retail market population computed by the Reilly's Law method and the trade area analysis method. The results suggest that, over the entire sample, the two measures of market population are statistically equivalent. However, Reilly's method computed a larger market population for smaller communities.

"Implications of Alternative Farm Policy Regimes on Community Retail Sales." David A. Henderson (ARED ERS USDA)
A model using data from the Corn Belt indicates the elasticity of retail sales with respect to crop sales, livestock sales, and government payments varies by type of retail business and size of community. The results are useful for evaluating the effect of alternative farm policies on rural retail sales.

"Value Added versus Value Leaked: High Value Agricultural Exports from a State Perspective." Stuart T. Nakamoto, Carol A. Ferguson, and John M. Halloran (University of Hawaii at Manoa)
Input-output models can provide valuable assistance in identifying sectors which have large positive impacts on the economy. In agriculture, the tendency to promote sectors with large processing components may be misguided. A more sound criterion is to look at the portion of value-added which is retained in the local economy.

"Measures and Determinants of Agricultural Diversification." Mary E. Young (University of Texas at Dallas)

Efforts to revitalize rural economies through agriculture-related diversification have increased in popularity. Six measures of regional agricultural diversification were calculated, and a model of the determinants of regional diversification was tested. The results suggest that diversification is significantly related to farm size, irrigation, other income sources, and location.

"How Diversified Is Your State's Agriculture?" Loren W. Tauer (Cornell University)
Each state's agricultural production diversification is measured for 1984 and 1988. Very little difference existed between the type of index used or the year computed. Linear regressions of the coefficient of variation of receipts on diversification measures imply diversification among states has no impact on variability of receipts.

Local Government and Finance (Tom Harris, University of Nevada, Reno, presiding)

"Size Economics versus Managerial Efficiency in Local Government: Do We Know What We Are Measuring? Edward Rudnicki and Steven C. Deller (University of Maine)
Allowing for managerial inefficiency in public education, the hypothesis of size economies is examined. While size economies are identified in the traditional model, no size economies are identified under the more general model of managerial inefficiency. These results suggest that previous studies may incorrectly attribute managerial inefficiencies to size economies.

"The Political Economy of Highway Appropriations for Rural Development." Teresa D. Taylor (TVA Agricultural Institute) and Josef M. Broder (University of Georgia)
This paper examines the allocation of public funds for highway construction. A public choice framework was developed to identify factors associated with highway construction in Georgia. Highway appropriations were found to be associated with economic, demographic, and physical characteristics of the locality and the distribution of political rewards to decision makers.

"The Distributed Lag between Transportation Expenditures and Rural Income and Employment." Laurence M. Crane and David J. Leatham (Texas A&M University)
Effects of Texas transportation expenditures on income and employment were evaluated using distributed lags. A 1% increase in transportation expenditures in rural counties increased farm income 1.93% distributed over four years, nonfarm income 0.86% over six years, farm employment 0.29% over five years, and nonfarm employment 0.37% over nine years.

"Improved Measures of Manufacturing Attraction: The Role of Industrial Site Hedonic Prices." Warren Kriesel (University of Georgia) and Kevin T. McNamara (Purdue University)
An estimated industrial site price is included in a manufacturing location model to examine the impact that site quality has on firms' location decisions. The model is estimated with an ordered, categorical logit model. The results suggest that site quality and other location attributes are important location determinants.

"Changes in Commercial Bank Lending for Agriculture and Real Estate Associated with Banking Regulation." George K. Townsley (Farmers Home Administration) and Mark D. Lange (Louisiana State University)
Changes in portfolios of banks in the U.S. southeastern bank market associated with changes in federal and state regulations are analyzed. Percent of total assets held in real estate and agricultural loans decrease and liquid asset positions increase as banking laws become less restrictive. Acquired banks respond similarly in asset adjustments.

New Directions in Extension Programming (Darrell Peel, Oklahoma State University, presiding)

"A Comparison of Risk Performance Measurements with Implications for Extension Programming." Bryan W. Schurle and William I. Tierney, Jr. (Kansas State University)
Three measurers of risk preference were collected from ninety farmers along with additional information about their farm operations. Two of these instruments were correlated while the third was not. Risk preferences appear to be related to characteristics of the operation which has implications for marketing and farm management extension programs.

"Obstacles to Communication in Water Policy Education." Amy Purvis, R. Jeffrey Burkhardt, and Roy R. Carriker (University of Florida)
Water policy education can be instrumental in defining a proactive role for individuals who are concerned about the changing interface between environmental quality and farming. Obstacles to communication occur because people have different viewpoints concerning environmental quality. Some insights are outlined concerning how to design effective water policy education initiatives.

"Both Urban and Rural Interests Have a Stake in the 'Farm' Bill: A Report on Roundtable Discus-

sions of the 1990 Agricultural Legislation." Laurian Unnevehr (University of Illinois)
The increasing role of nonfarm groups in the agricultural policy process creates an opportunity for public policy educators. Roundtable discussions of the 1990 agricultural legislation in Illinois brought together citizens from farm and urban backgrounds to exchange ideas. These meetings met a desire for communication between traditional farmers and environmentalists.

"Extension Microcomputer Education in Farm and Ranch Management in Texas." James M. McGrann and Donald Breazeale (Texas A&M University)
The potential of the microcomputer to become an important management tool was recognized early by the Farm and Ranch Management Extension faculty at Texas A&M University. The paper presents an evaluation of the intensive training courses, software development, and distribution effort. Participant demographic characteristics and evaluations provide information on the target audience and program effectiveness.

"An Evaluation of the Use of Enterprise Budget Information by County Agents." DeeVon Bailey and Douglas W. Eck (Utah State University)
A regression analysis was performed to determine the factors influencing the number of times county agents directly referred to published enterprise budget information in a year. The agent's understanding of the use of budget information in management decisions, the geographic units that budgets were published for, and receiving the budgets in multiple forms had significant positive impacts on the use of budgets by the agent.

Evolving Educational Responses (Ralph Christy, Louisiana State University, presiding)

"Student Perceptions of Cognitive Skill Achievement in Agribusiness Management." Dennis M. Conley (University of Nebraska)
Educators recognize the need to integrate higher-order cognitive skills into courses but have difficulty in trying new methods. Active participation in an agribusiness management game is tested, with lecture dominated class time reduced, to evaluate the effect on student use of cognitive skills.

"Innovating Teaching of a Commodity Price Risk Management Course for Agribusiness Students." Larry Martin and Francesco S. Braga (University of Guelph)
State-of-the-art communication technology was used to teach a senior course on risk management. The paper describes how to integrate classroom lecture with preparation of market reports, using both Reuters and other hard copy material. Student participation was an important part of this course.

"Dealing with Drought: A Review of Our Professions' Response and Ideas for Improving It." William I. Tierney and David L. Darling (Kansas State University)
The recent droughts were a challenge to our discipline. This paper examines how agricultural economists in Kansas and other midwestern states responded to producers' and public policy makers' need for timely information. It concludes with ideas for designing drought programs in the future.

"Determinants of Agricultural Economics Faculty Retirement." Josef M. Broder and Fred C. White (University of Georgia), Teresa D. Taylor (TVA Agr. Institute)
Relationships among faculty characteristics and retirement age were examined. Years of service to retirement programs, number of children, mental health, health trends, age at initial employment, faculty-spouse age differences were positively related to retirement age. Salaries, net worth, and extension appointments were inversely related to retirement age.

"Nebraska Integrated Resource Management Demonstration Herd Project." W. Marshall Frasier, George H. Pfeiffer, Richard J. Rasby, Gene H. Deutscher, and Don H. Hudson (University of Nebraska)
Cooperator herds were employed to demonstrate improved profitability in cow/calf operations in Nebraska as the result of alternative management practices implemented. An interdisciplinary team of specialists developed recommendations for each operation. Biological and financial data were collected and analyzed on each operation and used in various educational activities.

Posters

"Long-Run Supply, Technology Restrictions, and Selected Environmental Impact." Burton C. English (University of Tennessee), Thyrele Robertson (SCS USDA), and W. Robert Goodman (University of Tennessee)
Policies targeting production technologies will impact environmental issues, international trade concerns, and agricultural land-use patterns. This research describes relationships between the price and supply of commodities, erosion levels, and U.S. planted cropland acreage as elements of sustainable agriculture technology are incrementally assumed using the ARIMS linear programming model.

"The Effects of Capital Gains Tax Reduction on U.S. Natural Resources: Agriculture, Forestry, and Resource Conservation." Liu-Hsiung Chuang (SCS USDA), Ronald Durst (ERS USDA), Karen Liu (Forest Service, USDA)
This study examines the effects and implications on agriculture, forestry, and resource conservation of the president's proposed reduction in capital gains taxation. First, the president's proposal is contrasted with the capital gains tax provisions in place before and after the 1986 Tax Reform Act. A review of the major elements of the president's proposal and their economy-wide effects will follow, with particular emphasis on the relative effects on agriculture, forestry and resource conservation. Finally, specific effects of the president's proposal on agriculture, soil and water conservation, and forestry will be detailed.

"Cost Effectiveness of Water Quality BMPs in the Chesapeake Bay Program." Donald J. Epp and James M. Hamlett (Pennsylvania State University)
The CREAMS model is used to compare sediment and nutrient losses of three fields under seven different BMPs. Changes in the present value of field net income and societal costs are calculated and combined with CREAMS results to produce cost-effectiveness measures of each BMP.

"Wither Irrigation?" William Quinby and John Hostetler (ERS USDA)
Analysts who rely on recent trends in the Census of Agriculture to predict future acreage of irrigated land in farms will be in for a surprise. The 1987 irrigated area was low because short-term cropland diversions were high. The background trend remains positive. This is confirmed by census trends for irrigation dependence.

"Development of the Micro-Oriented Sediment Simulator II." Robert R. Alexander and Burton C. English (University of Tennessee)
MOSS is intended as an aid to soil erosion researchers and policy makers in assessing the offsite costs of various erosion scenarios. Primarily a national-level tool, MOSS estimates sediment entering waterways and tracks the movement of the sediment downstream. Sediment damage costs are calculated based upon distribution of the sediment.

"Decision Aids in Conservation." Gail E. Updegraff, John H. Stierna, Douglas A. Christensen, and Douglas J. Lawrence (SCS USDA)
The Soil Conservation Service (SCS) has developed a decision-making framework that requires site-specific quantitative monetary and nonmonetary information. The purposes of this poster paper are to disseminate information about the SCS decision-making process, obtain information about existing farm-level decision aids, and demonstrate the SCS crop budget generator program.

"Willingness to Pay, Perceptions of Right, and Illegal Salmon Fishing: An Assessment of Quebec's Recreational Salmon Fishing Policy." James R. Wilson and Roxane Bouchard (Université du Québec à Rimouski)
Average willingness-to-pay measures from a binary contingent valuation survey question were developed for different income groups and for different rivers in the province of Quebec. Preliminary results suggest that the disparity in both income and rights perceptions within the sample militate heavily against the successful achievement of a comprehensive "pay by the day" policy of river access rights throughout Quebec.

"Sampling CRP Contract Holders on Future Land Use." Robert W. Lenkner and M. J. Monson (University of Missouri)
The Conservation Reserve Program (CRP) removed significant acreage from production in Missouri. Anticipating the actions of producers upon expiration of CRP contracts requires information on the economic and demographic factors which influence their decisions. A survey and stratified sample of contract holders is utilized to elicit this information.

"Returns to Education in Rural Areas: Evidence of Weak Demand for Highly Educated Workers." Linda M. Ghelfi and David A. McGranahan (ERS USDA)
Rural areas exhibited weak demand for highly edu-

cated workers during the 1980s. Evidence of weak rural demand includes an increasing metropolitan share of jobs for the highly educated, smaller returns to education in rural areas, and outmigration of better educated rural workers to metro areas.

"Revitalizing Rural Florida: A Multi-Discipline Approach to Agricultural Economic Development." Timothy D. Hewitt and David Zimet (University of Florida)
As in many other areas an effort is underway in the Florida Panhandle to improve rural incomes and to diversify current agricultural activities. A multiagency approach was undertaken to attempt to attract agriculture related industries to the area as a way of strengthening the rural economy of north Florida.

"Economic Analysis of Selected Industries Dependent upon the Bridger-Teton National Forest." David T. Taylor, Robert R. Fletcher, and Jeanette M. Oster (University of Wyoming)
Input-Output analysis can serve as guide in evaluating the economic impact of structural change within a region's economy. In this study, the analysis is used to estimate the potential economic impact on selected Wyoming counties from the management alternatives proposed in the Bridger-Teton National Forest Plan.

"The Consequences of Fatal Farm Accidents in New York: Family Displacement and Foregone Income." Timothy W. Kelsey (New York Center for Agricultural Medicine and Health)
The effect on families of fatal accidents in farming, the nation's most dangerous occupation, is great. This study found 68% of victims' families in New York no longer operated their farms and 44% have moved. Average lifetime expected income lost was $338,795 per hired worker and $307,179 per operator.

"An Economic Analysis of the Social Costs of Brazilian Ethanol Production: 1977–87." Kevin Rask (Duke University)
Environmental concerns, foreign exchange crises, and high oil prices have led to increased world demand for alternative energy sources. A social cost benefit analysis of the Brazilian ethanol program is undertaken to evaluate the efficiency of production of this renewable resource. The results show significant net social costs to ethanol production in Brazil.

"NEMPIS: National Economic Milk Policy Impact Simulation." Harry M. Kaiser (Cornell University)
The purpose of this poster is to demonstrate a computer simulation program which simulates farm and retail market impacts of user-selected dairy policy and technology scenarios. The program, which is called National Economic Milk Policy Impact Simulator, is free to anyone supplying the author with a floppy diskette.

"The Packing Simulation Model." Constance L. Falk (New Mexico State University) and R. Joe Schatzer (Oklahoma State University)
The Packing Simulation Model is a microcomputer application program designed for researchers, extension personnel, bankers, packing managers, or other specialists who plan the operations of a packing facility or simulate its financial performance. PACKSIM produces pro forma financial statements for packing facilities based on flexible crop mixes and packing assumptions.

"An Application of Experimental Economics in Marketing Research." Dale J. Menkhaus, Glen D. Whipple, Ray A. Field (University of Wyoming) and Elizabeth Hoffman (University of Arizona)
Marketing research has focused primarily on assessing consumer appeal with little attention given to the important issue of value. In this study, experimental economics was used to determine the economic value consumers place on vacuum packaged retail beef. With information, the vacuum package enhances the value of beef.

"Reducing the Cost of Marketing Beef through Central Retail Fabrication and Packaging." D. E. Farris, J. B. Ward, R. A. Dietrich and D. W. Holloway (Texas A&M University)
Central fabrication and packaging of retail beef can reduce consumer beef prices as much as 10¢ per pound. A national beef fabrication and marketing model was developed to analyze the economics of seven alternative systems for producing retail beef for thirty regional U.S. markets. Estimates of comparative advantage in expanding fabrication and packaging plants were most favorable in the Southern and Central Plains.

"GMX: A Grain-Marketing Expert System." Larry Lev, James Cornelius, and John Bolte (Oregon State University)
The Grain-Marketing Expert (GMX) is a rule-based expert system that utilizes knowledge from grain marketing experts in conjunction with information provided by the producer to develop a personalized short-run marketing strategy. Field validation of the program has demonstrated that GMX is user-friendly and provides useful recommendations.

"Buyers' Power and Factors Influencing Pecan Farm Prices." J. C. Purcell, W. J. Florkowski, and E. E. Hubbard (University of Georgia)
Growers receive different prices for pecans because of quality differences determined by management

practices, genetic makeup of trees, and concentration of buyers. Results suggest that growers must eliminate inferior pecan varieties from orchards and may consider organizing cooperatives for the purpose of marketing pecans.

"Lead-Lag Price Relationship between Government and Private Retail Outlets in a Planned Economy." Wojciech J. Florkowski (University of Georgia)
Lead-lag price relationship was tested for vegetable prices on farmers' markets and government stores in Poland using monthly data from 1970 to 1986. Results suggest that farmers' market price adjusted faster to changing market conditions and could reflect the condition of the economy more accurately providing useful information to a central planner.

"Structure of Dairy Consumption in West Africa." Siegfried Debrah (International Livestock Centre for Africa)
Dairy consumption research has not received enough attention to Sub-Saharan Africa. The few studies that exist aggregate all dairy products as one commodity and do not differentiate among consumer categories. This study uses a disaggregated analysis and estimates income-group-specific demand parameters which are more useful in studying the consumption patterns of the various consumer categories as well as analyzing the implications of dairy self-sufficiency policy on families in different income strata.

"Evaluation of an Expert System for Apple Pest Management." A. Laughland, W. N. Musser, T. Bowser, E. G. Rajttte, C. E. Sachs, R. Crassweller, L. A. Hull, J. W. Travis, and K. Hickey (Pennsylvania State University)
Expert systems are a method for adapting management recommendations to specific production situations. This poster reports on a multidisciplinary evaluation of the release of an expert system to a pilot group of growers. Behavioral, social, technological, and economic aspects of the evaluation are reported along with implications for future distribution.

"Differences in Access to and Reliance on Public and Private Information Sources by Farm Size and Enterprise: Implications for Effective Information Transfer." Nona R. French (University of Georgia) and Jackie B. Langston (North Carolina Rural Economic Development Center)
Data from a survey of 700 North Carolina farmers is used to examine differences in successfully obtaining and reliance upon public and private sources for different types of information. Farmer characteristics will be employed in multinomial probit. Results will identify information gaps and effective information transfer modes for varying clientele.

"Measuring Teaching Quality in U.S. and Canadian Departments of Agricultural and Rural Economics." Josef M. Broder (University of Georgia), William J. Taylor and John B. Rowsell (Virginia Tech)
This poster presentation examines Student Evaluation of Teaching (SET) instruments and statistical summaries used by agricultural economics and related departments in the U.S. and Canada. Theoretically desirable attributes of SET instruments and statistics are identified. Effective SETs and statistical summaries currently being used are displayed and critiqued.

"Computer Analysis of Futures and Options Market Strategies." M. J. Monson and David Miller (University of Missouri)
Marketing strategies created through combinations of cash positions, futures and options contracts can result in complicated effective-price profiles. A computer program is developed as an aid to producers in visualizing the effective-price and effective-revenue profiles with complex futures and options position.

"Large-Scale, Cross-Commodity, Econometric, Trade and Policy Models: Can We Talk?" Hsin-Hui Hsu (ERS USDA CED Crops)
Large-scale commodity simulation models are limited in design for complicated operating and management concerns. An integrated interactive system of core models could expand analytical capability of individual models to achieve both better understanding and avoiding bias in the policy formulation. This poster presents five USDA ERS in-house models with an application of research design in examining the planting flexibility issue.

"Data: An Issue Whose Time is Now." Leroy J. Hushak (Ohio State University) on behalf of the AAEA Economic Statistics Committee
In late 1987, the Economic Statistics Committee of AAEA undertook to develop a major survey of data needs of rural social scientists and a symposium to address data issues. The survey and symposium were completed during 1989. The purpose of the poster is to report these efforts and to update AAEA members on current data initiatives.

"Concept Mapping in Teaching: A Tool for Integration and Communication." Deborah H. Streeter (Cornell University)
A technique called concept mapping can be used by teachers to emphasize meaningful (conceptual) learning over rote memorization. The maps presented illustrate the use of concept mapping to (*a*) integrate interdisciplinary ideas in a course in information systems and decision analysis and (*b*) identify conceptual problems in an independent study project.

"Economic Series Analyzer—A Computer Program for the Applied Analyst." Richard G. Heifner and Nicholas J. Powers (ERS USDA)
This completely menu driven software makes data analysis fun for students and analysts who desire a program with very low startup time. The program functions can be broadly categorized as (*a*) data manipulation, (*b*) graphics, (*c*) descriptive statistics and nonparametric tests, and (*d*) regression analysis.

"A Revolution in Data Use and Dissimination: Implications for Agricultural Economics." Alan Webb (ERS USDA ATAD), Karl Gudmunds (University of California, Davis) and Gene Hasha (ERS USDA CED)
Data manipulation has always been a cumbersome but necessary element in economic analysis and research. A new set of software programs built around major USDA data sets promises to facilitate initial data analysis. This poster will demonstrate the value of these developments to researchers, teachers, extension economists, and policy analysts and provide a basis for discussion of future developments.

"Motivation of Group versus Individual Behavior: An Educational Futures and Options Trading Club Application." Eluned Jones (Virginia Polytechnic Institute and State University), Russ Perkinson (Virginia Cooperative Extension Service), and Anthony Townsend (Virginia Polytechnic Institute and State University)
Group behavior, as manifested in an Educational Futures and Options Trading Club, indicated that group participation and decision making achieved greater success than individual programs. Financial involvement in concert with group and sub-group interaction influences the experiential learning aspect of the trading clubs.

"Prevailing Wage and Practice Surveys in Agriculture." Robert D. Emerson, Leo C. Polopolus, Sharon Moon, and Noy Chunkasut (University of Florida)
A research and training program for conducting prevailing wage and practice surveys in anticipation of foreign worker requests is displayed. A methodology is set forth for obtaining a representative sample of employers of seasonal agricultural labor. A significant training program component is the computerization of the questionnaire and interview process.

"Managing Main Street Business: A Proven Rural Revitalization Program." Larry B. Swain and Steven A. Schulz (University of Nebraska)
The "Managing Main Street Business" program has proven to be an effective new method of program delivery for the University of Nebraska Cooperative Extension. Workshop series are conducted in rural communities, particularly those designated as agriculture dependent. Contract instructors are used to deliver "custom fit" management programs to clientele throughout Nebraska.

"Developing Extension Education Programs on Macroeconomic Policy Linkages to Agriculture." William M. Snell, Orlando D. Chambers, and Craig L. Infanger (University of Kentucky)
This poster identified ways to implement/improve extension education programs on macroeconomic linkages to agriculture. Various advantages to the clientele, programming strategies, and support materials were presented. The poster display also contained flowcharts, graphical displays, and microcomputer screenshows to illustrate examples of monetary, fiscal, and trade policy linkages to agriculture.

"Microcomputers: A Tool for Distance Education." Joan R. Fulton (University of Minnesota)
A program utilizing microcomputers for homework assignments at a junior college in rural Saskatchewan is described. The benefits to the students, the college, and the instructor are identified.

"Learning About Corn Yield Response to Nitrogen Fertilizer When Rainfall Is Stochastic: A Simulation Model." Scott M. Swinton (University of Minnesota)
A microcomputer model simulates farmer learning about corn yield response to nitrogen fertilizer. The model uses a sequential regression algorithm to update estimates of the profit-maximizing fertilizer rate. Experiment leads to higher discounted net worth than passive or no learning strategies.

"Impact of the Federal Feed Grain Program on the Profitability of Alternative Cropping Systems." J. Randy Winter, Rick C. Whitacre (Illinois State University)
Replicated plots were utilized to examine the profitability of various rotations on highly productive Midwest farmland. Based solely on market returns, the rotations were more profitable than continuous corn. However, when the benefits of the 1985 Feed Grain Program were considered, corn production was most profitable. The results indicate that the benefits of the government program can influence farmers' crop production decisions.

"A Return-Risk Analysis Incorporating Capital Structure and Seasonability of Fresh Market Vegetables." J. W. Prevatt (University of Florida), L. L. Bauer, E. H. Kaiser, and P. J. Rathwell (Clemson University)
A Target MOTAD model was formulated to examine the return-risk relationships associated with capital structure and seasonality of fresh market vegetables. The impact of the target return level on enterprise

mix, risk magnitudes, the rate of change of risk magnitudes, and operating capital requirements were significantly different among seasons.

"Milk Yield Distribution within a Dairy Herd and Adjustment to BST Use." S. J. Monson, Timothy Bargary, and M. J. Monson (University of Missouri)
This research depicts a construct that recognizes the relationships between BST use and yield distribution within a herd. The distribution of milk yield within a herd proves to be a critical variable in determining the size of the dairy herd where a decrease in cow numbers will occur.

"Coordinated Programs: Farm/Ranch Management." John P. Hewlett and James J. Jacobs (University of Wyoming)
To efficiently utilize the limited resources of time and money, educational programs should be focused and an organizational structure established. These programs should be offered in a collaborative framework that recognizes the autonomy of all players, while giving each individual maximum flexibility in developing and providing his/her contributions.

"Assessing the Economics of Alternative Enterprises: A Case Study." Gayle L. Pounds, Larry W. Dorman, and Carole R. Engle (University of Arkansas at Pine Bluff)
The poster illustrates the process of analyzing the feasibility of an alternative enterprise, using baitfish production as an example. Capital investment requirements, annual cost and returns, cost decomposition, and cash flow budgets were estimated and analyzed for three farm sizes. Financial effects of fluctuations in selected parameters were estimated.

"Economics of Alfalfa Persistence and Replacement." Kevin C. Moore, Hans McDonald, John Coutts, Baryl Buchholz, and C. Jerry Nelson (University of Missouri)
A replacement decision model for continuous alfalfa production was developed. Emphasis was on stand life and phosphorous and potassium application. Optimal strategies for each plant nutrient simultaneously with stand life were determined. A stand age of eight years maximized annualized returns for both cases. Sensitivity analyses were performed and the solutions were found to be quite stable.

"The Preference Function of U.S. Wheat Policy during the Eighties." Arie Oskam (Wageninger Agricultural University) and Harald von Witzke (University of Minnesota)
A revealed preference approach was used to derive a policy preference function. Conscious decisions reveal the relation between the target variable of policy makers. The methodology was applied to U.S. wheat policy during the 1980s. Most consequences of decisions were calculated using WHEATSIM. The resulting preference function followed from a linear programming solution that minimizes calculated inconsistency of decision making.

"Farm-Level Impacts of Multilateral Trade Liberalization Case Studies of the U.S. and France." Christian Mainguy (ENITA-Dijon, France), C. Parr Rosson, III, Amy Angel (Texas A&M University), and Johnny Jordan (Clemson University)
A firm-level, recursive, simulation (FLIPSIMV) was used to estimate the financial impacts of multilateral trade literalization on selected case farms in the U.S. and France. Results indicate that all farms experience substantial decline in net cash farm income, loss of equity in the operation, and a decline in returns above variable costs. Declines in farm financial situation are most severe for the South Carolina farms and French farms. The Illinois farms were less adversely affected.

"Analysis of Grain Stocks Proposals for the 1990 Farm Bill." Frederick Nelson, Mike Price, Jerry Sharples, Paul Westcott, Robert Reinsel, and Harry Baumes (ERS USDA)
Proposed changes in U.S. stocks programs will contribute to an overall objective of moving towards market orientation in grain markets. Costs of the stocks programs may be reduced, but there will be less protection from price variability than with the old FOR. Producers will receive fewer benefits.

"Forecasting Wheat, Corn, and Soybean U.S. Exports with Fixed and Stochastic Coefficients Estimators." Roger Conway, Nathan Childs, Kevin Ingram, and Carlos Arnade (ERS USDA)
Do time-varying parameter models help provide useful export forecasts by incorporating volatility inducing factors into estimation? We compare various time-varying parameter models with fixed coefficients competitors and estimate soybean, corn, and wheat export equations for each model. Fixed coefficients models are found to be generally superior.

"EC Sugar Market Confronts GATT and EG 1992." Dale Leuck, Steven Neff, and Liana Neff (ERS USDA)
Trade negotiations in the General Agreement on Tariffs and Trade (GATT) imply possible elimination of the European Community (EC) sugar program, while an EC-wide reform initiative implies possible reallocation of EC production. Both initiatives reduce trade distortion by similar magnitudes, but each has different implications for the EC and countries having preferential sugar export arrangements with the EC.

"How Level Is the Playing Field?" Carl C. Mabbs-Zeno and Renata Penn (ERS USDA)
This poster presents producer subsidy equivalent for

twenty-eight countries showing how much support their producers receive as a result of government policies. Support varies among commodities within the United States as a result of both domestic pressures and the distribution of support among commodities by our competitors.

"Weather and Soviet Agriculture: Implications of an Economic Model." Robert L. Kellogg (ERS USDA) and Barbara Severin (Central Intelligence Agency)
Soviet agriculture is modeled as a function of capital, labor, weather, and government policy. The model is used to disentangle the effects of weather from the impact of government policies. Analysis indicates it will be difficult to domestically produce enough food to meet demand in the 1990s. Additional imports are likely.

"What Is an Agricultural Subsidy? The Case of Canadian Hogs and U.S. Corn and a Comparison with the FTA and the U.S. and Canadian GATT Proposals." Carol Goodloe (ERS USDA)
The decisions reached in the U.S. countervailing duty case against Canadian hogs and in the Canadian case against U.S. corn are compared to highlight similarities and differences in the criteria used to define subsidy. The two cases are then compared with the method used to calculate government support in the Free Trade Agreement and with some of the main features of the recently tabled U.S. and Canadian GATT proposals on subsidies.

Regional Differences in Growth, Exit, and Entry of Farms." H. Frederick Gale, Jr., and David Henderson (ERS USDA)
Matched records from the 1978 and 1982 agriculture censuses show that gross movements of farms are much greater than indicated by net changes observed in published data. Midwestern farms have the lowest rates of exit and are most likely to grow. Southern farms have the highest exit rates and are least likely to grow.

Award-Winning Theses

Fafchamps, Marcel. "Sequential Decisions under Uncertainty and Labor Market Failure: A Model of Household Decisions in the African Semiarid Tropics." Ph.D. thesis, University of California, Berkeley, 1989.

Using household survey data collected in Burkina Faso, maximum likelihood estimates of the parameters of a stochastic, multiperiod, nonseparable, nonlinear-quadratic household model are computed. Using those estimates, the impact of technological innovations on household behavior and welfare is simulated.

Uncertainty and the absence of labor markets are shown to dramatically reduce responsiveness to market incentives, thus explaining the apparent sluggishness of African farmers that is often imputed to their asserted lack of economic rationality. They also reduce the profitability of any type of technological change.

Alternative sources of cash income are essential determinants of technology adoption because they insure the household against bankruptcy. Household labor shortages prevent the household from reaping all the benefits of technological innovations.

Finally, technological innovations are much less attractive if they induce a loss of flexibility. Many land-saving technologies are thus penalized because they are embedded into inputs whose level cannot be adjusted over the agricultural season.

Peterson, Everett B. "The Farm-Retail Price Spread Revisited: A General Equilibrium Perspective." Ph.D. thesis, Purdue University, 1989.

This study determined how economic growth and imperfect competition in domestic food manufacturing affects the farm-retail price spread. Understanding these forces is important because they circumscribe the potential impact of public policies aimed at the food system. The impact of neutral technical change and changing factor endowments in a perfectly competitive economy were analyzed. The impact of income growth on the farm-retail price is ambiguous and depends on the source of the growth. Neutral technical change in the domestic economy, except in the agricultural sector, has little impact on the farm-retail price spread. Neutral technical change in domestic agriculture caused a reduction in the price spread.

Analysis of the effect of imperfect competition in domestic food manufacturing on the farm-retail price spread highlights the role of technology and preferences. The fact that potentially imperfectly competitive industries use relatively small amounts of agricultural inputs means that they have little impact on the derived demand for agricultural products. Second, substitutability among food products by consumers determines the direction of change in the farm-retail price spread.

Standiford, Richard B. "A Bioeconomic Model of California's Hardwood Rangelands." Ph.D. thesis, University of California, Davis, 1989.

Hardwood rangelands in California and elsewhere produce multiple products. Concern about overcutting of oaks on the California ranges raises the question of whether ranchers would cut fewer oaks if they were aware of the shadow value of the trees. The study develops a bioeconomic control model to analyze the value of oak stand densities on grazing, wild life, and fee hunting revenues.

Components of the model included oak tree growth, interacting annual forage production relationships, and a hunting revenue and cost function based on livestock density and oak tree canopy. The resulting nonlinear control model showed the bioeconomic interactions; seasonal grassland production was nested within the annual controls. Uncertainty was evaluated using chance-constrained controls. The empirical problem was solved using GAMS/MINOS software for a twenty-year horizon.

The model was run for several different site-specific scenarios. The results show that knowledge of the effect of oak density on wildlife and hunting revenues increases the optimal oak tree stand and reduces cattle stocking rates.

Engel, Brian K. "Relationships between Distributions of Price Expectations Implied by Futures and Options Markets with Distributions Elicited from Farmers and Merchandisers." M.S. thesis, University of Illinois, 1989.

The general purpose of the study is to provide a greater understanding of commodity price expectations and the conditions under which farmers' and merchandisers' expectations are reflected by those implied by futures and options. The study's four specific goals are to (*a*) elicit distributions of price expectations from samples of Illinois corn and soybean producers and grain merchandisers, (*b*) describe the shape and moments of producer and merchandiser expectations as well as those implied by futures and options markets, (*c*) compare expectations across samples to determine the conditions under which futures markets reflect expectations of market participants, and (*d*) identify and measure individual characteristics that may explain differences between producers' distributions and implied distributions.

The results indicate, first, mean price expectations of producer and merchandiser groups do not differ significantly from futures prices. Second, price variances perceived by the groups differ significantly from those implied by option premia. Third, Kolmogorov-Smirnov tests for goodness-of-fit indicate that nearby distributions of the groups do not differ significantly from distributions implied by futures and options, but more distant distributions of forecasts may. Finally, the goodness-of-fit of individual distributions could not be explained by characteristics of farmers, their farms, and marketing practices through regression analysis.

Gellner, Brett M. "An Analysis of the Demand for New Wood Panels and Other Forest Products in the Canadian and U.S. Construction Industries." M.Sc. thesis, University of Alberta, 1989.

The demand for nonveneered structural wood panels (NSP) has been increasing rapidly since the late 1970s in both Canada and the United States. It is hypothesized that the demand for NSP is governed not only by relative prices and technological change but also by the increasing market acceptance of these products, giving rise to dynamic factor demand adjustments.

Three general models are used to test this hypothesis: the static, dynamic partial adjustment, and dynamic logistic model. A generalized Leontief cost function is used.

The dynamic partial adjustment with Hicks-biased technical change provides the best representation of both the Canadian and U.S. construction industries. Construction firms have not instantaneously adjusted their factors of production to long-run equilibrium levels during the historical period, an assumption that is maintained in static models and in most of the available literature on these industries.

Stiegert, Kyle. "Price Spreads and Market Structure in the Beef-Packing Industry." M. S. thesis, University of Nebraska, 1989.

This thesis develops an empirical model to test price-taking behavior in input and output markets. The model is based on the variable profit function and is used to investigate noncompetitive behavior in the farm-wholesale channel in the beef-marketing industry. A parametric test of oligopoly/oligopsony conduct is developed through the use of conjectural elasticities in the live-cattle and carcass market. The impact of the cattle cycle and technological change on the beef industry conduct was also investigated. The hypothesis of price-taking behavior in the output market was soundly rejected. Conduct in the live-cattle market suggests a regime of accommodation rather than oligopsony power as has been found in other studies.

Award-Winning Undergraduate Paper

Computer Adoption Decisions—Implications for Research and Extension: The Case of Texas Rice Producers

Anne Marie Jarvis

This study identifies the characteristics of Texas rice producers who have adopted computers relative to nonadopters. Primary survey data obtained in the spring of 1990 was examined using logit analysis to identify how each characteristic influences the probability of computer adoption. Thirty-seven percent of the respondents use computers in their business. The results indicate that as farm size and business complexity increase so does the probability of computer adoption. Some evidence that the adoption of computer technology differs from production technology surfaced. Producers' decisions to adopt a computer are associated with the actions of their peers and family. Encouraging computer user groups and computer training courses for producers could encourage the adoption of computer technology.

Key words: adoption, computer, farm management.

Each day, agricultural producers make decisions that affect their business success. Producers are forced to make choices based on incomplete information within an uncertain decision environment. Environmental concerns, biotechnology advances, government programs, and computerized information systems all contribute to the complexity of decision making (National Research Council 1987, 1989; Salassi et al.; King and Sonka). Within this dynamic decision environment, producers must allocate limited resources among competing alternatives to achieve personally established objectives (Kay). To make allocation decisions, producers rely on information obtained from many sources, such as personal experience and records, other producers, magazines, newspapers, consultants, researchers, and extension personnel.

The management of diverse information is central to sound decision making. Computers can assist users in information management. Computer hardware technology has advanced rapidly in the last forty years from mainframes to programmable calculators to affordable microcomputers (Schmidt, *Wall Street Journal*). Further, software developments have increased the potential uses of computers in farm management. Today, a wide array of software is available to support office tasks, farm budgeting, record keeping, physical production, and whole-farm planning (Sonka, Buller). Producers identify the problem, assimilate the information, select an analytical technique, and evaluate the results.

Computers provide a tool to aid in decision making; they do not make decisions for producers. Computers assist producers in performing problem solving steps more efficiently by providing information on which they can base decisions (Tucker). How many producers, however, actually use microcomputers? Previous studies indicate computer adoption rates in agriculture ranging from 2.9% to 25.6% (Willimack, Putler and Zilberman). This study identifies the percentage of Texas rice producers who use computers and identifies the characteristics of computer adopters and nonadopters through logit analysis.

Currently, efforts are underway in Texas to develop farm-level expert systems (FLEX) software for rice and cotton producers (Stone et al.). Conceptually, the FLEX program will be composed of aids for production, marketing, policy, and finance decisions. The Weed Control Advisor (WCA), the first operational piece of RiceFLEX, will soon be released (Smith). Discussions are now in progress to evaluate the possibilities for organizing a multistate effort to develop expert system software for use by southern U.S. rice producers (J. Stansel, resident director, TAMU Agr. Res. and Extens. Ctr., Beaumont, personal communication, 21 Feb. 1990). After preliminary field testing of the WCA, it became apparent that substantial diversity exists among Texas rice producers' attitudes and abilities to use microcomputers in decision-making activities (Smith). This broad range of management's potential computer use poses problems concerning how to best serve producers

Anne Marie Jarvis is an undergraduate student in agricultural economics at Texas A&M University.

The author gratefully acknowledges the guidance of M. Edward Rister, James W. Mjelde, and James W. Richardson, associate professors and a professor, respectively, Department of Agricultural Economics, Texas A&M University, as well as other review comments provided by several other faculty members and students at Texas A&M University. Also, the Texas rice producers completing this survey are extended a special thanks.

through research and extension efforts. To effectively direct future research and extension efforts concerning software development and computer training courses, computer adoption by Texas rice producers needs investigation.

In previous studies, no direct variable to quantify management's impact on computer adoption appeared. No variables to capture the influence of peers' and families' use of computers on the adoption choice have been included either. The current study develops a logit model, where computer adoption depends on several variables identified in previous research (income, equity, education, off-farming income, age, consultant use, and number of laborers) and on variables not previously included (weighted production practices index, risk management techniques used, self-perception of management skills, number of producers known who use computers, and children's influence on computer interest).

Literature Review

Several factors affect a new technology's rate of adoption (Rogers). Included are attributes of the innovation and characteristics of the individual considering technology adoption. Economic theory states that costs and benefits should be weighed before an investment is made. Both costs and benefits of computer adoption, however, are difficult to quantify. Even so, researchers have developed models to quantify the returns of computer usage to farming operations. Net present value or capital budgeting analysis can be used to evaluate the returns of an on-farm computer. This type of analysis provides depth by simultaneously considering income taxes, timing of receipts and disbursements, and interest rates (Harrison and Williams, Mackey and McCarl).

Computer technology is different from production technologies. The success of the computer within a business depends on the human capital of the manager while the success of production technology is inherent in the innovation (McGrann, Tinsley, and Lanpher). The characteristics of the manager and his operation thus directly influence the computer adoption decision. Two types of analyses have been used to study these characteristics. First, descriptive statistics create a profile of producers who use computers and those who do not. Willimack found higher gross farm income, higher debt, crop production, and corporate structure to be associated with computer use for record keeping. Nakamoto, Leung, and Marutani found computer owners to be younger, to employ more full and part-time laborers, to farm more acreage, and to make higher gross income than those producers not owning computers. Van Tassell, Kay, and Martin found crop production, more acreage, and more thorough knowledge of financial tools to be associated with computer use.

Second, qualitative choice analysis can be employed to achieve greater statistical rigor in evaluating characteristics of adopters and nonadopters (Putler and Zilberman; Lazarus and Smith; Batte, Jones, and Schnitkey). When estimating the probability of computer adoption among Tulare County, California, farmers, Putler and Zilberman found farm size, education, and producers' involvement in a sales-related business to be significant characteristics. Lazarus and Smith found education, herd size, and partnership to be significant in computer ownership for New York dairy farmers. In their study of Ohio commercial farmers, Batte, Jones, and Schnitkey found acres, age, education, record use, total expenditures on information, and grain production to be significant characteristics within their model. All the characteristics above except partnership, age, and grain production were found to increase the probability of computer adoption.

Logit Analysis

Three statistical models available to analyze binary choice problems, such as to adopt or not adopt a technology, are linear probability, logit, and probit models. Logit analysis is employed in this study for several reasons. Within a linear probability model, the predicted probability of adoption can lie outside the 0 to 1 boundary imposed on probabilities. Such a result forces arbitrary defining of outcomes which are less than 0 or greater than 1 (Judge et al., Capps and Kramer). Both logit and probit models are transformations such that a cumulative distribution is estimated, thereby eliminating the 0–1 problem associated with the linear probability model. Empirical evidence suggests that neither logit nor probit has an advantage over the other (Capps and Kramer). The choice becomes a matter of convenience (Hanushek and Jackson).

The logit model is based on the logistic cumulative probability function represented by

$$(1) \qquad P_i = F(Z_i) = 1/(1 + e^{-Z_i}),$$

where P_i is the probability that the ith decision maker selects the first alternative, $Z_i = X_i\beta$, X_i is the vector of attributes associated with the ith decision maker, β is a vector of parameters to be estimated, and e represents the natural logarithmic base (Pindyck and Rubinfeld). In this equation, Z_i can range from positive infinity to negative infinity. The probability of adoption (P_i), however, lies between 0 and 1. Because equation (1) is a nonlinear function, maximum likelihood procedures are used to estimate the parameters (Harrell).

Evaluating a logit model requires examining both goodness-of-fit measures and the estimated coefficients. One goodness-of-fit measure is McFadden's R^2, calculated as

$$(2) \qquad \text{McFadden's } R^2 = 1 - \{\text{Log } L(\hat{\beta}_{ML})/\text{Log } (L_0)\},$$

where $L(\hat{\beta}_{ML})$ denotes the maximum value of the log-likelihood function and L_0 denotes the value of log-

likelihood function when all coefficients are set equal to 0 except the intercept. Empirical evidence suggests McFadden's R^2 typically lies between 0.2 and 0.4 (Sonka, Hornbaker, and Hudson). A second measure is the likelihood ratio test, which evaluates whether a relationship exists between all of the independent variables jointly and the dependent variable. The likelihood ratio test is computed as

$$\text{(3)} \quad \text{Likelihood ratio test} = -2\,[\text{Log}\,L_0 - \text{Log}\,(\hat{\beta}_{ML})].$$

This ratio is distributed as a chi-squared random variable with $k - 1$ degrees of freedom, where k is the number of parameters in the full model.

The final test for goodness of fit is the correct classification of decision makers. To calculate this measure, first the estimated probability ($\hat{P}_i$) for each observation is obtained. Second, based on a 50/50 classification scheme, producers are classified as adopters or nonadopters. If the estimated probability is less than or equal to 0.5, then the producer is classified as a nonadopter. If the probability is greater than 0.5, then the producer is classified as an adopter. The estimated classifications are then compared to the observed adoption and nonadoption within the data set (Capps and Kramer). A table of correct classifications is presented.

The estimated coefficients are also examined. Besides sign and significance of the estimated coefficients, how a change in an attribute will affect the probability of adoption is important. Because of the nonlinear nature of the logistic function, the effect of a changing attribute on the probability of adoption is found by calculating changes in probability, which are determined by (Pindyck and Rubinfeld)

$$\text{(4)} \quad \partial\hat{P}_i/\partial X_i = [e^{\hat{z}}i/(1 + e^{\hat{z}}i)^2]\check{\beta}_i.$$

Changes in probabilities can be calculated for any combination of X_i's. The changes in probabilities are calculated, as is usually the case, by setting each independent variable equal to its sample mean.

Data Source

Farm-level data were obtained through a mail survey of Texas rice producers in the spring of 1990. The survey development process involved three testing phases in which professors, producers, county extension agents, and other agribusiness professionals reviewed the draft survey instruments and made comments. Based on a modified form of Dillman's surveying method, the surveying process consisted of three steps: (*a*) all producers were mailed surveys, (*b*) nonrespondents were mailed reminder cards, and (*c*) those producers who had not responded in step 1 or 2 were contacted by telephone or by mail. Of the 770 surveys distributed, 65 were returned by producers who indicated they no longer produced rice, and 297 were returned by current producers. Of the responding producers, 285 surveys were usable, giving a 40% response rate from producers. Usable surveys are defined as those surveys whose information concerning variables included in the logit model are complete.

Probability of Computer Adoption

This study defines computer adopters as those producers who own and use a computer in their farm management. Those producers who own computers but do not use them for business purposes are considered nonadopters. Thirty-seven percent of the producers who responded have adopted computers. This adoption percentage is considerably higher than reported in previous studies.

Characteristics Included in the Model

For clarity of discussion, the characteristics are grouped according to (*a*) socioeconomic characteristics, (*b*) management skills, (*c*) farm operations, and (*d*) computer familiarity. Included in socioeconomic characteristics are three class variables (income, equity, education) and two continuous variables (*AGE* and *OFF*). Producers' income is broken down into gross farm income under \$100,000 (*INC*1); gross farm income between \$100,000 and \$500,000 (*INC*2); and gross farm income over \$500,000 (*INC*3). Equity was segmented into those producers with less than 40% equity (*EQUITY*1), those producers with 40% to 80% equity (*EQUITY*2), and those producers with more than 80% equity (*EQUITY*3) in their farm businesses. Education was grouped into three categories also: those with less than or equivalent to a high school education (*ED*1), those who attended college (*ED*2), and those managers who graduated from college (*ED*3); *AGE* represents the age of the respondent in years; *OFF* represents the percent of off-farm income relative to total gross income from all off-farm and on-farm activities.

Two continuous variables, *INDEX* and *MGT*, and four class variables, the *CONS* group and *RISK*, comprise the management skills; *INDEX* is a weighted average of production practices representing experts' perception of how innovative a producer is in terms of physical production. For this variable, a series of questions concerning fertilizer management, water management, crop rotation, ratoon crop management, variety selection, crop development prediction, harvest moisture, and on-farm storage were asked. Researchers at the Beaumont Agricultural Research and Extension Center weighted the practices on a scale of 0 to 10 as to the importance of each practice, with 0 being the least and 10 being the most important. The weights were adjusted to reflect different practices used by producers on the east and west side of Houston (J. Stansel, personal communication, 23 Apr. 1990). How skilled producers per-

ceive themselves to be at using financial management tools and economic concepts in their business is represented by *MGT*; *RISK* measures whether a producer uses risk management tools such as crop insurance and/or futures. The *CONS* group measures consultant usage: *CONS*1 denotes whether producers use financial consultants; *CONS*2 denotes whether producers use farm management consultants, entomologists, and/or agronomists; *CONS*3 represents whether county extension agents, extension specialists, and/or research scientists are consulted.

Farm operations represent the general farm business. A set of class variables representing livestock (*LSTCK*), corn and/or grain sorghum (*CRNSORG*), soybean (*SYB*), or cotton production (*CTN*) attempts to capture diversification. A second class variable, intent of future farm size (*DECREASE, SAME, INCREASE*), is also included. Three continuous variables, number of full-time employees (*LABOR*), rice acreage (*ACRES*), and number of entities (*ENTITIES*), attempt to ascertain size and business complexity's effect on computer adoption; *ENTITIES* identifies the number of separate farm businesses in which the producer is involved.

The familiarity grouping attempts to capture the producer's familiarity with computer users through two class variables, the *NO* group and *KIDS*. The decision to adopt or not adopt an innovation is influenced by peers and family (Rogers): *NO*1 represents managers who know either no or one producer that uses a computer, *NO*2 represents managers who know two producers using a computer, and *NO*3 represents managers who know three or more producers using a computer; *KIDS* represents that children's activities have increased the manager's interest in computers.

When estimating the model, *INC*1, *EQUITY*1, *DECREASE*, and *NO*1 are dropped to avoid a singular matrix. Because the dropped variables are embodied in the intercept, the results of each category should be interpreted relative to the intercept.

Logit Results

Table 1 includes the estimated logit model, significance tests, goodness-of-fit measures, sample means, and estimated changes in probabilities. First, the overall fit of the equation is examined. McFadden's R^2 equals 0.243, which lies within the expected 0.2 to 0.4 range. The likelihood ratio test is 89.2, which is significant at a p value of less than 0.001. The estimated model correctly classified 73.8% (210 of 285) of the respondents (table 2). Examining the classification of nonadopters (specificity) and adopters (sensitivity) indicates that the model classified nonadopters (83.3%, or 149 or 179) relatively better than adopters (57.5% or 61 or 106). The better prediction of nonadopters may be attributed to the larger number of nonadopters (62%) within the data set. Overall, the goodness-of-fit measures indicate that the model fits the data reasonably well.

The respective class variable groups' significance were tested using chi-square tests with m degrees of freedom, where m is the number of parameters being tested (Capps and Kramer, Harrell). This test is similar to the F-test used in linear regression models, but because of the nonlinear nature of logit analysis, a chi-square test is implemented. In those cases involving only a single 0–1 variable, the chi-square subgroup test is equivalent to the results of the t-test for significance of the individual coefficient.

Next, the estimated coefficients are examined. Income and equity are significant within the socioeconomic characteristics. Consistent with expectations, as gross farm income increases, the probability of computer adoption increases. Contrary to Willimack's findings, the estimated coefficients suggest that as producers' equity in the farm increases, they are more likely to use a computer. This result implies that as producers increase their equity interest, they are more able and willing to make the capital investment in a computer.

Within the management skill group, *INDEX* and *CONS*2 are significant. The sign of the *INDEX* suggests rice producers who exhibit more innovative production practices are less likely to adopt computers. This result may reflect the limited availability of production-oriented software. This observation, however, appears to substantiate the concept that computer technology adoption differs from production technology adoption. Further, it may infer that those producers who concentrate on production techniques may not be as concerned with management functions such as recordkeeping, budgeting, and market tracking—all tasks for which computers offer an advantage. A negative relationship with computer adoption is reflected by *CONS*2.

Final discussion within the management skill group deals with variables which were not significant. *RISK* was intended to capture the depth of producers' economic management. The lack of significance of *RISK* confirms previous studies' findings which suggest that rice producers do not have ready access to information for effective use of the futures markets (Elms et al.) and that rice producers do not use crop insurance (Knight et al.). The expectation for *MGT* was that those producers who consider themselves better financial and economic managers would be more likely to adopt computers. The results indicate, however, that the self perception of management skills does not significantly affect the probability of computer adoption. *CONS*3 denotes that a producer uses research and/or extension personnel in making management decisions. The expectation was that research and extension personnel use should have a significant positive influence on the probability of computer adoption. The lack of significance may indicate that current methods of reaching Texas rice producers to enhance computer adoption may need some modification.

Several variables in the farm operations group are significant: *CRNSORG, CTN, LABOR, ENTITIES, SAME,* and *INCREASE*. Estimated signs on

Table 2. Comparison of Observed and Estimated Computer Adoption, Texas Rice Producers, 1990

		Estimated		
		Nonadopters	Adopters	Total
Observed	Nonadopters	149	30	179
	Adopters	45	61	106
	Total	194	91	285
Correctly classified (210 out of 285)			73.8%	
Sensitivity (61 out of 106)			57.5%	
Specificity (149 out of 179)			83.3%	

CRNSORG and *CTN* reflect the nature of production. Management requirements to produce corn and/or grain sorghum are not generally as strenuous as those for rice or cotton. Therefore, the negative relationship with *CRNSORG* is consistent with information and management demands. In contrast, cotton demands high variable and fixed input costs. These high costs apparently encourage producers to closely monitor production, marketing, and financing in order to increase their profit margins. Consequently, the pos-

itive parameter for *CTN* suggests that producers producing cotton are more likely to adopt computers. As an indication of size and complexity, *LABOR* and *ENTITIES* exhibit a positive relationship with computer adoption. If producers intend to maintain or increase farm size, they are more likely to adopt a computer. This relationship suggests that producers who are going to continue to farm rice may recognize the computer's importance as an information assimilating and analyzing tool.

The computer familiarity group extends the scope of this study into areas not previously investigated. Social interaction as an influence in computer adoption (Rogers) is affirmed by the significant positive coefficients on variables *NO*3 and *KIDS*. These results indicate that producers are influenced by the actions of their peers and family. *NO*3 suggests that managers who know three or more producers using computers for their businesses are more likely to adopt computer technology. Producers whose children have experience with computers and who acknowledge this experience has increased their own interest in computers are more likely to use computers. When considering this relationship, it is important to keep in mind that those respondents who own computers only for their children's use are not considered as adopters.

The nonlinear nature of logit analysis requires that equation (4) must be used to estimate how an attribute will change the probability of computer adoption. Table 1 also includes the calculated changes in probabilities and the means on which the changes of probabilities are based. The interpretation of changes in probabilities for *INDEX*, for example, is as the value of *INDEX* increases one unit, the probability of computer adoption decreases 25.02% (O. Capps, Dep. Agr. Econ., Texas A&M University, personal communication, 31 May 1990). The remaining changes in probabilities given in table 1 have similar interpretations.

Conclusions and Implications

In times of increasing complexity in farm management, computer adoption reflects producers' attempts to better assimilate and utilize information. The 37.1% of Texas rice producers participating in the management survey who use computers in their management activities is greater than the percentages reported in previous studies. As size and complexity within the farming operation increases, the probability of computer adoption increases. Some confirmation that a difference exists between production technology and computer technology surfaced through the sign and significance of *INDEX* and *CONS*2. Those producers who intend to maintain or increase their operation's present size are more likely to adopt computers. The positive relationship between number of peers using computers and children's experience with computers offers insight into possible enhancement of computer usage.

Assuming a goal of research and extension is to increase computer adoption among producers, two main implications can be derived. These implications involve production management and familiarity. McGrann, Tinsley, and Lanpher contend that the decision to adopt computer technology is different from production technology. Comparing innovations within the Texas rice producing sector further confirms this position. For example, semidwarf varieties were introduced in 1983 (Texas Agricultural Experiment Station); Texas rice producers planted 88% of their acreage to semidwarfs in 1989 (*Rice Journal*). In comparison, affordable microcomputers were introduced in 1977 (*Wall Street Journal*); only 37% of the respondent group in this study have adopted computers. The visibility of an innovation and its apparent relative advantage influence its rate of adoption (Rogers). Other producers can witness a manager's production practices with semidwarfs and the resulting physical yield. Computers and their intangible values are not as observable. The difficulties in quantifying microcomputer costs and benefits make the relative advantage of computer adoption difficult to ascertain. Therefore, further research may be needed to more effectively quantify returns from microcomputer use.

Another feasible approach would be to focus on the familiarity aspect of computers. Resources may need to be diverted from software development into computer literacy programs. Encouraging computer users' groups among producers could increase the visibility of returns associated with computers use. That is, if some producers realize increased returns from using computers in their management activities, other producers may be more willing to adopt computers themselves. Encouraging computer skills for children is another possible way to reach producers. Extension specialists might consider working in conjunction with schools and youth groups to develop computer training programs.

Traditional research and extension methods to disseminate technology may not be functioning as well with microcomputers compared to production technologies. The intent here is not to advocate that everyone adopt a computer. As called for by McGrann and Breazeale, however, more information would be useful in regard to computer use in Texas agriculture. This study responds to that call with respect to Texas rice producers. Beyond apparent research and extension uses of this information, private sector hardware and software vendors seeking to assist the agricultural community may be served by the findings of this study.

Abstracts

"Optimal Advertising Budget for the Ontario Milk Marketing Board." Paula Conboy (University of Guelph), second-place paper.

In the last few years, the Ontario Milk Marketing Board has become quite active in fluid milk advertising, in an attempt to increase its market share of the nonalcoholic beverage market. To date, theoretical optimal advertising rules have been developed assuming advertising expenditures are a fixed cost. However, in Ontario, where such expenditures are financed through producer levies, the expenditure might more appropriately be regarded as a variable cost to the producer. In this study, a theoretical optimal advertising rule is developed and a suggested advertising expenditure for 1988 is derived. The research uses both synthetic and an estimated empirical model to determine this optimal level.

The result of the analysis suggests that the Ontario Milk Marketing Board's revenue net of advertising costs could be substantially increased if advertising is considered a variable cost when setting an optimal budget for advertising of fluid milk.

"Pricing Efficiency and Hedging Effectiveness in the Flaxseed and Rapeseed Futures Markets." David Thacker (University of Alberta), third-place paper.

This paper empirically assesses the forward pricing efficiency and producer hedging effectiveness of the flaxseed futures market as compared to the rapeseed futures market. Two tests of forward pricing efficiency relating to the forecasting accuracy of both markets are performed. The effectiveness of producer hedging in both markets is also investigated, with an estimation of the optimal hedge ratio and reduction in price variability resulting from hedging.

AAEA Business

Committee Reports

Report of the President

This year has been unique for the association, and as it concludes, future challenges are apparent.

This year, the resignation of Bruce Gardner as president-elect necessitated two elections for president-elect: one to fulfill Gardner's unfinished term, another for the normal transition of association officers.

North Carolina State University has informed the AAEA Executive Board that they have reluctantly reached the conclusion that they will be unable to host the AAEA meetings in 1993. They stated that "the facilities at Raleigh pose a number of problems . . . [that they] suggest we could have a high probability of an unfavorable experience for the Association." The board is currently considering alternative sites.

The ad hoc Adaptive Planning Committee has produced an important document that should prove to be an important catalyst to the association's long-range planning. Their excellent work will encourage us to focus on the issue of "what type of association do we want to be as we enter the next century?" Their report is thus a beginning, not a conclusion. Their report will be discussed in a symposium Monday at 3:30 P.M. in Buchanan A-106. All are welcome. The deliberations they have started will continue over the next year, but the committee and board need your opinions on the wisdom of and mechanisms for the broadening of the appeal of the association.

By all historical precedent, the Vancouver meetings are quite a success. Attendance of professionals is a recordbreaking 1,593. Total registrants are 2,325. We had over 685 reviewed papers and, even though more papers than usual were selected because of the additional meeting day, the acceptance rate decreased from 59% to 49%. Poster competition, in its third year, continues to be well received. This year we have 52 posters. The extra day allowed for more symposiums (57) to be accepted and for better integration with the Canadian Agricultural Economic and Farm Management Society, Western Agricultural Economics Association, and the Association of Environmental and Resource Economics.

After much success with pre- and post-conferences, we are evaluating this meeting, and we welcome comments. Thanks are due to Josef Broder for conducting this evaluation. You will find in your registration packet an evaluation sheet—please fill it out and return it as indicated. We will report the results in a forthcoming *AAEA Newsletter*.

We are experimenting with providing better continuing education experiences within the context of the regular meeting dates. Our first event, developed by the Professional Activities Committee and entitled *Nonmarket Valuation: Extending the Frontiers and New Applications*, has more than 230 registrants, so we know the interest is high. We plan to have another learning seminar next year. We also have good participation in our excellent preconferences: AAEA/CAEFMS; Agriculture and Rural Restructuring; Comparisons of the United States, Canada, and Europe; and Challenges for Extension Economists in the 1990s.

I owe thanks to many for this year. The AAEA Business Office staff, particularly Charlene Carsrud and Lona Christoffers, have been of great assistance throughout my presidency, as has our secretary-treasurer, Ray Beneke. My assistant, Debra Thunberg has been essential to the smooth functioning of the association business throughout the year. Both John Miranowski and Richard Perrin have completed their terms as board members, and both deserve special thanks for their excellent service. John has taken many special assignments in addition to the normal board responsibilities; Dick has been chair of the Finance Committee in a year when I have been requesting a major reexamination of the reporting format and board financial policy. He and his Finance Committee, as well as our secretary-treasurer, have contributed many hours to association business. Les Manderscheid will no longer be serving on the board; his term as past-president ends as mine begins. He has been most helpful in my transition from president-elect to president. My appreciation is also expressed to all the AAEA Executive Board members and editors; they have provided excellent counsel. It has been an honor and a privilege to serve as president of AAEA.

Sandra S. Batie, president

Report of the Secretary-Treasurer

The AAEA Business Office has worked with the Finance Committee in an effort to tell the association's financial story a bit more succinctly, and hence more comprehensibly, than in past years. The central theme of the story we have to tell is that the endowment created by astute financial management on the part of our predecessors have enabled the organization to support generously two exciting projects, The AAEA Foundation and *CHOICES*, without subjecting the financial health of the association to unacceptable risks. The association has nurtured the foundation during its start-up years with significant contributions to the latter's operating expenses. As the foundation becomes more robust, this subsidy will become less critical to its survival and progress. During the last

year, the association has paid a larger portion of the cost of publishing *CHOICES* because, as planned, other subsidies have decreased. In view of the fact that *CHOICES* has been so well received, it likely will be an important association activity for years to come. Thus, we can expect AAEA costs of supporting *CHOICES* to increase as other sources of financial support dwindle.

Not only are we fortunate as an organization in having a substantial endowment to help support our activities, but we have the good luck to have our portfolio perform well. Under the leadership of Chet Baker, William Tomek, Leo Polopolus, David Lins, and Ken Krause, the association in 1984 undertook a thorough analysis of alternatives for managing our portfolio and in 1985 placed our investments in the hands of the American National Bank of Chicago. After a lackluster beginning, this organization has performed well for us. You will note that about 50% of our assets of late have been in common stock. I want to point out that during 1989 our income from dividends, interest, and gains from sale of stock totalled $87,300. The good news is that this performance kept us well in the black for 1989. The bad news is that we face substantial deficits in 1990 and 1991. I have generously left explanations of how we propose to cope with these deficits to my good friend, Richard Perrin.

One trend that has been obvious during my six years as secretary-treasurer is the increasing resistance we as an organization face in attempting to coax subsidies from other organizations to support association activities. In past decades we have asked board members and others serving the association to obtain funds for travel expenses from their employing institutions or pay the bills themselves. This approach is more difficult to sell now than twenty years ago. Likewise, it is becoming more difficult to entice universities to hose our annual meetings and, unlike the situation of by-gone days, when they do agree to serve as hosts, universities are unwilling to provide extravagant subsidies in the form of unpaid support personnel and rent-free facilities.

I am pleased to tell you the Business Office has functioned with *esprit de corps* and competence as we have added more and more foundation activities to our mission and have added to the scope of the Employment Service. In addition, in recent years we have taken more responsibility in the business office for planning the annual meetings. The meetings have been a challenge for all of us this year; not everything has gone as we would have liked, but the Vancouver

adventure has provided a first-rate learning experience. Planning annual meetings not hosted by a university and hence not using generous amounts of personnel from the host institution makes heavy demands on the business office staff. We recognize that such meetings are the wave of the future, and we are developing the skills to accommodate them.

I would like to commend Lona Christoffers, our administrative coordinator, on the competent and enthusiastic service she has rendered the association during the past year. She has been unfailingly helpful, kind, and courteous in her professional contacts and has made many friends for the association. Charlene Carsrud has had an especially busy year in coordinating plans for the meeting this year because of the added complexities involved in meeting outside the United States. As some of you know, the association pays Charlene on a quarter-time basis—which, given the work she does, amounts to a highly productive investment for the association. She has developed into an expert on planning meetings. Jaye Stefani, who has major responsibility for the Employment Service, has worked patiently and persistently to serve more members and to make the operation a viable year-round factor in the job market.

Thus, the Business Office staff continues to serve creatively and diligently. As a group our staff members thrive on responsibility and welcome new challenges. If you have suggestions on how we can better serve the association, please share them with any of us.

Raymond R. Beneke, secretary-treasurer

Report of the Tellers Committee

Ballots for the elections of the AAEA Executive Board and the AAEA Foundation Governing Board were sent to and collected from the association members by the AAEA Business Office and secretary-treasurer and counted by the Tellers Committee in accordance with the constitution and bylaws.

The successful candidates were:

President-elect:	Bruce R. Beattie
Directors of the executive board:	Brady J. Deaton Katherine H. Reichelderfer
Members of the Foundation governing board:	Bruce F. Johnston John E. Lee, Jr.

A total of 3,826 packets of election materials were mailed to eligible members, compared to 3,924 in 1989 and 3,809 in 1988. There were 1,773 ballots returned by the 15 June deadline for a response rate of 46.3%. The response rate is down from the approximate 50% level of the previous three years. All ballots returned before the deadline were counted.

Daniel Otto, chairperson

Report of the AAEA Finance Committee

During the period August 1989–July 1990, the membership of the AAEA Finance Committee consisted of Walter Armbruster (Farm Foundation), David Barkley (Clemson University), Raymond Beneke (AAEA secretary/treasurer), Steven Hanson (Michigan State University), David Kohl (Virginia Polytechnic Inst. & State University), Michael Mazzocco (Texas A&M University) and Richard Perrin (N.C. State University).

The financial base of the association remains strong, as reflected by the financial reports. During 1989, total equity of the AAEA (with portfolio at market value) increased by nearly 20%, to a little over $1 million, and the additional 4.5% increase in portfolio value during the first six months of 1990 increased this equity even further.

However, several considerations suggest that this picture of robust financial health is misleading. First, the portfolio gains could easily by reversed with a decline in the market. Second, despite the improved equity position, we experienced a much smaller increase in the value of the general fund (we experienced a loss with portfolio valued at cost), which is a better measure of the unencumbered resources of the association. Third, operating expenses exceeded operating revenue by $72,270 in 1989, after a surplus of $37,136 in 1988. Projections indicate a larger deficit for 1990 and larger yet for 1991.

The reasons for this increasing operating deficit are that prices have risen during the past five years while dues have not, the association has undertaken an increasing share of the cost of publication of *CHOICES* during this period, and the association has been providing increasing services to the membership.

In response to this situation, the AAEA Executive Board has adopted the policy that 3% of the value of association equity is to be used to meet operating expenses, and recommended a 33% increase in dues. The membership approved this increase. While one-time expenditures for moving the *AJAE* offices and for publishing a membership handbook will cause another operating budget deficit in 1991, the financial projections for the next two years are much improved.

Richard K. Perrin, chairperson

Report of the *AJAE* Editor (1989–90)

This report marks the close of the fourth year of operations for the Illinois editorial office of *AJAE*. During the past year we accomplished a smooth transition in journal printing from Heffernan Press to Edwards Brothers in Ann Arbor, Michigan. The results for AAEA members and subscribers have been improved timeliness in publication of the *Journal* and lower publication costs. Contributing to timeliness is the shift in printing of the proceedings of the winter meetings from the May issue to the August issue.

New submissions of manuscripts in the most recent twelve-month period (1 July 1989 to 30 June) totaled 370 manuscripts, equaling the record high of two years ago. These submissions continue to reflect strong support from international authors, economics departments, business schools, agencies, and institutes, as well as the traditionally significant source of new submissions from agricultural economics departments in land grant universities. These submissions are heavily dominated by research-oriented manuscripts, although a respectable number of extension, teaching, and other nonresearch pieces are received as well. Basically, the mix of published articles reflects the mix of submitted material, with the dominance of research-oriented articles following through from submission to publication.

We have continued to emphasize timeliness in the handling of manuscripts, as indicated by the frequency distributions and averages of handling times for the various submission categories of manuscripts and reviewers reported in table 1. During the past year, the response times on the original submission averaged 70 days, with a response on 77% of these occurring within a 90-day period, 93% within 120-day period, and 99% within 150 days. The average response times on second and third submissions were 26 days and 4 days, respectively. Table 1 also indicates a frequency distribution for reviewer response times for each submission category. The average response times of reviewers on the initial submission was 48 days, with an average of 45 days for second submissions.

During 1990, we will publish 92 articles, 8 comments and 6 replies in volume 72 of the *Journal* for a total of 106 refereed items. The publication rate is 29% of the manuscripts submitted during the year. Besides the refereed material, the August 1990 issue will contain 21 invited papers and discussions from the winter meetings and the December issue will contain the invited papers, discussions, addresses, and other related items from the 1990 meetings.

The 1990 volume will also contain sixty-one book reviews under the excellent leadership of Dale Adams, the book review editor. The range of books under review continues to be broad in terms of subject matter, style, and global perspective.

The operating expenses of the Illinois editorial office of *AJAE* totaled $31,514 over the twelve-month period from 1 July 1989, to 30 June 1990. The office has continued to operate in a cost effective manner, and the support provided by the Department of Agricultural Economics at the University of Illinois is appreciated.

Other special activities of the editor during the past year included (*a*) the development of guidelines for data availability and documentation of research procedures that now is published as item 5 on the inside of the back cover of the *Journal*. The text of the guideline is

> Authors are expected to document their data sources, models, and estimation procedures as thoroughly as possible, and to make data used in their analyses available to other researchers for replication purposes. If for legal or proprietary reasons, the data cannot be made available to all potential users, this limitation should be noted. Submission of appendices, model documentation, and other supporting materials with the manuscript is acceptable in order to facilitate the review process.

(*b*) the development of a storage policy for back issues of the *Journal*, and (*c*) revisions in the eligibility requirements for participation in the outstanding *AJAE* article award, that basically allows articles by asso-

ciate editors and previous award winners to be considered each year. The results of each of these activities were approved by the AAEA board.

The board of associate editors has continued to provide timely and high quality evaluations of manuscripts, counsel on matters affecting *Journal* policy, and participation in the selection of the outstanding *Journal* article award. The board's support is invaluable to the operations of the editorial office and to the quality of content of the *Journal*. During the past year, associate editor Bruce Gardner concluded his term of service and we welcome the addition of Julian Alston to the board of associate editors. Besides the 20-member board, we also involved more than 550 individuals in the manuscript review process, some providing several reviews. Their names are listed in an appendix to this report. Other continuing and productive members of the editorial staff include editorial assistants Phyllis Blackford and Donna Cline, technical editor Martha Luzader, and senior associate editors Phil Garcia and John Braden.

Thank you very much.

Peter J. Barry, editor

Report of *CHOICES* Editor

The four 1989 issues of *CHOICES* included material prepared by 136 authors, the same number as in 1988. As in earlier years, several, but not all, authors were members of the association. From the beginning of *CHOICES* in 1986, authors who are not members of the association have been welcome participants in the dialogue in *CHOICES*.

Circulation of the magazine at the end of 1989 was slightly over 14,000. Subscriptions have declined somewhat since then as less effort was focused on the promotion of subscriptions. The association continues to receive substantial financial support for *CHOICES* from USDA agencies and from university deans, many of whom purchase group subscriptions to send to clientele in their respective states.

Arrangements for subscription fulfillment that were initiated in 1989 continue. These activities are carried out by the AAEA Business Office at Ames.

The editor receives manuscripts, works with the advisory council in selecting material for the magazine, and directs the preparation and the mailing of the magazine.

There continues to be a need for more short articles. In addition, during the coming months there will be significant efforts made to attract more authors from other countries.

A Kellogg Foundation project is being conducted jointly by the American Agricultural Economics Association and the American Agricultural Editors' Association. The project activities are closely related to *CHOICES*.

Under the auspices of the project, press releases have been prepared and distributed on eleven articles which appeared in the fourth 1989, and first and second 1990 issues of *CHOICES*. In addition, press conferences were held when each of these issues was released. A backgrounder for agricultural press people focused on "The Evolution of Food, Farm, and Resource Policy" was held in April 1990 in St. Louis.

The Kellogg Foundation-financed project continues until August 1992. The project is experimental in nature. It, of course, is testing if the two organizations can effectively cooperate to the mutual benefit of their memberships. In addition, the association is challenged to appraise if these types of activities are appropriately conducted by the association and how such activities might be financed in the future.

Lyle Schertz, editor

Report of the *Newsletter* Editor

No major problems have been experienced thus far with the transition. Bruce Greenshields has been organized, cooperative, and insightful. Thanks are also expressed to Pam Patterson and Barb Fausch of the AAEA Business Office. Barb expeditiously replaced Pam as newsletter secretary after the second issue of 1990, when Pam accepted employment with the Cooperative Extension Service. Barb overcame some initial trepidation and quickly developed excellent computer skills.

We published and mailed a total of 14,500 copies of the first three issues of 1990, relative to 13,100 for the same 1989 issues. Publications costs have remained between 26¢–31¢ per copy. However, because of an increase in postage plus new clerical expenses, our deficit for 1990 to date is −$3,451 relative to −$1,971 for the same 1989 issues. If recent-year trends continue, the last three issues for 1990 will reduce this year's deficit.

The newsletter format has been changed to right-hand justification and includes "Food for Thought" quotes to minimize white space and add a bit of of intellectual content. A procedural change has been elimination of the responsibility for cross-referencing personnel changes by our production staff, a change made for two reasons: (*a*) to reduce errors, e.g., determining whether a person hired by School A was a "Resignation" or "Recent Graduate" from School B; and (*b*) to reduce the work load on our production staff. Notice of the procedural change was published twice in the newsletter and three times in the bimonthly reminder letter to department heads. The change has helped and apparently been readily accepted. I have received no complaints.

Because of sporadic problems with our current printer, e.g., improper pagination, the possibility of reducing production expenses, and our interest in improving the newsletter's physical attractiveness, we are investigating alternative printers. A draft cover page from another printer is attached.

When space permits, I will institute a new column titled, "Making Connections," aimed at sharing some of the diverse cultural and intellectual resources in our profession. Several authors have agreed to write eclectic essays of approximately 1,000 words on interdisciplinary subjects of their choice, with an economic component. Topics will not compete with papers appropriate for the *AJAE* or *CHOICES*. Lyle Schertz likes and supports this idea. All comments and suggestions are welcome.

Mike Ellerbrock, editor

Report of the AAEA Awards Committee

As outgoing chairperson of the AAEA Awards Committee, I will offer a few reflections about the award's process as I have observed it over the last three years of committee activities. The first, and most important, factor to stress is that the process of selecting awards across the several categories for which the association provides recognition operates very smoothly. A large number of nominations (in some cases including several items of documentation) are submitted each year, and they receive thorough evaluation from members of the profession. The willingness of large numbers of the association's members to devote their time and energy to this task make this process possible. The AAEA members who chair the individual award committees deserve special mention and appreciation for the considerable time, effort, and leadership they devote to the process. The AAEA is fortunate to have members who willingly give their talent to this important task. (The names of the individuals who this year served the association in these roles are listed at the end of this report.)

A second issue to recognize is that the evaluation process for each of the award areas can be difficult. The "Quality of Communication" and the "Distinguished Policy Contribution" categories, however, have an additional challenge arising because of the diversity of materials presented within those categories. Often committee members are faced with the difficult task of comparing different forms of media (for example, books vs. multimedia presentation). Also committee members often have to evaluate the intellectual effort of a group of scholars versus the contribution of a single author. These differences cause difficulty for committee members. A number of times this has led to the suggestion that group and individual awards be given in these categories. Another suggestion is to limit or further define what forms of media are appropriate for submission. Personally, I do not favor the development of further awards or

limits on media forms. Rather, it has served the association well to rely upon the professional judgment of the committee members to make these difficult choices.

A third factor occasionally raised is whether AAEA membership is a requirement for submission of an entry. Careful reading of the Awards Program instructions (Article V of the AAEA Bylaws as listed in the 1987 *AAEA Handbook and Directory*), indicates that membership is not a requirement for any award. The issue of membership is addressed only in two categories, where the wording relates to who may submit nominations, not the status of the nominee. If AAEA membership is a desired requirement for nominees to the award's program, it is my opinion that an amendment to Article V of the ByLaws is needed.

A fourth factor relates to the relatively small number of nominees for awards in some of the categories. In particular, the subcategories within the "Distinguished Extension Program" and the "Distinguished Policy Contribution" award categories have relatively small numbers. Reviewing annual reports of this committee over the last decade, I was surprised to find that publication of the number of the nominees is a relatively recent phenomena. I would urge that the information on number of nominees continue to be published each year so that association members can have better information about the likelihood of success within specific categories. A listing of the number of submissions for each award, the number of awards, and individuals receiving recognition this year is given in table 1 below.

The award-winning titles and the names of the award recipients also follow. Unfortunately, there were two errors in the Awards Ceremony brochure distributed at the annual meetings. With the "Quality of Communication" category, the editors of the USDA report, "Agricultural-Food Policy Review, U.S. Agricultural Policies in a Changing World," were incorrectly identified. In the "Outstanding Masters Thesis" category, Brett M. Gellner's first name was misspelled. I apologize for these errors and the correct citations are noted below.

It has been an honor to serve as general chair of the Awards Program this year. The assistance of President Batie and Lona Christoffers, of the AAEA Business Office, were instrumental to our successfully conducting the awards evaluation process and their assistance is greatly appreciated. In addition I would like to repeat my appreciation for the support of past Presidents Mandershield and Padberg in the two prior years I served in this capacity.

Annual Awards

Distinguished Undergraduate Teaching

Less than ten years' experience. **Dorothy A. Comer,** University of Florida.

More than ten years' experience. **Bernard L. Erven,** Ohio State University.

Distinguished Extension Programs

Individual. **Ross O. Love,** Oklahoma State University, "Intensive Financial Management and Planning Support" (IFMAPS) program.
Group. "Farm Financial Management and Planning" (FINPACK), University of Minnesota, **Richard Hawkins, Dale Nordquist, and Robert Craven.**

Distinguished Policy Contribution

Otto Doering, Purdue University, for his applied public policy research and education on energy use planning and public utility regulation in the state of Indiana.

Publication of Enduring Quality

Alan Randall, Berry C. Ives, and Clyde Eastman. "Bidding Games for Valuation of Aesthetic Environmental Improvement." *J. Environ. Econ. and Manage.*, 1974. Randall was at the University of Kentucky and Ives and Eastman were at New Mexico State University at time of article's publication.

Outstanding Journal Article

Thomas W. Hertel. "Negotiating Reductions in Agricultural Support: Implications of Technology and Factor Mobility." *Amer. J. Agr. Econ.* 71(1989):559–73.

Quality of Communication

Kenneth L. Robinson, Cornell University. *Farm and Food Policies and Their Consequences*. Englewood Cliffs NJ: Prentice-Hall, 1989.
Ivan Roberts, Graham Love, Heather Field, Nico Klijn. *U.S. Grain Policies and the World Market.* Canberra: Australian Bureau of Agricultural and Resource Economics, July 1989.
Honorable Mention. **Suchada V. Langley and Kathryn Lipton.** *Agricultural-Food Policy Review, U.S. Agricultural Policies in a Changing World.* Washington DC: U.S. Department of Agriculture, Econ. Res. Serv. Agr. Econ. Rep. No. 620, Nov. 1989.
Carol S. Kramer, ed. *The Political Economy of U.S. Agriculture, Challenges for the 1990s.* Washington DC: National Center for Food and Agricultural Policy, Resources for the Future, 1989.

Quality of Research Discovery

Robert G. Chambers, and Richard E. Just, University of Maryland. "Estimating Multioutput Technologies." *Amer. J. Agr. Econ.* 71(1989):980–95.
Jeffrey T. Lafrance, and W. Michael Hanemann, Montana State University and University of California-Berkeley, respectively. "The Dual Structure of Incomplete Demand Systems." *Amer. J. Agr. Econ.* 71(1989):262–74.

Outstanding Ph.D. Theses

Marcel Fafchamps. "Sequential Decisions Under Uncertainty and Market Failure: A Model of Household Behavior in the African Semi-arid Tropics." University of California, Berkeley (Alain De Janvry, advisor).
Richard Bergen Standiford, IV. "A Bioeconomic Model of California's Hardwood Rangelands." University of California, Davis (Richard Howitt, advisor).
Everett Bryon Peterson. "The Farm-Retail Price Spread Revisited: A General Equilibrium Perspective." Purdue University (Thomas W. Hertel, advisor).
Honorable Mention. **Satheesh V. Aradhyula.** "Policy Structure, Output Supply and Input Demand." Iowa State University (Stanley Johnson, advisor).
David Simon Kraybill. "A Computable General Equilibrium Analysis of Regional Impacts of Macroshocks in the 1980s." Virginia Polytechnic Institute and State University (Tom Johnson, advisor).
Thomas Iver Wahl. "Modeling Dynamic Adjustment in Japanese Markets Under Trade Liberalization." Iowa State University (Gary W. Williams and Dermot Hayes, advisors).
Alfons Weersink. "The Distributional Impacts of Technical Change on the U.S. Dairy Sector." Cornell University (Lauren Tauer, advisor).

Outstanding Master's Theses

Brett Miles Gellner. "An Analysis of the Demand for New Wood Panels and other Forest Products in the Canadian and United States Construction Industries." University of Alberta (Luis Constantino, advisor).
Brian Kent Engel. "Relationships Between Distributions of Price Expectations Implied by Futures and Options Markets with Distributions Elicited from Farmers and Merchandisers." University of Illinois (Robert Hauser and Sally Thompson, advisors).
Kyle Stiegert. "Price Spreads and Market Structure in the Beef Packing Industry." University of Nebraska (Azzaddine M. Azzam, advisor).
Honorable Mentions. **Hector Rodolfo Malarin.** "An Analysis of Irrigation Equipment Investment for Georgia Coastal Plain Farms." University of Georgia (Donald Reid, advisor).
James Roger Clemmons. "Economic Models of the Demand for Species Variety in Sport Hunting." University of Florida (Walter Milon, advisor).
Swati Bhargava. "A Stochastic Dominance Analysis of Broiler Growout Housing Investments." University of Delaware (Conrado M. Gempesaw, II, advisor).

Steven T. Sonka, chairperson

Report of the AAEA Foundation, 1989–90

The AAEA Foundation has completed five years of operation. Activities continued at an accelerated rate during the past year in both program and finance categories.

Program Activities

The Foundation has adopted the following priority areas of activities—*CHOICES*, Minority Professionals, Student Development, and International Travel.

AAEA fellows committee. Three years ago the AAEA Foundation took the lead in contacting AAEA Fellows for the purpose of evaluating their relationship to the association. This resulted in the establishment of a roster of fellows willing to give seminars and lectures to 1890 and similar institutions. The Foundation hosted a Fellows Breakfast at the 1989 annual meeting. Fellows were invited to express their thoughts with respect to the association and their relationship to the association. As a result of comments made at the breakfast, the Foundation president suggested to Association President Batie that a committee of fellows be appointed by the association, which has been done.

Minority travel grants. The foundation is pleased to report that seven $500 grants were made to support attendance at the Vancouver meeting.

Student travel grants. The foundation also provided fifteen student travel grants for the Vancouver meeting. The AAEA student advisor assisted in the selection of those who received grants.

Library materials and University of La Molina, Peru. The foundation provided support for sending library materials, including issues of the *AJAE*, to this University.

Appreciation clubs. The Fred Waugh Appreciation Club was recognized at a special ceremony at the USDA in the fall of 1989, when a USDA auditorium was named in his honor.

The W.E. Grimes Appreciation Club was chartered at the fall 1989 meeting of the Foundation Board. Its charter was presented at the University of British Columbia. Donations and pledges now stand at approximately $16,000.

Financial Report

Financial status. Assets of the foundation were approximately $120,000 30 June 1990. This represents a 26% increase from a year earlier. Much of this increase can be attributed to the appreciation clubs, but some has been the result of an increase in the value of the foundation investment portfolio. The foundation has a considered investment policy with a 6% spending rule.

Even though the assets of the foundation have increased significantly, they are still considerably short of our goal. An endowment in excess of $1 million is needed to fund the priority projects that have been established by the foundation.

Corporate fund raising. With leadership from Larry Boger and Gene Swackhamer, a corporate fund raising program was launched during this past year. Corporations being contacted are mainly those that have AAEA members as employees. Each member of the foundation board has an assignment to contact certain corporations on this list. Results to date have been modest, but those with experience with this type of fund raising know that patience and persistence are required.

Asset management. Two years ago the foundation adopted guidelines for the investment of foundation assets as well as a 6% spending rule. This has permitted the foundation to hold some of its assets in a form to permit greater growth and earnings. The future of the foundation is now more certain than it was at that time. As a consequence, the guidelines adopted two years ago are being reviewed in light of the current outlook for the foundation.

The foundation notes, with great appreciation, the annual support provided by the association to the foundation. Even though we have made progress in improving our capital funding, we very much hope the annual allocation can be continued. This allocation permits the foundation to tell prospective donors that most of any contribution they may make will support the foundation programs rather than be used for administrative expenses.

Members of the foundation board for 1989–90 by class: elected by AAEA membership, Lawrence Boger, John R. Brake, Emery N. Castle, Kenneth R. Farrell, Jean D. Kinsey, W. Burt Sundquist; representative from AAEA Executive Board, Walter Armbruster, Lester Manderscheid, Richard K. Perrin; appointed by board, Gene L. Swackhamer, Gary L. Seevers; ex officio, Raymond R. Beneke. Officers for 1989–90 were Emery N. Castle, president; Lawrence Boger, vice-president for finance; Jean D. Kinsey, vice-president for program.

Board members who have completed their elected or appointed terms are Emery N. Castle, Jean D. Kinsey, Lester Manderscheid, and Richard K. Perrin. Newly elected members for a three-year term are Bruce Johnston and John Lee. Officers nominated for 1990–91: Kenneth Farrell, president; Lawrence Boger, vice president for finance; Burt Sundquist, vice president for programs.

Emery N. Castle, president
AAEA Foundation Governing Board

Committee on Women in Agricultural Economics

The Board of the Committee on Women in Agricultural Economics [Joyce Allen (1988–90), Deborah Brown (vice-chair), Gene Futrell (AAEA Board Representative), Sermin Hardesty (1989–91), Joy Harwood (1989–91), Helen Jensen (past chair), Vickie McCracken (1988–90), and Eileen van Ravenswaay (chairperson)] met twice via teleconference. The CWAE chairperson appointed 12 subcommittees and 2 liaisons to carry out CWAE activities. These were published in the fall issue of the *CWAE Newsletter*.

At the request of the AAEA Board, the *CWAE Newsletter* became self-supporting this year by charging a $5.00 annual subscription fee for three issues published in the spring, summer, and fall. The fall 1989 newsletter, containing a subscription notice, was mailed free to all AAEA members. The 1990 spring issue was mailed to approximately 170 subscribers, with complimentary copies distributed free of charge to women graduate students. The summer issue will be mailed out following the 1990 annual meetings. Joy Harwood was editor and produced all three issues (Deborah Brown and Coletta Moser were subcommittee members).

Because it is costly to advertise, the CWAE Board has requested the AAEA Board to allow the *CWAE Newsletter* subscription charges to be included on the AAEA annual billing form. The AAEA Membership Committee has supported this request and forwarded it to the AAEA Board for action. The CWAE Board has also requested that the *CWAE Newsletter* be included on the omnibus subscription form sent to reference rooms and libraries.

The Graduate Student subcommittee (Hui-Shung Chang, chair; Mary Marchant and Lydia Zepeda, members) surveyed department chairs to identify a person in each department to receive and distribute complimentary copies of the *CWAE Newsletter*. These contact persons were asked to distribute the news-

letter to women graduate students and to display the newsletter in the department library, reference room, or bulletin board.

The survey was also used to collect information on women faculty and graduate students. It was found that, on average, agricultural economics departments have 1.7 women faculty members; 30% of their masters students and 21% of their Ph.D. students are women.

In order to get a larger and more diverse set of job announcements in the *CWAE Newletter*, letters were sent to potential employers by the employment subcommittee (Linda Calvin, chair; Kristin Allen, Cheryl Danley, Jill Findeis, Emily McClain, and Sermin Hardesty, members) telling them about the *CWAE Newsletter* and encouraging them to advertise there.

Notices were put in the AAEA and CWAE newsletters about the availability to potential employers of a direct mailing list of women AAEA members. This list, which includes information about AAEA members' areas of specialization, was maintained by our membership subcommittee (Helen Jensen, chair); Carole Nuckton, member) in cooperation with the AAEA Business Office (Lona Christoffers). The list currently consists of 361 women who comprise 8.8% of the members of AAEA. This number is down from 418 women a year ago.

The Elections subcommittee (Edna Loehman, chair; Catharine Halbrendt, Jean Kinsey, and Vickie McCracken, members) solicited nominations for the 1990–91 CWAE vice-chair and two board members to serve two-year terms during 1990–92. They developed a ballot with two nominations for vice-chair and four nominations for board members. The ballot was mailed by Lona Christoffers to all women AAEA members and all subscribers of the *CWAE Newsletter*, and 127 ballots were returned. The election for vice-chair was won by Joy Harwood, and the new board members are Julie Caswell and Bonnie Colby. Continuing CWAE board members are Deborah Brown (chairperson), Eileen van Ravenswaay (past chair), Sermin Hardesty (1989–91), and Joy Harwood (1989–91). There will be one less member of the CWAE Board during the 1990–91 year because Joy Harwood is both a continuing board member and the vice-chair.

The Planning subcommittee (Joyce Allen, chair; Margaret Andrews and Tanya Roberts, members) summarized results from a questionnaire distributed at last year's CWAE luncheon. This summary was used for planning this year's activities. The subcommittee published a questionnaire on career development in the fall 1989 *CWAE Newsletter*. Only twenty-five responses were received. Margaret Andrews summarized results in the spring 1990 *CWAE Newletter*.

The Professional Activities subcommittee (Stephanie Mercier, chair; Kate Buckley, Christina Gladwin, Rebecca Lent, and Ann Vandeman, members) organized two career workshops for the 1990 AAEA meetings. The workshop on career and family featured a panel of speakers from government, academia, and the private sector. The workshop on sexual harassment featured Jan Salisbury. The Farm Foundation provided $1,000 for the speaker and the Resources and Technology Division of ERS USDA provided $450 for videotaping.

The Research subcommittee (Catherine Lemieux, chair; Sandra Archibald and Patricia Duffy, members) organized a symposium for the 1990 AAEA meetings entitled "Pitfalls and Rewards of Theoretical and Applied Research: Implications for Young Professionals." Three panelists presented a variety of viewpoints. An abstract will be prepared for the December *AJAE*.

The Arrangements subcommittee (Eileen van Ravenswaay) hosted a reception and informal discussion with Donald McCloskey on "The Feminization of Economics" at the 1990 AAEA annual meetings. The subcommittee also arranged the CWAE annual luncheon, combined this year with the annual business meeting.

The Archives subcommittee (Ardell Lundeen, chair, and Sylvia Lane) maintained copies of the *CWAE Newsletter* and reports of the CWAE Board and subcommittees.

The Finance subcommittee (Valerie Vantreese) reported that there may be little need for this subcommittee. Lona Christoffers of the AAEA Business Office maintains the financial records for CWAE, and these could be reported on a regular basis to the CWAE chairperson. As of July, Lona Christoffers reported that CWAE has $2,379.46 in its accounts after covering expenses for the AAEA meetings and the *Newsletter*. This amount reflects the fact that subscription fees appear to adequately cover *CWAE Newsletter* expenses, and the Farm Foundation and the Resources and Technology Division covered the major costs for the workshops at the AAEA meetings. Consequently, the $2,000 made available by ERS through a previous cooperative agreement remain available for projects during the 1990–91 year.

Last July, Maureen Kilkenny submitted a proposal to the CWAE board suggesting the development of a scholarship fund. The board met via teleconference in September and decided to establish a subcommittee to further develop the proposal. In May, the Scholarship subcommittee (Maureen Kilkenny, chair; June Grabemeyer, Sermin Hardesty, Helen Jensen, Vicki McCracken, Tanya Roberts, Jean Sussman, and Eileen van Ravenswaay, members) submitted a draft proposal for the CWAE Board to study. The board teleconferenced in June and decided that the proposal should be submitted to CWAE members at the annual CWAE business meeting. The board also decided that if CWAE members decided to establish a CWAE scholarship, this should be done through the AAEA Foundation Board with a minimum endowment target of $33,333. The subcommittee drafted a summary proposal and a questionnaire for distribution at the annual CWAE business meeting.

Eileen van Ravenswaay, chairperson

Minutes

Minutes of the AAEA Executive Board Meeting, Orlando, Florida, 15–16 December 1989

Present: Voting Members:
Armbruster, Batie, Eidman, Futrell, Gardner, Libby, Manderscheid, Miranowski, and Perrin

Members ex officio:
Barry, Beneke

Guests:
Bollman, Carsrud, Christoffers, Howe, Johnston, Martin, Shumway, and Schertz

The meeting of the Executive Board of the American Agricultural Economics Association convened at 8:00 A.M., Friday, 15 December 1989, in the Margate Room of the Stouffers Resort Hotel in Orlando, Florida. Lester Manderscheid gave a report of the nominating committee's activities and welcomed the nominees for president-elect, Warren Johnston and William Martin, as guests for the meeting.

1. President Sandra Batie opened the meeting with introductions. MOTION: It was moved by Lester Manderscheid to accept the July 1989 Baton Rouge minutes as printed. Vernon Eidman seconded. Motion carried.

2. Batie asked for suggestions on the agenda, added several herself, and recorded additional items suggested by the board.

3. Peter Barry affirmed the association has a long-term contract with University Microfilms in Ann Arbor, Michigan, for putting the *AJAE* on microfilm and microfisch. Royalties are paid to the association on a yearly basis for sales/rentals of this material.

4. It was announced that Mike Ellerbrock from East Texas State University was appointed the new *AAEA Newsletter* editor. Mike has adjusted the deadline for submission of newsletter items to the 15th of the month preceding publication, rather than the 20th of the month.

5. Progress is being made toward the finalization of volume 4 of the Post Literature Review. Lee Martin has stated that publication should appear in the spring of 1990.

6. Support for CAST by the AAEA was discussed briefly but no action was taken by the board.

7. The special election to select a president-elect was discussed. The importance of timeliness for this project was emphasized, and a decision was made that ballots must reach the secretary-treasurer by 1 February 1990 in order to be counted.

8. Walter Armbruster announced the intention of the AAEA Foundation Governing Board to fund up to $2,000 for support of travel of minority professionals and up to $2,000 for travel for undergraduate students. Both grants are intended to support travel to the upcoming summer meeting in Vancouver.

9. Batie reported that Clifton Wharton, Jr., had agreed to give the fellows address at the Vancouver meeting.

10. John Miranowski reported that an agreement has been reached with the National Agricultural Library in Washington, DC, to house the archives of the association. After the agreement is signed, Miranowski will work with Wayne Rasmussen to develop appropriate procedures for transferring items to Washington, and for any cataloging/indexing of proposed materials. A notice will be placed in the association newsletter to inform the membership of these plans and to suggest that any member in possession of potential archive materials contact the AAEA Business Office.

11. World Food Day was discussed but no action was taken.

12. Batie reminded the board that the ASSA meeting will be held in Atlanta, Georgia, 27–30 December 1989. Because no board meeting will be held at this meeting, there will be no association compensation for board members who elect to attend. She reminded the board that the AAEA reception is to be held Wednesday evening, 27 December at 5:30 P.M. She also distributed to the board the programs for the AAEA portion of the meeting.

13. Updates from various AAEA committees were provided as follows:

Awards. Deb Thunberg, Batie's assistant, will be the official photographer for the Vancouver meeting.

Adaptive Planning. Reported elsewhere in these minutes.

Ad-Hoc Committee on Economic Education. Identified reasons for an AAEA/JCEE (Joint Council on Economic Education) affiliation, affirmed that a liaison exists between AAEA and NAEE (National Association of Economic Education) and submitted an invited paper session proposal on why and how AAEA should be involved with youth economic education.

Economic Statistics Committee. Prepared draft resolutions concerning: (*a*) standard rural statistical areas and (*b*) environmental monitoring; conducted follow-up activities to data conference.

Employment. Reported the undergraduate brochure is in final stages of revision.

Extension. Identified possible activities for inclusion in the 1990 program.

Fellows Activities. Is considering an organized symposium at the 1990 meeting.

Finance. Reported elsewhere in these minutes.

Information Retrieval. Called attention to the AERO Conference to be held in March 1990.

International. Reported on plans for the Vancouver meeting.

Professional Activities Committee. Provided suggestions for improving the annual meeting.

Professional Relations between the People's Republic of China and the United States. Reported that several subcommittees are at work on proposals for the Vancouver meeting as well as a liaison with the professional association in agricultural economics and related areas in the PRC.

Ad-Hoc Committee on the Professional Relations Between the USSR and the United States. Approved the proposal for Joint Soviet/American Committee on Agricultural Economics and the organization of sessions for the Vancouver meeting.

Resident Instruction. Proposed both an invited paper and "invited symposium" for the Vancouver meeting.

Selected Papers. Reported on selected topic leaders; announced deadline for papers as 22 February.

Selected Posters. Announced deadline for posters as 8 March.

Student Section. Reported that a representative from the University of Guelph has been added to facilitate interaction with Canadian schools for the Vancouver meeting.

14. Charlene Carsrud reported on possible rotation sites for future annual meetings. After discussion concerning places where the association has already met, the board decided that two locations which would be likely candidates to include in the rotation in the West are San Diego, California, and Reno, Nevada. The board agreed to tentatively designate the following sites in the Midwest for further study: Minneapolis, Minnesota; Kansas City, Missouri; and Columbus, Ohio. Because the association is meeting in Baltimore in 1992 and the board has now seen Orlando, the decision was made to look at Atlanta, Georgia, as a third eastern location. Canadian cities nominated for inclusion in the rotation were Vancouver, Quebec City, and Toronto. Carsrud was asked to bring information about the suggested sites to the August board meeting.

15. Carsrud reported that, after three years of negotiations with the Soil and Water Conservation Society and convention and hotel people in Baltimore, we now have the information we need to sign contracts to secure the space needed for the Baltimore 1992 meeting. There was concern that the cost of meeting in Baltimore would be high, but a group of hotels will be selected that would provide participants a reasonable assortment of hotel rates ranging from low to high. The board decided Carsrud should make the necessary arrangements to meet in Baltimore in 1992. It was suggested that the Northeastern Association also be contacted about a joint meeting in Baltimore.

16. President Batie noted that the board needed to discuss the length of the annual meeting at Vancouver. MOTION: Walter Armbruster moved to add an additional day to the 1990 annual meeting. Miranowski seconded. Motion carried. It was decided to have registration and the joint reception on Saturday, 4 August. Carsrud is to contact the Industry and International Committees to check the feasibility of holding the two banquets on different days. The opening session will start after lunch on Sunday. The president will coordinate AAEA activities with those of the other associations meeting at the same time. Conflicts on scheduling will be resolved by the president with the assistance of the business office.

17. Carsrud reported having had a conversation with Marc Johnson from Kansas State University about the 1991 meeting to be held in Manhattan, Kansas. In early September she mailed him copies of several reference materials that he might use in planning the annual meeting. Contact will be made with Johnson after January. A preliminary planning meeting will be scheduled as soon as a new president-elect has been elected.

18. President Batie asked for a report on the Baton Rouge meeting. Carsrud pointed out that a complete accounting of expenses accrued at the meeting has not yet been received from Louisiana State University but is expected shortly. Batie requested that a copy of the final analysis of the budget be faxed to her as soon as it is complete and expressed a desire to have board members informed concerning the financial outcome of the 1989 meeting.

19. The board decided to use the *AAEA Newsletter* for an item explaining to members why the annual meeting registration fee is $70.00. MOTION: Richard Perrin moved that the annual meeting registration fee for those with a senior membership be reduced to one-half of the regular fee. Gene Futrell seconded. Motion carried.

The board adjourned for supper at 7:30 P.M. to reconvene at 8:30 P.M. for the purpose of Fellows selection.

20. Miranowski led the board through the Fellows selection process and reviewed the guidance provided in the constitution and by-laws on criteria for selection and the procedures followed in past years. After several rounds of sequential balloting, nine names emerged to be forwarded to the Fellows Selection Committee.

The Board adjourned at 10:45 P.M.

The Board reconvened at 8:00 A.M., 16 December 1989, with additional business items.

21. Futrell presented a proposal from the Extension Committee for a one-day pre-conference "Challenges For Extension Education in the 1990s." MOTION: Manderscheid moved to approve the preconference. Armbruster seconded. Motion carried.

The Extension Committee recommended the continuation of the commodity outlook session as a regular part of the annual meeting. MOTION: Armbruster moved to approve the recommendation. Futrell seconded. Motion carried.

The Extension Committee recommended the addition of a policy session which would complement

the outlook session at the Vancouver meeting. This proposal was not approved; however, it may be resubmitted as an organized symposium.

22. Two proposals for learning workshops presented by the Professional Activities Committee were discussed. Lawrence Libby will contact Paul Barkley of the PAC to develop one of the proposals and to coordinate the details with President Batie. The workshop would be blended in the regular program. MOTION: Manderscheid moved that a learning workshop be approved. Eidman seconded. Motion carried.

23. Ray Bollman, president of the Canadian Agricultural Economics and Farm Management Society, presented a proposal for a joint AAEA/CAEFMS preconference on "Agriculture and Rural Restructuring." This program parallels a proposed symposium planned by the community network group. MOTION: Armbruster moved to accept the Canadian proposal and for Bollman to coordinate with the community network group to reach an agreement. Manderscheid seconded. Motion carried.

24. Two program proposals from the Committee On Women in Agricultural Economics were discussed. These proposals, based on the topics of "Career and Family" and "Sexual Harassment" will be blended into the regular program format at the Vancouver meeting. MOTION: John Miranowski moved to approve these workshops. Libby seconded. Motion carried.

25. A proposal from the Resident Instruction Committee on "Critical Issues in Graduate Agricultural Economics Education" was discussed. This proposal uses an "invited symposium" format in order to provide a forum for discussion from the floor. The presentations will not be automatically published in the *AJAE*, but presenters are invited to submit their papers through normal procedures. MOTION: Futrell moved to approve this proposal as a committee sponsored symposium. Eidman seconded. Motion carried. Futrell is to inquire as to the feasibility of video taping this program.

26. Richard Shumway, president of the Western Agricultural Economics Association, presented the paper sessions being planned by his group. These sessions are primarily method oriented. WAEA will strive to avoid times that conflict with other sessions. Shumway also proposed having a joint awards program.

27. Richard Perrin, chair of the Finance committee, reported that the revision of the financial statements for the association and the foundation are being designed to give more complete and concise information about our financial status. These forms will be ready by the August meeting.

Perrin reported that the AAEA Foundation had responded negatively to the proposal that financial and supervisory oversight for *CHOICES* activities be delegated to them. Oversight for activities will remain as they are now, with the three presidents.

28. Proposed changes to the bylaws reported by Manderscheid, regarding the president-elect and the newsletter editor, were tabled until the August meeting.

29. Bruce Gardner led a discussion of invited paper proposals for the Vancouver meeting. The topics agreed upon and the persons who could function in each case as an organizer are as follows:

Resource Economics
(1) Douglas Southgate (AERE)—Resource Degradation in Third World (C. Howe)
(2) Canadian No. 8—Sustainable Development (Bollman)
(3) Charles Howe (AERE)—Agriculture-to-Urban Water Transfer (Bollman)

Rural Development
(4) Ralph Christy—Rural Development and Disadvantaged Groups (Libby)

Demand and Marketing
(5) Richard Shumway (WAEA)—Demand Analysis Issues (Shumway)
(6) Wayne Purcell—Livestock Concentration (Armbruster)

Cost, Technology and Investment
(7) Mary Ahearn—International Cost Comparisons (Miranowski/Bollman)

International Development
(8) Gershon Feder—Agricultural Credit (Perrin)
(9) Truman Phillips—Food Insecurity (Manderscheid)
(10) Vincent Cusumano (International Committee)—Aid and Structural Adjustment in Third World and Eastern Europe (Armbruster)

International Trade
(11) P. Lindsey—United States/Canada Free Trade Agreement (Bollman)
(12) Canadian No. 3—Pacific Rim (Bollman/Futrell)

Agriculture Policy
(13) Canadian No. 2—Stabilization Policy (Bollman)
(14) Canadian No. 9—Political Economy of Canada (Bollman)

Economic Education
(15) Kim Reda-Wilson—Youth Economics Education (Batie)
(16) Richard Shumway (WAEA)—Applied Welfare (Shumway)

Batie set a deadline of 31 January for submission of definite plans for each session.

30. Lyle Schertz, editor of *CHOICES* Magazine, gave a review of *CHOICES* activities for 1989, as well as an overview of the Kellogg Project. One press conference has been held in connection with the fourth quarter 1989 issue of *CHOICES*. More then twenty press people were present. Future plans for *CHOICES* include: (*a*) a press conference tentatively planned to focus on each of the 1990 issues, (*b*) identification of a person to take on the subscription promotion responsibilities, and possibly the advertising responsibility, (*c*) Schertz also called the board's attention to the memorandum of understanding between the as-

sociation and Lyle Schertz, which provides for adjustment in compensation for Schertz consistent with the percentage change in salary schedule for GM-15 employees of the U.S. government. Under this arrangement Schertz indicated his 1990 salary would be $44,030.00. He also recommended that the board approve the expenditure of approximately $8,000 for the purchase of a McIntosh computer and printer which would facilitate magazine preparation. MOTION: Miranowski moved the association authorize the purchase of an Apple McIntosh computer for *CHOICES*. Libby seconded. Motion carried.

Schertz discussed with the board the need for an associate editor to insure the long-term survival of *CHOICES*, help with the technical part of the preparation activities and to take over subscription promotion activities. This person is not to be an editor but would be a part-time employee with Schertz as overseer. MOTION: Miranowski moved to ask Schertz, with the help of the President's Council, to prepare a position description for an associate editor with a $40,000 limit on expenditures. Armbruster seconded. Motion carried.

31. Otto Doering, chair of the Adaptive Planning Committee reported on that committee's progress. Such questions as "Where is agricultural economics headed? How is the association viewed by the members? What is and should be the central core of the association's functions?" have been addressed. Areas for potential growth opportunities of the association were explored. These included the unbundling of publications and altering the structure of the association to encourage more participation by "federated" groups. MOTION: Manderscheid moved the board approve the distribution of a preliminary report by the Doering committee before the Vancouver meeting and the scheduling of a symposium at Vancouver with a revised report distributed as soon as possible after the close of the summer meeting. Perrin seconded. Motion carried.

32. Peter Barry reported that Julian Alston had replaced Bruce Gardner on the Board of Associate Editors for the *AJAE*. Barry discussed the storage policy being used for back issues of the *Journal* by Edwards Brothers. The recommendation to include the proceedings of the winter meeting in the August issue rather than the May issue was approved. Miranowski led a discussion regarding a notation on the release of restrictive data if cited in articles in the *Journal*.

33. Raymond Beneke presented a partial list of awards available to agricultural economists or economists but concluded that, historically, appropriate candidates had been nominated by other organizations.

34. Futrell reported on the AAEA affiliation with the Consortium of Social Science Associations (COSSA), and recommended that AAEA make a strong effort to utilize that affiliation in support of broad research thrusts of particular importance to agricultural economists. MOTION: Armbruster moved that we continue our COSSA affiliation at a cost of $2,000 for 1990 and a liaison be appointed from an AAEA Committee. Futrell seconded. Motion carried.

MOTION: Armbruster moved that the president establish an AAEA committee to develop a strategy and plan to enhance the involvement of the AAEA in initiatives related to the rural social sciences. Libby seconded. Motion carried.

35. A letter from the chair of the Council of Professional Associations on Federal Statistics (COPAFS) was circulated. After discussion, Batie indicated she would confer with Leroy Hushak (AAEA's representative to COPAFS) regarding the benefits of the association affiliation with COPAFS. MOTION: Manderscheid moved to approve the COPAFS request for a $6,930 contribution for 1990. Miranowski seconded. Motion carried.

36. Batie reported on a request by the Economics Statistics Committee to use surplus preconference funds. The business office reported that not all preconference bills have been paid, and the financial outcome of the venture is not now known. It was agreed that surplus funds do not revert to the sponsoring committee. Several members suggested to President Batie that she invite the committee to make additional requests of the board if they had special, high priority needs for funds.

37. The following by-law changes were proposed: Article V, introductory paragraph and Section 5, second paragraph should read as follows:

Introduction to Article V: Insert the following as a complete second paragraph preceding Section 1.

> Each award program is administered by a subcommittee. The chairperson of each subcommittee is expected to organize the evaluation process to ensure that subcommittee members do not directly evaluate entries in which the members are potential award recipients or, for the theses awards, in which members have served as major advisor of a potential award winner. Subcommittee chairpersons are ineligible for an award from the program category they are administering.

Section 5, Second Paragraph:

> If an article is selected to receive both the Outstanding Journal Article award and the Quality of Research Discovery or Quality of Communication award, the matter shall be resolved by the chair of the Awards Committee in consultation with the recipient or recipients involved in such a way that only one award is received.

MOTION: Manderscheid moved we approve these changes. Perrin seconded. Motion carried.

38. The following by-law change was proposed: Article V, Section 5, Item C:

> The editor and associate editors of the *American Journal of Agricultural Economics*, with the editor as chair, shall choose an outstanding article in the volume published preceding the year of recognition.

> *All articles are automatically eligible for consideration except (i) those nominated for other AAEA published research awards with the approval of the author(s); (ii) the President's address; and (iii) the Fellow's lecture.*

MOTION: Perrin moved we approve this change. Armbruster seconded. Motion carried.

39. There was discussion about a proposal that a Joint Soviet/American Committee on Agricultural Economics be formed to facilitate interaction with Soviet colleagues. MOTION: Manderscheid moved to approve the Joint Soviet/American Committee proposals contingent on development of financial arrangements satisfactory to the board. Miranowski seconded. Motion carried.

40. The following resolution from the AAEA Economic Statistics Committee was presented:

WHEREAS there is a large and increasing demand for small area data as revealed by the Survey on Priorities for Data on Agriculture and Rural Areas and other sources, and

WHEREAS this increasing demand for data is brought about by the growing concern about a wide array of issues concerning rural viability, and

WHEREAS many data items available for urban counties cannot be published for rural counties because of disclosure rules, and

WHEREAS there exists a set of defined urban areas called Metropolitan Statistical Areas (MSAs), and

WHEREAS the MSA concept is transferable to rural counties.

BE IT RESOLVED THAT appropriate federal statistical agencies be given the responsibility and the financial resources to define Rural Statistical Areas (RSAs), which are groups of counties similar in concept to MSAs, covering rural counties of the United States. Each RSA should encompass in so far as possible an economic trading area, be small enough to be of use in local analysis and planning, and yet be of sufficient size that data can be compiled for the RSA without disclosure violations. MOTION: Manderscheid moved we approve this resolution. Eidman seconded. Motion carried.

41. The following resolution from the AAEA Economic Statistics Committee was presented:

WHEREAS there is a large and growing concern about the lack of systematic monitoring of key aspects of the natural environment as revealed by the Survey on Priorities for Data on Agriculture and Rural Areas and other sources, and

WHEREAS this is a result of increasing public awareness of the importance of environmental quality and natural resources as evidenced by regulations of ground and surface water quality from a variety of point and nonpoint sources of pollution.

BE IT RESOLVED THAT appropriate federal statistical agencies be given the responsibility and the financial resources to establish an ongoing and coordinated system of key indicators of environmental quality and the natural resource base. MOTION: Manderscheid moved we approve this resolution. Eidman seconded. Motion carried.

42. A discussion ensued regarding the format used for organized symposia, with possible redesign to be initiated at the Vancouver meeting. The Professional Activities Committee recommends that the board work closely with the selection committee to establish guidelines to enhance the quality of the organized symposia at the Vancouver meeting. PAC will evaluate the symposium program as part of an overall evaluation of the summer meeting.

43. A proposal from the Student Section–AAEA requesting additional funding support for student activities was discussed. MOTION: Manderscheid moved that the association support the SS–AAEA with a $1,500 allocation to be used as they see fit. Libby seconded. Motion carried.

44. A joint proposal from Kimberly Reda-Wilson and Lyle Schertz to fund travel of the two of them to the New York offices of the Joint Council on Economic Education to learn about JCEE activities was discussed. MOTION: Armbruster moved to instruct Schertz to use the *CHOICES* budget to fund this travel. Miranowski seconded. Motion carried.

45. Batie read a proposal from the Committee on Youth Education on Agricultural Economics. This proposal will be referred to the AAEA Foundation for possible action.

46. Futrell presented a request by the Extension Committee to conduct a direct mailing of materials to extension members encouraging participation in extension activities at Vancouver. The board approved this request and suggested the total cost not exceed $500.00.

47. A discussion of overhead on grants/contracts resulted in the recommendation that all interest accrued on accounts being held by the association be credited to the association treasury and not earmarked for individual projects.

Perrin presented to the board the following declaration of policy related to the general fund:

> All gains and losses from financial assets (interest, dividends, and capital gains from all cash and portfolio assets except those of the AAEA Foundation) will accrue to the General Fund. Accounts for special projects and organizing committees will neither accrue interest nor otherwise share in gains and losses from the association's financial assets.

MOTION: Perrin moved we adopt this policy. Miranowski seconded. Motion carried.

48. Futrell commented on the Extension Predictor's Award offered by Merrill Lynch. He suggested that the AAEA Committee should be involved in determining the criteria for selection.

49. Beneke proposed a plan to edit and reproduce the video tapes prepared for the 75th anniversary of the association into a usable and marketable item. The board suggested that this plan needed additional study and should be brought before the board in a more mature stage of development.

50. Beneke presented a packet of materials from Goodwill People-To-People Travel Program discussing the possibility of the AAEA offering its members a foreign study/travel program. Several questions concerning the association's liability and related difficulties arose and the issue died for lack of support.

51. A report from the Employment Service regarding their work on revising the recruiting brochure was discussed. MOTION: Eidman moved we support this activity up to $2,600. Manderscheid seconded. Motion carried.

52. The following change to Article IV, Section 3. of the By-laws was proposed:

> Any member of the association may nominate any living member for the honor of election as Fellow by submitting the name to the secretary-treasurer of the association not later than *1 November* or an earlier date if so announced in the *American Journal of Agricultural Economics* or any other communication to the membership.

MOTION: Manderscheid moved we accept this proposal. Miranowski seconded. Motion carried.

The meeting adjourned at 8:00 P.M., 15 December 1989.

Respectfully submitted,
Raymond R. Beneke
Secretary-Treasurer

Minutes of the AAEA Executive Board Meeting, University of British Columbia, Vancouver, B.C., Canada, 3–4 August 1990

Present: Voting members:
Armbruster, Batie, Eidman, Futrell, Johnston, Libby, Manderscheid, Miranowski, and Perrin

Members ex officio:
Barry, Beneke

Guests:
Beattie, Carsrud, Christoffers, Deaton, M. Johnson, Reichelderfer, Veeman, Willis and committee chairs, editors, and representatives as reported in the minutes

The meeting of the Executive Board of the American Agricultural Economics Association convened at 8:07 a.m. in the Faculty Club at the University of British Columbia in Vancouver on Friday, 3 August 1990. The first order of business was a review of the agenda by those members present. Several items were added to the agenda. The minutes of the December 1989 meeting were approved as corrected. President Sandra Batie welcomed the newly elected members of the board, president-elect Bruce R. Beattie and directors Brady J. Deaton and Katherine H. Reichelderfer. Batie announced the new members on the AAEA Foundation Governing Board are Bruce F. Johnson and John E. Lee, Jr. Batie introduced Michelle Veeman, president-elect of the CAEFMS.

1. Appointments for special awards committees, particularly the world food prize, were discussed. Warren Johnston will talk to R. Jim Hildreth regarding a nomination for this award.

2. During a discussion led by Walter Armbruster regarding grants for travel to the International Association of Agricultural Economists conference to be held in Tokyo in 1991, he announced the availability of approximately eight $1,500 travel grants. The AAEA Foundation will be asked to consider providing funding for two or more grants to supplement those that will be available through the association.

3. Batie announced that Council of Social Science Associations on Federal Statistics had asked for and had been provided a $2,000 dues payment for AAEA for 1990.

4. Batie discussed the International Agribusiness Association and its relationship to the AAEA. The consensus among board members was that the AAEA should offer to cooperate with the new association in any way that might be useful, including, but not limited to, joint meetings on occasion as well as working together in publicizing, promoting and distributing journals published by both organizations.

5. Batie announced that the Northeastern Agricultural and Resource Economics Association will plan to meet jointly with the AAEA in Baltimore in 1992, along with the Soil and Water Conservation Society. Batie also indicated that the Rural Sociology Society is interested in the possibility of joint meetings in 1993.

6. Peter Barry reported on the AJAE operations for 1989–90. He indicated that during the past year the *Journal* had effected a transition in printing from Heffernan Press to Edwards Brothers in Ann Arbor, Michigan. Editor Barry indicated that it appears that AAEA members and subscribers will benefit from improved timeliness in publication of the *Journal* and also from lower publication costs. Barry indicated that new submissions of manuscripts in the most recent twelve-month period (1 July 1989 to 30 June 1990) totaled 370 manuscripts, equaling the record high of two years ago. According to Barry, the mix of published articles reflects the mix of submitted material, with the dominance of research-oriented articles following through from submission to publication. Editor Barry stated that the editor's office has continued to emphasize timeliness in the handling of manuscripts. He indicated that during the past year the response times on original submissions averaged 70 days, with the response on 77% of these occurring within a 90-day period; 93% within a 120-day period; and 99% within 150 days. The publication rate was 29% of the manuscripts submitted during the year.

Barry reported that other special activities of the editor during the past year included (*a*) the development of guidelines for data availability and documentation of research procedures that now is published as item 5 on the inside of the back cover of the *Journal,* (*b*) the development of a storage policy

for back issues of the *Journal,* and (*c*) revisions in the eligibility requirements for participation in the Outstanding *AJAE* Article Award. MOTION: After an evaluation by Barry, John Miranowski moved to adopt a policy to increase the range of selected articles to 110–120 articles per year in order to reduce the waiting period for publication, at an additional cost of approximately $5,000. Richard Perrin seconded. Motion carried.

7. Perrin gave a preliminary report of the Finance Committee in which he emphasized the operating expenses of the association had exceeded operating revenue in 1989 and that the discrepancy would be still greater in 1990 and 1991. He emphasized that the association had no deficit in 1989 because of the revenue we had received in gains on sale of stock during 1989. The discussion then ensued as to what policy the board ought to pursue in placing a ceiling, if any, on the amount of resources to be accumulated in our portfolio. The matter of raising dues also came up for discussion. Batie suggested that we postpone consideration of these items until it became clear what our budget needs would be in 1991.

8. Mike Ellerbrock reported on the operation of the *AAEA Newsletter*. He indicated that the transition from Bruce Greenshields as editor to Ellerbrock had been made with a minimum of disruption. Ellerbrock reported that the association had published and mailed a total of 14,500 copies of the first three issues of 1990. He indicated that publication costs will remain somewhere between 26¢ and 31¢ per copy; however, because of an increase in postage and clerical expenses, the editor expects the *Newsletter* to operate at a deficit in 1990. The *Newsletter* format has been changed to a right-hand justification and now includes "Food for Thought" quotes, which serve to minimize the amount of white space in the publication. He also indicates that he intends to institute a new column entitled "Making Connections" aimed at sharing some of the diverse cultural and intellectual resources of the profession. Armbruster suggested that highlights of committee reports should appear in the *Newsletter*. Perrin asked Ellerbrock for a comparison of employment advertisements between the *AAEA Newsletter* and the *CWAE Newsletter*.

9. Batie directed the attention of the board to a letter which she had received from Paul Weller, executive director of the American Agricultural Editors Association. In the letter Weller argued that the editors' association ought to share in the interest earned on the Kellogg Project since this was a joint effort of the two associations. Members of the board indicated that the association had a policy of several years' standing that project committees within the association do not share in any interest that might accrue from funds which the committee, for one reason or another, has accumulated. Batie will talk to Lyle Schertz about the matter and will also write to Weller explaining our policy.

10. Warren Johnston indicated that he had appointed a search committee for the *AJAE* editorship starting in 1991. He indicated that Vern Eidman and Larry Libby would be serving on the committee and that anyone who had any suggestions should contact the committee.

11. Manderscheid introduced the matter of a single candidacy in subsequent presidential elections. Batie indicated there had been a significant volume of communication on this subject. These communications had reflected strong feelings on both sides of the issue. A thorough discussion of the pros and cons of the issue ensued. Manderscheid indicated that the present policy of choosing two candidates, both with superior qualities, had been followed for many years. No action was taken to change the present practice.

The meeting adjourned shortly after 12:00 and reconvened at 1:20 p.m.

12. Batie raised questions on several matters of budget policy. MOTION: Miranowski moved that the board adopt a rule that in lieu of gains on sale of stock or losses, the board budget 3% of the value of the portfolio for support of activities of the association. Seconded by Manderscheid. Motion carried. There was further discussion of instituting a cap on the total amount of funds which the board would permit to accumulate in the investment portfolio. This issue was not resolved.

13. MOTION: Perrin moved that the dues for regular members be increased from $45.00 to $60.00 and that dues for other categories of membership be increased proportional to the increase in regular member dues. Johnston seconded. Motion passed.

14. Lyle Schertz announced that a contract was being negotiated between the association and p.s. Express as assistant to the editor for *CHOICES*. This contract should be in place by 1 September 1990. Schertz reported on the operation of *CHOICES*. He called the board's attention to the fact that with the fourth issue of *CHOICES* in 1990 the association will have completed five years of publication of this magazine. He indicated that he had been considering ways in which the association could commemorate having achieved this milestone. Ideas which he advanced as possibilities included an extra edition of *CHOICES* in 1991 or a special issue which included extra pages. He also suggested that the association might sponsor an essay contest in which the contributions deemed most creative would be awarded a prize. The most outstanding contributions might be published in the special edition of *CHOICES* Magazine. No action was taken on any of these suggestions. The editor was asked to update the board on his current thinking on a commemorative issue at the November meeting and include a budget for the project.

Editor Schertz also discussed the possibility of placing on CD-ROM the copy from all issues of *CHOICES* that had thus far been published. In this format materials contained in all issues of *CHOICES* to date could be readily searched at a very low cost. Schertz indicated that the best estimate he could provide at this stage of the cost of this project would approximate $10,000. The board indicated this suggestion needs further exploration.

Schertz also reported upon the project he has un-

dertaken in cooperation with the American Agricultural Editors Association to better communicate America's farm policy issues to the public. This effort is being supported by a grant from the Kellogg Foundation. Schertz indicated that eleven press releases based on articles in three issues of *CHOICES* had been prepared, and that there had been three press conferences held at the National Press Club in Washington, D.C. Each set of press releases had been sent to approximately 800 people involved in the food and agricultural press. Schertz also indicated that one press backgrounder had been held in St. Louis in April 1990. The focus of this activity was the development of a better understanding of the evolution of food, farm, and resource policy from the mid-1850s to the present. This backgrounder plus one press conference have been placed on video tape. All three press conferences were audiotaped. Schertz indicated that more effort would be given in the upcoming year to preparation of video materials for distribution to the press.

Schertz reported on the meeting of the Joint Council on Economic Education that he and Kim Reda-Wilson attended in New York. The purpose of the meeting was to explore the advisability of AAEA developing a working relationship with the JCEE, and to glean information useful in preparing a proposal that AAEA undertake to rework materials that appear in *CHOICES* for use in secondary schools.

15. Perrin reported on the problems that North Carolina had encountered in attempting to work out plans to accommodate the 1993 summer meeting. The group at North Carolina State charged with making arrangements concluded that adequate facilities in Raleigh, N.C. were not available for such a meeting. They explored the Winston-Salem area as an alternative and concluded that although this would not be an ideal location, it would be preferable to Raleigh. The board decided not to make a decision on the 1993 location at this time but to give more consideration to the problem at the November meeting. Charlene Carsrud was instructed to provide the board with more detailed information on Winston-Salem as well as Orlando and any other sites she may deem feasible. This information is to be presented at the November board meeting.

16. Marc Johnson, from Kansas State University, reported that plans are going forward for the 1991 meeting. He indicated there are other activities taking place on the Kansas State campus which may provide competition for preconferences. Johnson reported that, otherwise, plans for the meeting were progressing well and that the staff at Kansas State was looking forward to showing members of the association what Kansas had to offer.

17. Miranowski reported on a workshop presented by the Institute of Food Technologists held 26–27 February 1990, in Washington, D.C., on "Achieving the Full Potential of Integrated Pest Management." The IFT is asking the AAEA to place its name on the list of professional societies endorsing this workshop report. Miranowski explained why the association should not endorse this report.

18. Wen Chern reported for the China Committee. He said that the committee was again sponsoring a symposium dealing with agricultural trade which would be a part of the 1990 AAEA annual meeting. Professor Chern indicated that Francis Tuan and Peter Calkins had been editing the proceedings of the Conference on Chinese Rural Development that was held in connection with the Baton Rouge Meeting in 1989. According to Chern, the Chinese committee is making arrangements to cosponsor a conference to be held in Beijing in 1992. Chern asked for board approval to undertake this project in Beijing. Manderscheid cautioned the committee to be very careful about using the AAEA name and asked the committee to keep their board representative informed as to progress. The project was supported in principle, but the committee was asked for more specifics on details and to keep in close touch with the president.

The board adjourned at approximately 5:30 P.M. to reconvene again at 8:00 A.M. on Saturday morning.

Batie called the meeting to order at 8:03 A.M. on Saturday, 4 August.

19. Mary Ahearn appeared on behalf of the Economic Statistics Committee and indicated that the committee was publishing the proceedings of the data conference which it sponsored in 1989. Ahearn also indicated that the committee had taken the initiative in organizing a symposium on data confidentiality to be held at the 1990 summer meetings. She indicated that the committee is planning a conference on Economic Accounting of Commodity Cost and Returns to be held on 20–22 February 1991. Ahearn reported that their 1989 preconference had created a surplus of several thousand dollars in the AAEA accounts. She requested that the board allocate $3,000 of this amount to support travel of four or five young professionals to the February 1991 conference on Economic Accounting of Commodity Costs and Returns.

Ahearn also reported for the National Agricultural Statistics Service. She indicated that, although hiring had been curtailed throughout the fiscal year as a result of budget constraints, the agency is proceeding to collect data on chemical applications as a first stage in providing estimates for the USDA Water Quality Initiative. The agency is also preparing for an important role in providing data in support of the USDA Food Safety Initiative.

20. Michael Mazzocco reported for the Selected Papers Committee, that 685 papers were received and reviewed by 231 reviewers, with 334 accepted. These papers were combined with 35 accepted papers from the CAEFMS.

The committee recommends that the early submission date for papers be continued. The submission form should be included in the November-December issue and the January-February issue of the *AAEA Newsletter* along with the "Call for Papers" in both issues. The committee recommends the revising of the number of topic areas and broadening the scope of the remainder. It also recommends a limit be placed on the number of submissions with which an individual may be affiliated, perhaps three to four. The

board suggested that the committee proceed slowly toward changing the rules. Mazzocco and Tom Knight are to write a new call for papers and a call for reviewers.

The committee also suggested an allocation of $2,500–$3,000 to the institution in support of the Selected Papers Committee to offset expenses to the department (telephone, postage, supplies, and student workers).

21. Paul Barkley appeared before the board representing the Professional Activities Committee. The one-half day learning workshop on nonmarket valuation techniques held at the 1990 meeting was a tremendous success with over 250 registrants. PAC will ask to organize two or three such workshops for the 1991 meeting. Barkley suggested that any excess revenues from the 1990 meeting be held in reserve for future learning workshops. Batie informed him of the existing policy not to do this, but the board would consider new requests for funds for future learning workshops.

The PAC distributed a questionnaire at the Vancouver meeting for the purpose of evaluating the meeting. Josef Broder (University of Georgia) is coordinating this effort.

22. The following amendments to the AAEA Bylaws regarding the awards program were presented:

> The addition of the following paragraph to the introductory section of Article V and suggest that it become the second paragraph: "Award nominees must be members of the AAEA. In the case of multiple authorship or of a group nomination at least one person must be a member of AAEA. The membership requirement is waived in the case of the Outstanding Master's Thesis Award."

MOTION: Manderscheid moved we adopt this bylaw change. Vernon Eidman seconded. Motion failed.

> Delete Section 8 of Article V. This section reads: "Section 8. Undergraduate Recipient. The Association shall provide one ticket to the official awards banquet or similar event at no charge for each undergraduate recipient of an Association award provided the recipient is present and in attendance at the awards ceremony."

This section appears unnecessary in view of the current award program format. MOTION: Manderscheid moved we adopt this by-law change. Perrin seconded. Motion carried.

MOTION: Walter Armbruster moved that the bylaws be rewritten without reference to gender and to make all reference to *AJAE* spelled out to read *American Journal of Agricultural Economics*. Miranowski seconded. Motion carried.

23. The following amendments to the constitution were presented: (changes are underlined)

> Article VI. Officers. Change Section 2 to read:
>
> "Section 2. Appointed. The executive board shall appoint a Secretary-Treasurer, an editor of the American Journal of Agricultural Economics, *an editor of Choices and an editor of the AAEA Newsletter*, all of whom shall serve for one-year terms and may succeed themselves in office."
>
> Article V. Executive Board. Change Section 1 to read:
>
> "Section 1. How Constituted. The Secretary-Treasurer, the editor of the American Journal of Agricultural Economics, *the editor of Choices*, and, upon designation by the executive board, the Presidents (or designees) of any national or regional Associations, shall be members ex officio (nonvoting) of the executive board."

These changes will be voted upon at the Annual Business Meeting.

24. The following amendments to the bylaws were presented: Article VI. Duties of Officers. Change Section 4 to read: "Section 4. Appointments. As an operating procedure, the executive board may reach agreements with appointees to the position of Secretary-Treasurer, editor of the American Journal of Agricultural Economics, *editor of CHOICES and editor of the AAEA Newsletter* for appointments of three to five years with the provision of an evaluation preceding reappointment each year and a performance review at the end of the three- to five-year appointment if an additional three- to five-year term is being considered. However, nothing in the agreement between the executive board and a candidate for either position shall be deemed to create a contractual obligation beyond that specified in the Constitution of the Association." MOTION: Manderscheid moved we adopt this by-law change. Miranowski seconded. Motion carried.

> Article XV. Editorial Advisory Board for *Choices*. Change title to: "*Choices*." Add new Sections 1 and 2:
>
> "Section 1. Role of executive board. The executive board shall:
>
> a) Elect the editor of *Choices*.
> b) Approve the criteria used in selecting other staff.
> c) Determine long-run policies affecting *Choices*.
> d) Determine the annual budget for editorial operations and printing of *Choices*.
>

The Board shall approve the general content, establish long-run policies and determine the annual budget for the *AAEA Newsletter*. The editor will be responsible for determining the content of each regular issue, and be responsible for printing and other operational policies."
>
> Renumber former Articles XVI. and XVII. as Articles XVII. and XVIII.

Manderscheid moved we adopt this by-law change. Miranowski seconded. Motion carried.

25. Armbruster reported on the National Agribusiness Education Commission report *Agribusiness Education in Transition: Strategies for Change*. A follow-up project, based on encouragement by the USDA Office of Higher Education, will assist in implementing recommendations. The project, "Strengthening Agribusiness Programs, Phase II," will bring together agriculture and business educators with human resource professionals from food and agriculture industries to design a plan for implementation. Steve Sonka, University of Illinois, will represent the AAEA on the steering committee for the project.

26. John E. Lee, Jr. of ERS USDA appeared before the board. Lee discussed the electronic database that the ERS is creating. He indicated that the service operates under the same confidentiality requirements as does the National Agricultural Statistics Service. Lee said it is a policy of the ERS to make data as widely accessible as possible, and a system is being developed to assure maximum legal access to data generated by new pesticide surveys. Lee indicated that the ERS next year would be celebrating its 30-year anniversary.

Lee presented a proposal regarding the Frederick V. Waugh Memorial Lecture Series. This lecture series would be an annual lecture, beginning with a special plenary session at the 1991 annual meeting. Nominations for speakers will be solicited through various media with a nominating committee making the final selection. Motion: Perrin moved to accept the proposal. Futrell seconded. Motion carried.

27. Otto Doering spoke to the board regarding CARAFE (Coalition for Advancement of Research on Agriculture, Food, and Environment). They have asked the AAEA on several occasions to join with them. The board will discuss this again at the fall meeting to decide whether we want representation and to make a contribution to this effort.

28. Doering spoke for the Adaptive Planning Committee. Their report was presented to the membership via the July-August *AAEA Newsletter*. The feeling has been that the membership is interested in broadening the interest base of the association. The committee suggested the board attend the symposium at the Vancouver meeting designed to discuss the report and to get feed-back from people as to the feeling on the broad issues. The report will be discussed in greater detail at the fall meeting.

29. The board then went into executive session to consider the reappointment of the secretary-treasurer. The secretary-treasurer was reappointed for the next year.

The board adjourned at approximately 12:00 to reconvene again at 1:30 p.m.

30. Charlene Carsrud of the business office reported that the final tally from the Baton Rouge meeting in 1989 had indicated a total of 1,453 participants registered for the meeting. This resulted in a net profit of $2,438.

31. Carsrud also reported that it appeared as if attendance at the Vancouver meeting would be one of record-breaking numbers. As of 30 July, 2,146 had registered, with a record number of spouses, guests, and children attending.

32. Emery Castle, president of the AAEA Foundation, appeared before the board with his 1989–90 report. Castle reported that foundation activities continued at an accelerated rate during the past year in both program and finance categories. The foundation supported the minority travel grant project with eight $500 awards to attend the Vancouver meeting. The foundation also provided student travel grants for a total of $1,600 for undergraduate travel to Vancouver. Castle encouraged the association to continue with their generous support which helps permit the foundation to tell prospective donors that most of any contribution they make will support the foundation programs rather than be used for administrative expenses. Castle also announced that the foundation board may wish to increase the number of appointed members that sit on their board in the future.

33. Raymond Beneke, secretary-treasurer, reported that he had been in contact with Emerson Babb regarding the contract with the University of Minnesota Press to publish volume 4 of *A Survey of Agricultural Economics Literature*. Because of the changes and time delay in getting this volume to print the press is no longer able to publish the book at the agreed-upon rate, and would need up to an additional $3,500, which amount could be deducted from earned royalties from the book. Motion: Manderscheid moved to give Beneke permission to negotiate with Minnesota Press to reach amiable conditions to publish the book. Miranowski seconded. Motion carried.

34. Lona Christoffers of the business office reported that the foundation would be presenting the Waldo E. Grimes Club Charter to Marc Johnson, head of the Department of Agricultural Economics at Kansas State University of the Awards Program August 6. Christoffers reported that there are two appreciation clubs in progress right now, The Harry R. Wellman Appreciation Club and the Gerald R. Dean Appreciation Club.

35. Glenn L. Johnson, Jim Bonnen, and Fred Buttell reported on Phase III of the Social Science Agricultural Agenda Project (SSAAP). The Phase III presentations have been very useful in preparing SSAAP publications. They presented a proposal for a pre- or postconference to be held at the 1991 summer meeting in Manhattan, Kansas, entitled "Multidisciplinary Workshop on Results from the Social Science Agricultural Agenda Project." Batie responded that the AAEA agreed to cosponsor this event at the Kansas meeting.

36. The proposed agenda for the annual business meeting was accepted as printed.

37. The written report from Lynn W. Robbins, chair of the Agribusiness Committee, was discussed. Activities of the committee over the last year included the WRCC meeting held in Las Vegas to discuss issues relating to agribusiness, and an informal review of the Adaptive Planning Committee report.

38. The written report from Kim Reda-Wilson, chair of the ad hoc Committee on Economic Education, was discussed. The committee unanimously agreed that a working relationship between AAEA and the JCEE would be mutually beneficial. The ad hoc committee requests that an invited paper session on economic education be included in next year's AAEA annual meeting. It is also suggested that a followup AAEA Committee on Economic Education be selected with a guaranteed three-year appointment, to allow for long-range planning.

39. The written report from John P. Nichols, chair of the Committee on Employment Services was discussed. A new "Careers For the Future" brochure has been produced, with Cathy Hamlett (Penn State University) as chair of this subcommittee. Don Ethridge, chair of a subcommittee to survey the agricultural economics departments, reported that results of the survey will be summarized and disseminated at a later date. Credit was given to Jaye Stefani of the AAEA Business Office, who provides the leadership for the Employment Center activities.

40. A written report by Kirby Moulton, chair of the Extension Committee was discussed. He pointed out the various extension activities planned for the Vancouver meeting, and stated that progress has been made in stimulating Extension members' interest in participation in AAEA activities.

41. A written report by George Hoffman, chair of the Industry Committee, was discussed. The primary activity of the committee over the past year has been the development of two programs for the summer meeting: The industry outlook session and the industry banquet. Hoffman made suggestions as to how the Adaptive Planning Committee report would fit in with the industry group and also made comments regarding the dues structure currently being utilized for industry memberships.

42. A written report by Alan Baquet, chair of the Information Retrieval Committee, showed that the committee had secured ten travel grants from Farm Foundation for reference room personnel to attend the AERO workshop along with several committee members. Also, an organized symposium at the Vancouver meeting on end user computing had been organized.

43. A written report by Vince Cusamano, chair of the International Committee, indicated this committee was instrumental in organizing the international banquet at the 1990 meeting and in promoting the organization of symposia and invited papers on international topics of interest to the committee and the association. The committee has also taken the lead in organizing the AAEA travel grants program to the 1991 International Agricultural Economists Association meeting in Tokyo.

44. A written report from Lionel Williamson, chair of the Committee on Opportunities and Status of Blacks in Agricultural Economics, indicated that a revision of the *Directory of Black Agricultural Economists* is being disseminated, along with the new brochure on *Outstanding Black Agricultural Economists*. Williamson reported that the proceedings of the preconference program held at Southern University in 1989 should be ready for distribution by late summer.

45. A written report of the Resident Instruction Committee submitted by Dorothy Comer, chair, explained the progress being made on a special symposium on graduate programs in agricultural economics in the United States and Canada. The committee plans to meet in Vancouver to set goals and identify specific assignments.

46. A written report of the Tellers Committee, chaired by Dan Otto, was reviewed, showing the following results for 1990–91: president-elect Bruce R. Beattie; director Brady J. Deaton; and director Katherine H. Reichelderfer. Foundation Governing Board members are Bruce F. Johnston and John E. Lee, Jr.

47. A written report by LeRoy Hushak on the Council of Professional Associations on Federal Statistics (COPAFS) was reviewed. He reported continued work on data issues, work on new bylaws and articles of incorporation, and active participation in COPAFS activities. He thanked the board for providing $1,000 of support for travel in 1990 and hopes this support will continue in 1991. MOTION: Perrin moved the board continue to provide $1,000 support for Hushak for 1991. Armbruster seconded. Motion carried.

48. A written report by Dan Tilley, chair of the Membership Committee, was reviewed. Items regarding *CWAE Newsletter* subscription charges and changes in foreign postage charges had been addressed by the board earlier in the meeting. The membership report showed membership fell approx-

imately 10% from 1987–89. The role of the membership committee in 1990–91 will be to develop and implement a marketing plan for AAEA.

49. Sam Cordes, chair of the 1990 Poster Committee, appeared before the board to report on the progress on the poster session project. Cordes reported that he encountered no major difficulties in arranging for the poster sessions. He indicated that seventy-nine proposals were submitted. This compares to thirty-nine submissions in 1989. Of the seventy-nine proposals submitted and evaluated, fifty-two or 65.8% were accepted. Cordes believes that poster session activity is not as challenging as it might be because there is a perception among some people that poster presentations are not appropriate for some types of work in the profession, such as highly rigorous theoretical approaches and complex empirical work. Cordes thinks that it is precisely the latter type of work which lends itself particularly well to a poster presentation. Cordes reported that 1990 was the third year for poster presentations and the second year that poster proposals were selected on a competitive basis. He said that in his judgment the poster sessions ought to have a prime time spot on the association's program agenda and also that the posters should be located in a high traffic area. Both of these conditions obtained for the 1990 meetings. He suggested particular attention be given to time and location, particularly until the poster concept is firmly established as an integral part of the annual program. Carsrud reported that a number of poster presentations required that a computer be included in the exhibit. She indicated that the cost of supplying all of the computers requested had been prohibitive in 1990 and urged that in subsequent years entrants be required to supply their own computing facilities for their exhibits.

50. Steve Sonka reported as chair of the AAEA Awards Committee. Sonka points out that a large number of nominations are submitted each year, and each receives thorough evaluation from members of the profession. Sonka believes that this process has now been refined to the point where it operates smoothly. He pointed out that the Quality of Communication and the Distinguished Policy Contribution categories offer a special challenge because of the diversity of materials which are typically presented within these categories. The fact that committee members or evaluators are faced with the difficult task of comparing different forms of media, for example books versus multimedia presentation, complicates the process as does the fact that individual efforts must sometimes be compared with the same efforts of a group of scholars. He indicates that one possibility would be to have both group and individual awards given in some categories. Sonka indicated that there was ambiguity as to whether AAEA membership is a requirement for an entry in the awards program. He expressed concern over the relatively small number of nominees in some categories; in particular, the Distinguished Extension and the Distinguished Policy Awards have relatively small numbers of entries. He believes that it is important to continue to publish the number of entries in all categories so that association members can have better information about the likelihood of success within different categories.

51. CWAE requested that arrangements be made on the AAEA membership forms for a $5.00 subscription fee to be added for those members who wish to receive the *CWAE Newsletter*. MOTION: Armbruster moved that the membership application and renewal form include as an option the $5.00 subscription fee for those members who wish to receive the *CWAE Newsletter*. Perrin seconded. Motion carried.

52. Perrin passed out a revised budget for 1990 and a proposed budget for 1991. Beneke went through the budget item by item. Minor modifications were made by the board. MOTION: Perrin moved that the board approve the revised budget for 1990 and the proposed budget for 1991. Armbruster seconded. Motion carried.

53. Raymond Beneke, secretary-treasurer, reported that the endowment created by astute financial management on the part of our predecessors and a rising stock market has enabled the organization to support generously two exciting projects, the foundation and *CHOICES* magazine, without subjecting the financial health of the association to unacceptable risks. One trend which has been obvious is the increasing resistance we as an organization face in attempting to coax subsidies from other organizations to support association activities. We see this in asking board members and others serving the association to obtain funds for travel expenses, as well as enticing universities to host our annual meeting. The business office staff continues to serve creatively and diligently. Beneke reported that as a group they thrive on responsibility and welcome new challenges.

54. Before adjournment, past president Manderscheid and retiring board members Perrin and Miranowski shared their thoughts with the board on the occasion of their having completed their three-year term. Manderscheid indicated that he would be leaving the board after having served six of the past eight years. All three wished the board success in their future deliberations and expressed their appreciation for the opportunity they had been accorded to serve on the board.

The meeting was adjourned.

Respectfully submitted,
Raymond R. Beneke, secretary-treasurer

Minutes of the AAEA Foundation Governing Board Meeting Vancouver, British Columbia, Canada, 5 August 1990

Present: Voting members:
Armbruster, Brake, Castle, Farrell, Kinsey, Manderscheid, Perrin, Sundquist, and Swackhamer

Absent:
Seevers

Members ex officio:
Beneke

Guests:
Christoffers, Lee

The meeting of the Governing Board of the AAEA Foundation was called to order at 5:30 p.m. in the North Committee Room of the Walter Gage Complex on the campus of the University of British Columbia. President Emery Castle welcomed the newly elected board member, John E. Lee, Jr. The other new board member, Bruce Johnston, was unable to attend.

Castle gave a brief report on the state of the foundation. After five years of operation, activities continue at an accelerated rate in both the program and finance categories. The foundation is pleased to report that eight $500 grants were made to support minority travel to Vancouver. In addition, student grants totaling $1,600 were provided for travel to Vancouver. The Waldo E. Grimes Club was chartered at the fall 1989 meeting of the foundation board and the certificate of charter will be presented to Marc Johnson, head of the Department of Agricultural Economics at Kansas State University at the Awards Program August 6.

Walter Armbruster announced that the AAEA would be sponsoring eight $1,500 travel grants to attend the International Conference of Agricultural Economists in Japan in August 1991. It was suggested that it would be a suitable project for the foundation to sponsor additional grants to the conference in Japan. MOTION: Armbruster moved the foundation allocate two or more travel grants of $1500 each for minority professionals to attent the international conference in Japan in 1991. Kenneth Farrell seconded. Motion carried. Farrell and Burt Sundquist will work on a modification of previous travel grant guidelines and criteria for publication in the September *Newsletter* with recommendations on details at our November meeting. Farrell and Sundquist also agreed to coordinate this activity with the AAEA International Committee.

Lester Manderscheid gave the report of the Nominating Committee. Officers nominated for 1990–91 include Ken Farrell, president; Burt Sundquist, vice-president–programs; and Larry Boger, vice-president–finance. MOTION: Manderscheid moved we approve this slate of officers by unanimous ballot. Motion seconded. Motion carried.

Castle expressed his thanks to Jean Kinsey, who is retiring from the board, for her dedication and service over the past three years, and also to Gene Swackhamer and Larry Boger for their fund-raising efforts. Control of the meeting was turned over to the newly elected president, Ken Farrell.

Farrell announced that the fall board meeting would be 2–3 November 1990 in either Kansas City or Minneapolis. Raymond Beneke announced that he and the business office were preparing revised financial statements for presentation at the fall meeting. Farrell and Armbruster will present a report on appreciation club guidelines for the board's review.

Respectfully submitted,
Raymond R. Beneke, secretary-treasurer

Minutes of the Annual Business Meeting, Vancouver, British Columbia, Canada, 6 August 1990.

President Sandra S. Batie called the meeting to order at 8:00 a.m. in the War Memorial Gym on the campus of the University of British Columbia. The minutes of the 1989 annual business meeting, Baton Rouge, Louisiana, were approved as printed in the December 1989 *AJAE*.

1. Batie reported on the results of the election. Election material had been mailed out to all who had paid their 1990 dues by 1 April 1990. Elected were Bruce R. Beattie, Montana State University, president-elect; Brady J. Deaton, University of Missouri, director; and Katherine R. (Kitty) Reichelderfer, Resources for the Future, director. Bruce F. Johnston, Stanford University, and John E. Lee, Jr., ERS USDA, were elected members of the AAEA Foundation Governing Board.

2. Batie reported on a successful term of office as president of the association. (The complete report of the president appears elsewhere in this issue.)

3. Raymond Beneke gave the report of the secretary-treasurer. (The complete report of the secretary-treasurer appears elsewhere in the issue.)

4. Richard Perrin, chair of the Finance Committee, reported that the financial base of the association remains strong. However, Perrin emphasized that this picture of robust financial health is misleading and that large deficits are expected in 1991. Perrin moved the association raise its dues from $45.00 to $60.00 for regular membership with proportionate increases for the other categories of membership. The motion was seconded. There was no discussion. Motion passed. The revised 1990 budget and the 1991 budget were submitted to the members in attendance. Both budgets were approved without discussion, additions, or corrections. (A complete Finance Committee report appears elsewhere in this issue.)

5. Peter Barry, editor of the *American Journal of Agricultural Economics*, reported on the progress of volume 72 and other activities of the *AJAE* editor's office. He pointed out that the board had authorized a 10% increase in articles to be printed in order eventually to reduce the time between acceptance and publication of articles. (A complete report of the editor appears elsewhere in this issue.)

6. Lyle Schertz, editor of *CHOICES* magazine, reported that he would look with favor upon more

one- and two-page manuscripts being submitted for possible publication. He also indicated he would like to include material from a larger number of international authors. He reported that the joint Kellogg project between the AAEA and the AAEdA is facilitating the flow of material in *CHOICES* out to the press. (A complete report of the editor appears elsewhere in this issue.)

7. Mike Ellerbrock, editor of the *AAEA Newsletter*, reported that the transition of the newsletter editorship was made with a minimum of disruption and that the publication of the newsletter is progressing well. A new column is being developed for publishing eclectic essays and will be entitled "Making Connections." (A complete report of the editor appears elsewhere in this issue.)

8. Speaking on behalf of the AAEA Foundation Governing Board, Emery N. Castle, president, reported the foundation has assigned priority to supporting activities in the following areas: (*a*) *CHOICES* and communications, (*b*) minority professionals, (*c*) student development, and (*d*) international travel. Castle announced he would be presenting the Waldo E. Grimes Appreciation Club charter to Marc Johnson, head of the Department of Agricultural Economics at Kansas State University. (The AAEA Foundation report appears elsewhere in this issue.)

9. Lester V. Manderscheid read the proposed changes to the AAEA constitution: (change shown in bold print):

Article VI. Officers. Section 2 Appointed should read: "The executive board shall appoint a Secretary-Treasurer, an editor of the *American Journal of Agricultural Economics*, **an editor of *CHOICES* and an editor of the** *AAEA Newsletter*, all of whom shall serve for one-year terms and may succeed themselves in office."

Article V. Executive Board. Section 1 How Constituted shall read: "The Secretary-Treasurer, the editor of the *American Journal of Agricultural Economics*, **the editor of** *CHOICES*, and, upon designation by the executive board, the presidents (or designees) of any national or regional Associations, shall be members ex-officio (non-voting) of the executive board."

Manderscheid moved these changes be adopted. Motion seconded and carried.

10. Bruce R. Beattie, president-elect, read the following resolution:

RESOLUTION

Whereas the officers, members, families and guests of the American Agricultural Economics Association wish to recognize the efforts and warm hospitality of our hosts for the 80th Annual Meeting held at the University of British Columbia on 4 August to 8 August 1990.

Be it resolved that the American Agricultural Economics Association expresses its gratitude for this effort and hospitality to Rick and Marla Barichello and others affiliated with the Department of Agricultural Economics at UBC for assisting and advising local special events and activities and to the UBC Conference Staff members who have worked diligently with our business office staff to organize this year's annual meeting.

Be it resolved that the American Agricultural Economics Association expresses its appreciation to Charlene Carsrud, annual meeting coordinator; Lona Christoffers, business office coordinator; Jaye Stefani, employment center coordinator; and their associates in the AAEA Business Office, for their yeoman efforts in facilitating this meeting. Beattie moved that this resolution be accepted. The motion was seconded and approved.

11. Batie expressed her appreciation to the membership, the board, and the business office professionals, and presented the gavel to president-elect Warren E. Johnston.

12. Johnston recognized the retiring board members, Lester V. Manderscheid, John Miranowski, and Richard K. Perrin, for their service to the board and the association. He reminded the group of the ASSA meeting to be held in Washington, D.C., in December 1990, and issued an invitation to the membership to attend the 1991 annual meeting at air-conditioned Kansas State University in Manhattan, Kansas.

The business meeting adjourned.

Respectfully submitted,
Raymond R. Beneke, secretary-treasurer

Objective

The American Agricultural Economics Association (AAEA) seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy.

AAEA

—publishes the *American Journal of Agricultural Economics*, the *AAEA Newsletter*, *Choices*—The Magazine of Food, Farm, and Resource Issues, and, periodically, a *Handbook-Directory* of AAEA members;
—plans and conducts an annual meeting of the membership;
—sponsors awards for Distinguished Undergraduate Teaching, Distinguished Extension Programs, Distinguished Policy Contribution, Publication of Enduring Quality, Outstanding Journal Article, Quality of Communication, Quality of Research Discovery, Outstanding Master's Thesis, and Outstanding Ph.D. Dissertation;
—recognizes prominent agricultural economists as Fellows;
—operates the AAEA Employment Service for agricultural economists.

Membership and Subscriptions

AAEA is a professional society for agricultural economists and others who are interested in agricultural economics. A nonprofit organization, AAEA is committed to furthering knowledge about the economics of agriculture, rural communities, and natural resources.

Membership in the AAEA will bring you *Choices*, the *AJAE*, the *AAEA Newsletter*, and other occasional AAEA publications, permit you to use the AAEA Employment Service, and allows you to attend the annual meetings.

Calendar year dues are: $45, regular members; $22.50, senior (retired and 65) and junior (student) members; $67.50, family members; $150, industry members. Lifetime membership is available for members who are at least 55.

Subscription prices: *American Journal of Agricultural Economics*—$65 per year ($73 overseas); single copies, $14.50. *Choices*—The Magazine of Food, Farm, and Resource Issues—$32.50 per year ($52.50 overseas); single copies, $10. *AAEA Newsletter*—$12 per year ($17 overseas).

For further information about the American Agricultural Economics Association, contact the AAEA Business Office, 80 Heady Hall, Iowa State University, Ames, Iowa 50011-1070 (515-294-8700).
